When we compare tetrabutylammonium iodide and bromide, the following rationalization of the experimental results can be made. The small value of 4.21 seems reasonable for the N^+–Br distance in an ion pair. We note that the iodide is more highly associated than the bromide: for the former, $A = 0.78 \exp(101/D)$ while for the latter, $A = 0.11 \exp(133/D)$. The smaller exponent for the iodide corresponds of course to the greater size of the iodide ion compared to the bromide, but the large difference in coefficients A_0 requires comment. Part of A_0 is an entropy term $\exp(-\Delta S/R)$, but this should be practically the same for Bu_4NBr and Bu_4NI. Therefore the only explanation remaining is that the association constant of Bu_4NI contains an additional energy term $\exp(u/kT)$ which is independent of dielectric constant. The ratio 0.78/0.11 equals $e^{1.95}$, so an energy of about $2kT$ is required to stabilize iodide–N^+ pairs with respect to bromide–N^+ pairs. We suggest that this energy is the potential between the N^+ center and the dipole which it induces in the highly polarizable iodide ion, after coulomb forces have brought the pair to near contact (and withdrawn from the medium of dielectric constant D). The larger values of $\mathring{a}$ from J_1 then represent averages between contact diameters in stable pairs and diameters from collisions which do not lead to pair formation, *i.e.*, collisions with the periphery of the quaternary ion from which the bromide ion diffuses away again. In the case of the iodide ion, the additional induction force comes into play at contact and makes most collisions lead to pairs which later disassociate when they acquire sufficient thermal energy.

Another difference between bromide and iodide must be mentioned: the Walden product for the former drops sharply, starting at about 50% dioxane, which we mean some specific interaction

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

between the bromide ion and dioxane which does not occur with the iodide (and picrate), and which increases the effective size of the free bromide ion. Until bromide–iodide comparisons are made in other solvent mixtures, however, further speculations seem pointless.

Before discussing the results in the mixtures of higher dielectric constant, we shall present some data on the viscosity of aqueous solutions of tetrabutylammonium bromide. We acknowledge with thanks measurements made by Dr. Joan B. Berkowitz, which supplement those in the literature.[6] The results are summarized in Table VI, where the

TABLE VI

VISCOSITY OF Bu_4NBr IN WATER AT 25°

.0175	.026	.0012	1.43	6.10
			1.34	5.98

first two columns give concentration in equivalents per liter and specific viscosity $\eta_{sp} = (\eta - \eta_0)/\eta_0$, respectively. As is well known, there is a square root term in the viscosity of electrolytic solutions in addition to the Einstein term $5\phi/2$ (and also higher terms than $c^{1/2}$ from long range forces, which we shall neglect here). For 1 – 1 salts

$$\eta/\eta_0 = 1 + S_\eta c^{1/2} + 5\phi/2$$

where

$$S_\eta = \frac{\beta^*\Lambda_0}{320\lambda_0^+\lambda_0^-}\left\{1 - 0.6863\left(\frac{\lambda_0^+ - \lambda_0^-}{\Lambda_0}\right)^2\right\}$$

For Bu_4NBr in water, $S_\eta = 9.07 \times 10^{-3}$. The quantity η'_{sp} in the table is defined as

$$\eta'_{sp} = \eta_{sp} - S_\eta c^{1/2}$$

It serves to isolate the volume effect in which we are interested. It will be seen that $\eta'_{sp}/c = 5\phi/2c$ is quite constant; further, if we equate $\phi/c = \delta$ with $4\pi NR^3/3000$, we obtain the average value 5.98 Å. for the hydrodynamic radius of the tetrabutylammonium ion. Thus direct viscosity measurements confirm the hydrodynamic term whose presence was suggested first by the conductance data for tetrabutylammonium iodide. It should perhaps be mentioned that the Dole–Falkenhagen term $S_\eta c^{1/2}$ in the viscosity is to be omitted in the conductance equation, because it describes transfer of momenta over distances large compared to $(1/\kappa)$, *i. e.*, refers to bulk flow of the solution.

Finally, we consider tetrabutylammonium bromide in the range of higher dielectric constants. Here, association is so slight that the y *vs.* x method becomes far too sensitive to experimental error. The conductance equation was therefore rearranged to the form

$$\Lambda'' + J_2c^{1/2} = \Lambda_0 - y(0)c$$

where the approximations $\Lambda = \Lambda_0$ and $f^2 = 1$ are made in the ion association term. The quantity on the left was plotted against c, using $\mathring{a} = 5.5$ to evaluate J_2; straight lines were obtained, with slopes $y(0)$ given in Table VII.

TABLE VII

TETRABUTYLAMMONIUM BROMIDE IN WATER–DIOXANE MIXTURES AT 25°

% Dioxane	D	$y(0)$	Λ_0	A	$A\Lambda_0$	$J_1(5.5)$	$5\delta/2$
0	78.48	−28	97.475	0.62	61	248	(2.2)
10	70.33	8	80.805	0.76	62	255	(2.3)
20	61.86	110	67.575	1.00	68	273	1.40
30	53.28	163	57.26	1.38	79	319	1.34
35	48.91	185	53.085	1.78	95	357	1.45
40	44.54	235	49.44	2.24	110	415	1.42
45	40.20	272	46.30	3.16	146	498	1.73

The problem then is: given the sum $y(0) = J_1(a) - A\Lambda_0 - 5\Lambda_0\delta/2$; to evaluate the components. The plot of log A *vs.* $1/D$ from the dioxane-rich range was extrapolated linearly into the water-rich range to give the values of A shown in the table. Then the round value $\mathring{a} = 5.50$ was used to evaluate J_1; this value was chosen to be consistent with the value which $\mathring{a}$ from Table V appeared to be approaching in the mixtures of higher dielectric constant. We then were able to evaluate

$$5\Lambda_0\delta/2 = J_1(5.50) - A\Lambda_0 - y(0)$$

The results are given in the last column; if we disregard the first two values (where the uncertainty in the slopes of the Λ''–c plots is naturally very great and for which the longest log A *vs.* D^{-1} extrapolation was made), we obtain $5\delta/2 = 1.47 \pm 0.13$. to compare with the direct viscometric value of 1.34 ± 0.06 of Table VI.

Discussion.—If ion association depends on the parameter $b = e^2/aDkT$, then there are two ways of varying the extent of association of a given electrolyte: by varying the DT product by change of temperature, or by using solvent mixtures to change D. The latter is by far the more convenient method, and the constancy of the a-values reported here argues that it is an experimentally valid method. One might have some misapprehensions on the score of selective solvation, but when it is recalled that both solvents are usually present in tremendous molar excess over the electrolyte present in the range ($\kappa a < 0.2$) where the data are susceptible to the present analysis, constancy of solvation appears to be a safe assumption. Exceptions might be expected to appear only when one component of the mixed solvent is present at minute concentrations.

While we report here only four cases which show that the logarithm of the association constant is a simple linear function of reciprocal dielectric constant, we believe that the result is general. Seen in retrospect, it does seem logical that a thermodynamic approach[9] to the problem of ion pair formation should be preferable to a statistical one, because the former concerns itself only with reagents and products and the associated free energy difference and ignores mechanism. The Denison–Ramsey treatment has further advantages over the

Bjerrum model which we have used for so long: (1), only ions in contact are counted as pairs; (2), no quibbles about an arbitrary limit of integration arise; and (3), association is not automatically excluded beyond a critical value of the parameter b.

Another former tool must, in our opinion, also be discarded as obsolete in the analysis of conductance data. Our earlier calculations[10] of limiting conductance and "dissociation" constants by various modifications of the Ostwald dilution law were subject to the recognized (but then unknown) hazard of error due to the inclusion in K of terms of higher order arising from long range interionic forces. In solvents of low dielectric constant, the association term is the controlling one, so the error there was not very large: for example, our early analysis[4] of the data for Am_4NNO_3 in 80% dioxane gave $K = 9.0 \times 10^{-4}$ which is in almost exact agreement with the value of A^{-1} given in Table III. These earlier methods may therefore still be used as a convenient approximation for $A \gtrsim 100$. But in solvents where association is less marked, and especially when it is only moderate, then the earlier methods can only lead to erroneous results.

Our present point of view is that association can in principle and does in fact occur in any solvent. The extent to which the alkali halides, for example, associate in water is presumably small, but if the limit of A as D increases is not zero, then a non-zero concentration of ion pairs must be present at any non-zero concentration. We hasten to admit that the actual amount may be quite small. The device of mixed solvents offers an experimental approach to a quantitative answer to the question, of course.

It should be mentioned that the presence of a non-vanishing A will not change the value of Λ_0 found by the Λ'''–c extrapolation method,[3] but a small change in $\mathring{a}$ will result. Likewise, inclusion of the $5\Lambda_0\delta/2$ term for most simple inorganic salts will only change $\mathring{a}$ by a small amount; since $\delta \sim R^3$ and since the alkali ions certainly have radii not greater than half that of the tetrabutylammonium ion, the δ-term will be roughly an order of magnitude smaller for the alkalies than that for the quaternaries, *i.e.*, $5\Lambda_0\delta/2 \approx 0.25\Lambda_0$. Since $J_1(a)$ is several times Λ_0 in aqueous solutions, no drastic change in $\mathring{a}$ is to be expected from inclusion of the viscosity term. Self-consistency, however, requires that if one linear term is retained, all should be.

Microwave Absorption and Molecular Structure in Liquids. XIX. The Effect of Internal Field upon Molecular Relaxation Times in Liquids[1]

BY ROBERT C. MILLER[2] AND CHARLES P. SMYTH

RECEIVED JANUARY 22, 1957

The effect of the internal field in a liquid upon the dielectric relaxation time of its molecules is examined by comparing the macroscopic relaxation time of a highly polar liquid with that of a liquid consisting of molecules of the same size and shape as those of the polar liquid, but with very small dipole moment. Alternatively, the comparison is made between the pure polar liquid and its dilute solutions in a non-polar solvent. After correction for viscosity differences in most cases, the assumption is made that the macroscopic relaxation time of the pure liquid of low polarity or of the dilute solutions of the polar liquid is equal to the molecular relaxation time of the highly polar liquid. The molecular relaxation times thus obtained are compared graphically with those calculated by means of the various available equations. It becomes evident that the relation of the molecular relaxation time to the macroscopic relaxation time is dependent not only upon the dielectric constant of the liquid, but also, to some extent, upon the molecular shape. Consequently, no equation thus far proposed for calculating the molecular relaxation time from the directly measured macroscopic relaxation time of a polar liquid is wholly adequate, but that proposed by Powles and obtained by O'Dwyer and Sack as a first approximation is the most nearly adequate.

It has been common practice in discussing the relations between dielectric relaxation and molecular size and shape and liquid viscosity to use as the basis of discussion the macroscopic relaxation time τ_M or the critical wave length, $\lambda_m = 6\pi \times 10^{10}\tau_M$, at which the measured dielectric loss is a maximum. This is certainly justified in the case of dilute solutions and, in the case of pure polar liquids, has been commonly considered preferable to the use of a molecular relaxation time calculated by means of the Debye theory based upon the Lorentz expression for the internal field of the liquid.

Calculation of Molecular Relaxation Times.—The macroscopic relaxation time may be written

$$\tau_M = \beta\tau_\mu \tag{1}$$

where τ_M is the molecular relaxation time and β a factor correcting for the effect of internal field. From the original equations of Debye[3] based on the Lorentz internal field

$$\beta = \frac{\epsilon_0 + 2}{\epsilon_\infty + 2} = 1 + \frac{\epsilon_0 - \epsilon_\infty}{\epsilon_\infty + 2} \tag{2}$$

where ϵ_0 is the static dielectric constant and ϵ_∞ is the optical or infinite frequency dielectric constant. Powles[4] has proposed an approximate expression for the internal field which gives

$$\beta = \frac{3\epsilon_0}{2\epsilon_0 + \epsilon_\infty} = 1 + x \tag{3}$$

where

$$x = \frac{\epsilon_0 - \epsilon_\infty}{2\epsilon_0 + \epsilon_\infty} \quad (4)$$

O'Dwyer and Sack,[5] in a more exhaustive treatment, have obtained an expression which leads to

$$\beta = 1 + x + \frac{3x^2}{(1-2x)(1+x)} = \frac{1-2x^3}{(1-2x)(1+x)} \quad (5)$$

where x is given by eq. 4.

When ϵ_0 approaches infinity, both equations 2 and 5 require that β also approach infinity, while equation 3 requires that it approach 1.5 as a limit. As a first approximation, neglect of the third term, equation 5 becomes identical with (3). Neglect of the difference between the macroscopic and the molecular relaxation time is equivalent to taking β as equal to 1.

Consideration[6] of the relaxation times and viscosities of the closely related liquids, pyridine, γ-picoline and toluene, led to the conclusion that equation 3 was the best approximation for these liquids. It is the purpose of this paper to apply a similar approach to the considerable body of results now available for testing these equations. For toluene, the dipole moment of the molecule is so small that the internal field is too small to produce any considerable difference between the macroscopic relaxation time and the molecular, that is, $\epsilon_0 - \epsilon_\infty = 0.11$ at 20° gives $\beta = 1.025$ from equation 2, $\beta = 1.016$ from equation 3, and $\beta = 1.005$ from equation 5. When the experimental results are examined presently, it will be evident that these small departures of the values of β from 1 are negligible in comparison with other factors. It is, therefore, justifiably assumed that the macroscopic relaxation time and the molecular are indistinguishable for toluene and for other molecules of similarly small polarity. It is reasonable to assume that γ-picoline or 4-methylpyridine, which has a molecule almost identical in size and shape with that of toluene, has a molecular relaxation time practically identical with that of toluene except for the effects of viscosity. For a spherical or nearly spherical molecule, it has been found[7,8] that the effect of viscosity is small. For such molecules, it has, therefore, been neglected, as a rough approximation, in the following discussion. In previous papers of this series, it has been found that many liquids with unsymmetrical molecules show a rough proportionality between relaxation time and viscosity as indicated by the Debye theory.[3] Consequently, for the comparison of two liquids other than those with nearly spherical molecules, the relaxation time of one is multiplied by the inverse ratio of the two viscosities. If τ_1 is the observed macroscopic relaxation time for a liquid with unsymmetrical molecules of low polarity or for dilute solutions of molecules of high polarity in a non-polar solvent ($\tau_1 = \tau_{M_1} = \tau_{\mu_1}$) and τ_{M_2} is the observed macroscopic relaxation time for a liquid 2 with molecules of high polarity ($\tau_2 = \tau_{M_2}$) and size and shape similar to those of liquid 1, it is assumed that

$$\tau_{\mu_2} = \tau_{\mu_1}(\eta_2/\eta_1) \quad (6)$$

or

$$\beta = \tau_{M_2}/\tau_{\mu_2} = \tau_2\eta_1/\tau_1\eta_2 \quad (7)$$

Equation 7 provides a means of obtaining approximate values of β for comparison with those calculated by means of equations 2, 3 and 5.

Experimental Results

Table I gives for the pair of liquids, 1 and 2, in the first column the difference between the static dielectric constant and the optical dielectric constant of the polar liquid, the ratio of the two observed relaxation times, and the ratio corrected by means of equation 7 for the assumed effect of viscosity. For the nearly spherical molecules, τ_{M_2}/τ_1 is taken as β. When liquid 1 is indicated as a solution, liquid 2 is the solute. In Fig. 1 these values of β are plotted against the corresponding values of $\epsilon_0 - \epsilon_\infty$, while the three curves represent the values of β calculated by each of the three equations.

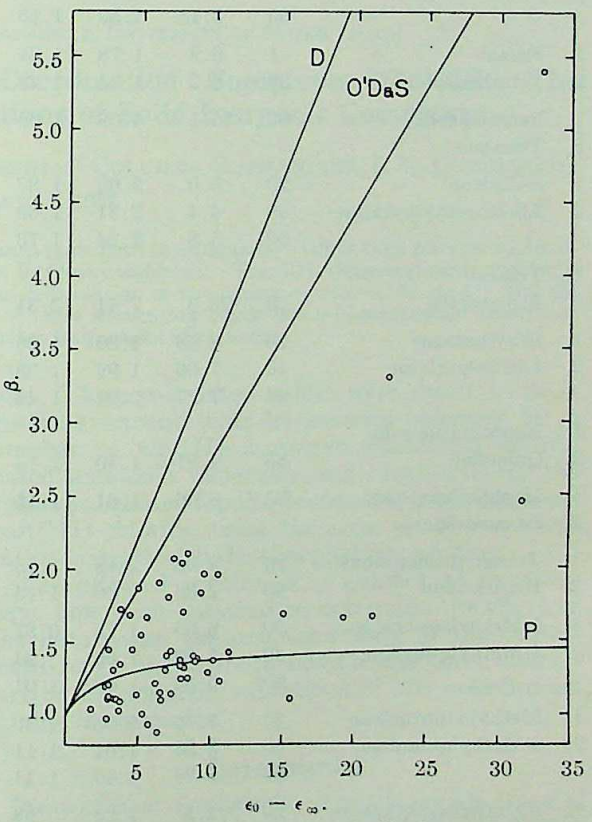

Fig. 1.—Plot of β against $\epsilon_0 - \epsilon_\infty$. Circles represent experimental values. Curve D represents values calculated by means of Debye equation 2; curve O'D & S, values calculated by means of O'Dwyer and Sack equation 5; curve P, values calculated by means of Powles equation 3.

Discussion of Results

The equations under examination by means of the data in Table I were derived for the case of a spherical molecule in a continuous medium and do not take into account the effects of differences in molecular shape and dipole location in the molecule. They may, therefore, be expected to apply with different degrees of approximation to different liq-

uids. The application of a viscosity correction in the case of non-spherical molecules and its neglect in the case of approximately spherical molecules is arbitrary, but, in view of the observed behavior of a large number of liquids, seems to be the best available approximation. An unavoidable approximation is the use of the viscosity of the solvent in place of that hindering the rotational orientation of a solute molecule completely surrounded by solvent molecules. However, when the highly polar molecule is of the same size and shape as the solvent molecule or the molecule of low polarity with which it is compared, the error resulting from this approximation is probably not serious. In the calculation of the curves in Fig. 1 a single value, 2.0, is used for the optical dielectric constant in calculating the Debye and the O'Dwyer and Sack curves, although higher values would lower the curves and give somewhat better agreement with the values of β in Table I. However, the effect of using permissibly higher values for ϵ_∞ would not be sufficient to alter the conclusions as to the applicability of the equations.

In Fig. 1, where the values of β in Table I are plotted against those of $\epsilon_0 - \epsilon_\infty$, the points scatter widely, as might be expected in view of the approximations which have been pointed out. The points lie well below the curve based on the Debye application of the Lorentz internal field and, except for four points just outside this area, between the abscissa axis corresponding to $\beta = 1$ and the O'Dwyer and Sack curve, these two lines forming approximate lower and upper limits for the values of the internal field correction. For values of $\epsilon_0 - \epsilon_\infty$ below about 16, the Powles curve seems to give a very rough average of the observed values of β. For the few points above $\epsilon_0 - \epsilon_\infty = 16$, that is, for high internal field, the Powles equation undercorrects, while that of O'Dwyer and Sack overcorrects. If the values of β in Table I are plotted against $(\epsilon_0 - \epsilon_\infty)/(\epsilon_\infty + 2)$ from equation 2 instead of against $\epsilon_0 - \epsilon_\infty$, the points do not fall as far below the curve given by equation 2 as they do in Fig. 1, but they still show clearly the inapplicability of equation 2. If they are plotted against $x = (\epsilon_0 - \epsilon_\infty)/(2\epsilon_0 + \epsilon_\infty)$ from equation 4, the points lie between the abscissa axis and the curve given by equation 5 as approximate lower and upper limits, respectively. As in Fig. 1, many of the points lie below and many above the curve given by equation 3, which may still be regarded as giving the most adequate approximation for the largest number of liquids.

July 5, 1957

The influence of molecular shape upon the internal field is evident in the values of β in Table I and the points in Fig. 1. For the roughly spherical molecules of the substituted methanes, the effect of the internal field is greater than that calculated by means of the Powles equation, a discrepancy which would be still greater if the correction for the effect of viscosity were not omitted. The flattening of the sphere to the roughly oblate spheroidal form of the substituted benzene and pyridine molecules reduces the effects of the field to amounts close to those calculated by means of the Powles equation, an apparent exception being 2,6-dimethylpyridine, the points for which lie close to the O'Dwyer and Sack curve. Elongation of the flattened structure as in the quinoline, isoquinoline and substituted naphthalene molecules reduces the effects of the field below those calculated by the Powles equation. That the decrease in field effect is not merely the result of increase in molecular volume is shown by the fact that pyridine and the monomethyl and monohalogenated pyridines and benzenes have about the same molar volumes as the tetrasubstituted methanes under consideration. The strong local fields of the highly polar cyanide and nitro groups raise the effects of field well above those calculated by the Powles equation for nitrobenzene and benzonitrile, but the effect is much smaller in the case of the larger 1-nitronaphthalene.

It is evident that the macroscopic dielectric relaxation time of a polar liquid is usually greater than the molecular relaxation time but not nearly as much greater as is indicated by calculation based on the Lorentz internal field. The Powles equation and the identical first approximation obtained by O'Dwyer and Sack seems to be the best approximation for the calculation of the molecular relaxation time from the macroscopic, but it is a very rough approximation.

Infrared Absorption Spectra of Inorganic Coördination Complexes.[1a,b] XII. The Characteristic NH_3 Deformation Vibrations of Solid Inorganic Complexes

BY G. F. SVATOS, D. M. SWEENY, SAN-ICHIRO MIZUSHIMA,[2] COLUMBA CURRAN AND J. V. QUAGLIANO

RECEIVED JANUARY 19, 1957

The infrared spectra of a number of solid metal ammine complexes have been investigated. It has been possible to determine the three deformation vibrations of the ligated molecules in these complexes. The NH_3 degenerate deformation is observed in the region of 1650–1560 cm.$^{-1}$; the NH_3 symmetric deformation in the region of 1350–1150 cm.$^{-1}$; and the NH_3 rocking frequency in the region of 950–650 cm.$^{-1}$. Each of these absorption bands has a characteristic absorption profile. A theoretical explanation for the range of these deformation frequencies is presented.

Introduction

Infrared spectra of solid ammine coördination compounds of the transition metals have been subject to several investigations.[3-7] The comparative ease of preparation and the wide diversity of substituents possible in this series have emphasized the importance of a definite characterization of the absorption bands, which may be attributed to the NH_3 grouping upon complex formation.

Mizushima, Nakagawa and Quagliano have recently characterized the deformation vibrations of coördinated ammonia molecules in Co(III) ammines.[8] Using a Urey–Bradley type potential function, the frequencies of the degenerate and symmetric deformations and the rocking vibrations have been calculated for the $Co(NH_3)_6^{+++}$ ion. These calculated values were shown to be in good agreement with frequencies observed for a number of Co(III) ammines containing coördinated ammonia molecules and, furthermore, the values calculated for the deuterated hexammine cobalt(III) chloride, using the same set of force constants, agreed with the observed frequencies.

The infrared spectra of a number of ammines have now been obtained to determine the effect of the nature and the oxidation state of the central metal atom on the frequencies of the three characteristic deformation vibrations of the coördinated ammonia molecules.

Experimental

Preparation of Compounds.—The compounds listed in Table I were prepared by methods similar to those given in the references in the last column. Most of the compounds were dried by heating under reduced pressure in an Abderhalden apparatus for several hours at 110°. All other compounds listed in Table II were supplied by Dr. D. N. Sen.[9]

Absorption Measurements.—Spectra were obtained by means of a Perkin–Elmer Infrared Spectrophotometer Model 21 with a sodium chloride prism. Preparation of the potassium bromide disks was carried out according to the procedure of Stimson and O'Donnell[10] as described in a previous article.[4]

The frequency values for the NH_3 deformation vibrations are listed in Table II.

Discussion

The previous calculation[8] of normal frequencies for the NH_3 ligand was based on the following potential function

$$V = \Sigma \frac{1}{2}K_i(\Delta r_i)^2 + \Sigma \frac{1}{2}H_{ij}r_i^0 r_j^0 (\Delta\alpha_{ij})^2 + \Sigma \frac{1}{2}F_{ij}(\Delta q_{ij})^2 + \text{linear terms}$$

where r_i and r_j are bond lengths with equilibrium values r_i^0 and r_j^0; α_{ij} bond angles and q_{ij} distances between non-bonded atoms. In addition K, H and F represent stretching, bending and repulsive force constants, respectively.

The deformation frequencies depend on the bending force constants H(HNH) and H(HNM), and the repulsive force constants, F(H· · ·H) and F(H· · ·M), where M denotes the central metal. Of these constants H(HNH) and F(· · ·H) are the same as those used for the calculation of the vibrations of ammonia (NH_3), ammonium ion (NH_4^+), and the deuterated products (ND_3 and ND_4^+).[23] Therefore, these two constants have the same value throughout the series, whereas the remaining two, H(HNM) and F(H· · ·M), depend considerably on the nature of the central metal, M.

The calculation showed that the degenerate deformation frequency depends on H(HNH) and F(H· · ·H), the rocking frequency on H(HNM) and F(H· · ·M), and the symmetric deformation frequency on all four constants. It follows from these relationships that the difference in the nature of the central metal atom should be reflected very strongly in the value of the rocking frequency, considerably in the symmetric deformation frequency and little in the degenerate deformation frequency.

The frequencies of the deformation vibrations fall in characteristic regions of the spectra for all metal–ammine complexes reported. The degenerate deformation appears between 1650 and 1560 cm.$^{-1}$, the symmetric deformation between 1350 and 1150 cm.$^{-1}$ and the rocking vibration between 950 and 650 cm.$^{-1}$. The absorption profiles of the deformation are also quite characteristic. The degenerate deformation is broad and of moderate intensity, the symmetric deformation is quite sharp and very intense, and the rocking vibration band is very broad and intense.[24]

The effects of the nature and oxidation state of the central metal atom on the deformation frequencies are revealed by the data in Table II. It is evident that the rocking frequency decreases

in the following order: Pt(IV) > Pt(II) > Co(III) > Pd(II) > Cr(III) > Cu(II) > Ni(II) > Co(II). Univalent silver is somewhat out of line, the ammonia ligands in $[Ag(NH_3)_2]^+$ having a rocking frequency slightly greater than that in $[Cu(NH_3)_4]^{++}$. The presence of rocking frequencies in the spectra of the hexammine Ni(II) and Co(II) complex ions indicates that the nitrogen-to-metal bonds have covalent character; the relatively low frequencies along with the paramagnetism of these complexes indicate sp^3d^2 outer orbital type bonds.

The rocking frequencies show a large variation and are thus very sensitive to the nature and oxidation state of the central metal ion. This is understandable from the above discussion of the nature of the rocking vibration.

The symmetrical bending frequencies of coördinated ammonia molecules show a similar variation with the nature of the N–M bond but the percentage difference in frequency in going from the Co(II) to Pt(IV) ammines is not so great as for the rocking frequencies. Moreover, the degenerate frequencies show little variation with the nature of the N–M bond. These observations are also in accord with the foregoing discussions of the natures of the symmetric and degenerate deformation vibrations.

The neutral $Pt(NH_3)_2Cl_2$ molecule (12) has a lower rocking and a lower symmetric deformation frequency than the $[Pt(NH_3)_4]^{++}$ ion (8) and a similar effect is observed in the Pd(II) compounds (13 and 6). The effect of the charge of the complex itself on the ammonia deformation frequencies is seen also in the series of cobalt(III) ammines (compounds 17, 16, 15 and 14). (The position of the rocking band at 790 cm.$^{-1}$ in compound 17 is not accurately known as the NO_2 group also absorbs strongly in this region). Both the rocking and symmetrical deformation frequencies increase, in general, with increasing positive charge on the complex. This increasing positive charge coincides with increasing number of ammonia molecules in these Co(III) complexes.

The replacement of the carbonate group in the $[Co(NH_3)_5CO_3]^+$ ion (compound 24) by a sulfate group (compound 27) has no effect on the rocking frequency, and replacement by an oxalate group (compound 28) has very little effect on either the rocking or the symmetric deformation frequencies. In the $[Co(NH_3)_5X]^{+2}$ ions (compounds 18 to 21 and 26), an appreciable lowering of the rocking and symmetric deformation frequencies occurs only where X is a hydroxyl group. The replacement of an inner chlorine atom by a nitro group in the $[Cr(NH_3)_5Cl]^{++}$ ion (compounds 10 and 11) results in an appreciable increase in the these deformation frequencies.

The spectra of these metal ammine complexes are being determined in the cesium bromide region in these laboratories to study the nature of the lower frequencies, as reported in a previous paper.[25]

The Synthesis of Certain Ethylenediamineplatinum(II) and (IV) Bromides and Iodides[1]

BY GEORGE W. WATT AND ROBERT E. MCCARLEY

RECEIVED MARCH 16, 1957

Methods for the synthesis of ethylenediamine coördination compounds of certain halides of platinum(II) and (IV) in high yield and high purity are described. It is shown that $[Pt(en)Br_2]$ and its isomer $[Pt(en)_2]PtBr_4$ may be separated quantitatively owing to the solubility of the former in liquid ammonia at −33.5°.

In the course of studies on the lower oxidation states of platinum,[2] we have had occasion to prepare numerous ethylenediamine coördination compounds of platinum halides. Although many of the corresponding chlorides have been synthesized and are well characterized, they are not desirable as starting materials for reactions in liquid ammonia owing to their generally low solubility. Accordingly, the necessary bromides and iodides were prepared. The syntheses described below either correspond to compounds not previously reported or represent new and/or improved procedures.

Experimental

Methods.—Platinum, when present as the only nonvolatile component, was determined by ignition to the metal; otherwise, platinum was reduced to the metal with hydrazine, dissolved in aqua regia, and determined spectrophotometrically.[3] Halogens were determined as silver halide; where halogen was covalently bonded in complexes, it was displaced with ethylenediamine prior to precipitation.

All X-ray diffraction patterns were obtained using a Hayes unit, Cu Kα radiation, an Ni filter, a tube voltage of 35 kv., a filament current of 15 ma. and exposure times that varied with the nature of the sample. All of the X-ray diffraction data reported here are assembled in Table I and include only the six most intense lines for each compound for which such data are not already available; more nearly complete data are tabulated elsewhere.[4]

For potentiometric titrations, the potential was measured with a Leeds and Northrup type K potentiometer, a platinum indicator electrode, and a saturated calomel reference electrode.

Materials.—Unless otherwise indicated, all chemicals employed in this work were reagent grade materials that were used without further purification.

Hexabromoplatinic acid was obtained by dissolving finely divided platinum in bromine and concentrated hydrobromic acid followed by boiling to remove excess bromine and acid. Massive platinum was dissolved in aqua regia and the re-

sulting solution was evaporated to dryness several times with concentrated hydrobromic acid to expel hydrogen chloride and oxides of nitrogen.

Potassium hexabromoplatinate(IV) was prepared from solutions of hexabromoplatinic acid by the method of Weber.[5]

Ethylenediammonium hexabromoplatinate(IV) was formed by slow addition of ethylenediamine to a cold solution of hexabromoplatinic acid. This brilliant red salt is only sparingly soluble in water. *Anal.* Calcd. for $(C_2H_{10}N_2)_2PtBr_6$: Pt, 26.5; Br, 65.1. Found: Pt, 26.5; Br, 64.7.

Tetrabromoplatinate(II) ion was, in some instances, prepared by the reduction of potassium hexabromoplatinate(IV) with potassium oxalate by the method of Bülman and Anderson.[6] This reaction however is quite slow, and complete reduction is achieved only by evaporating the reaction mixture to a small volume.

Since, in other cases, it was desirable to form the free acid in the absence of extraneous by-product ions, conditions were devised for the production of this ion by electrolytic reduction. A platinum wire cathode was immersed in 220 ml. of solution containing 3 g. of platinum as hexabromoplatinic acid. A platinum wire anode was immersed in a solution of potassium chloride that was connected to the cathode compartment by a potassium chloride–agar bridge. The catholyte was stirred vigorously, the current was maintained at *ca.* 0.1 amp., and the cathode potential was followed by means of a Leeds and Northrup No. 7664 *p*H meter using a saturated calomel reference electrode. During the course of the electrolysis, the color of the solution changed progressively from maroon-red to the deep red-brown color characteristic of the tetrabromoplatinate(II) ion. Concurrently, the potential gradually became more positive but there was no definite break in the time *vs.* potential curve. Accordingly, the appearance of a deposit of platinum on the cathode that appeared after about 60 hr. was taken as the end-point for the reduction process. As evidenced by the nature of the products obtained upon treatment of the product solutions with ethylenediamine, reduction is incomplete unless time is allowed for deposition of a considerable quantity of platinum on the cathode. The current efficiency is *ca.* 10%.

Synthesis of Platinum(II) and (IV) Halides.—In several of the cases that follow, numerous procedural variables were studied, but only the final procedures that gave optimum results are described.

Ethylenediaminedibromoplatinum(II), $[Pt(en)Br_2]$.—This compound was prepared by a method similar to that used by Basolo, *et al.*,[7] for the synthesis of the corresponding chloride.

A suspension of 10.5 g. (0.0140 mole) of potassium hexabromoplatinate(IV) in 50 ml. of water was reduced to potassium tetrabromoplatinate(II) with 2.57 g. (0.0140 mole) of potassium oxalate 1-hydrate,[6] and treated with 1:10 aqueous ethylenediamine *in 0.1-ml. portions* at room temperature. After each addition, the reaction was allowed to proceed to completion (*i.e.*, until the *p*H of the reaction mixture $\cong$ 6) before the next portion was added. During the reaction of the first portion of ethylenediamine solution, iridescent green crystals [see ref. 2] separated and continued to form until 0.5 ml. of the base had been added. This product (0.85 g.) was removed by filtration and the reaction was continued in the same manner. Upon addition of the next portion of the diamine, bright yellow crystals formed and after addition of 5 ml. of the diamine, 2.60 g. of this product was separated. Another crop (1.87 g.) of this same product was separated after adding an additional 3 ml. of ethylenediamine solution. A final incremental addition of 2 ml. of ethylenediamine solution provided a mixture of yellow crystals contaminated with a pale green solid. (Subsequent work—see below—has shown that this yellow product $[Pt(en)Br_2]$ is contaminated with a polymerization isomer. Conditions leading to the formation of $[Pt(en)Br_2]$ while minimizing the formation of the isomer are embodied in the procedure given.) The total yield was 4.47 g. or 77% based on potassium hexabromoplatinate(IV). *Anal.* Calcd. for $[Pt(en)Br_2]$: Pt, 47.0; Br, 38.5. Found: Pt, 46.9; Br, 38.7.

Ethylenediaminedibromoplatinum(II) is soluble in liquid ammonia at −33.5° apparently without reaction. Evaporation of the solvent from the yellow solution provided yellow crystals that gave an X-ray diffraction pattern identical with that of the solid originally dissolved. When a mixture of the yellow solid and its green polymerization isomer is treated with liquid ammonia at −33.5°, the former dissolves while the latter remains as a brown insoluble ammoniate. Pure $[Pt(en)Br_2]$ was recovered from the ammonia solution; the ammonia-insoluble brown ammoniate was deammoniated at 10^{-2} mm. at room temperature to provide the original green component of the mixture. Yellow $[Pt(en)Br_2]$ is also readily soluble in *N*,*N*-dimethylformamide, from which the bromide may be recrystallized by addition of water. If, however, these solutions are heated to *ca.* 50°, decomposition resulting in deposition of elemental platinum occurs.

Bisethylenediamineplatinum(II) Tetrabromoplatinate(II), $[Pt(en)_2]PtBr_4$.—A solution of tetrabromoplatinic acid was divided into two equal portions, ethylenediamine was added to one portion at 80–90° until all of the solid dissolved whereupon this was added to the other portion of the original solution. The pale green crystals that separated in quantitative yield were washed with water and dried at 110° for 2 hr. *Anal.* Calcd. for $[Pt(en)_2]PtBr_4$: Pt, 47.0; Br, 38.5. Found: Pt, 47.1; Br, 38.5.

As a means of providing evidence (other than that arising from the mode of synthesis) for the identity of the ionic components of this salt, precipitation of $PtBr_4^{2-}$ as the silver salt proved unsuccessful at or below room temperature owing to incomplete reaction; precipitation at elevated temperatures is impractical because of formation of silver bromide. Accordingly, the presence of two distinctly different ionic species containing platinum(II) was demonstrated by the potentiometric titration method of Grinberg and Ryabchikov.[8] Thus, 0.2801 g. of the salt was suspended with efficient stirring in 110 ml. of 1.0 *N* hydrochloric acid solution at 25° and titrated with 0.1384 *N* sodium bromate solution; the results are given in Fig. 1. About 4 hr. was required for the titration to the first end-point, at which stage all of the solid had dissolved and the color of the solution was pale yellow. Titration to the second end-point required only 30 min.; the final solution had an intense yellow color, and should be expected to contain $[Pt(en)_2Br_2]PtCl_4$ and/or its isomers. Evaporation of the solution to a small volume yielded 0.1 g. of orange colored crystals. *Anal.* Calcd. for

$[Pt(en)_2Br_2]PtCl_6$: Pt, 45.0. Found: Pt, 44.3. The calculated end-points for oxidation of half and all of the platinum to the 4^+ oxidation state are 4.87 and 9.75 ml. of titrant, respectively. The end-points established by means of a differential plot are 4.68 and 9.75 ml.

Bisethylenediamineplatinum(II) Bromide, $[Pt(en)_2]Br_2$.—Although this compound should be formed readily by the action of ethylenediamine upon either $[Pt(en)Br_2]$ or $[Pt(en)_2]PtBr_4$, the reaction with the latter was found to be impractically slow. Accordingly, 1.87 g. of $[Pt(en)Br_2]$ was suspended in 30 ml. of water, treated with 1 ml. of ethylenediamine and heated at 80–90° for 4 hr. A small quantity of residual solid was removed by filtration, the filtrate was diluted with 500 ml. of ethanol, and cooled to 0°. The fine white crystals that separated were filtered, washed with ethanol, and dried at 110°. The yield was 1.96 g. or 92% based on $[Pt(en)Br_2]$. *Anal.* Calcd. for $[Pt(en)_2]Br_2$: Pt, 41.1; Br, 33.6. Found: Pt, 41.1; Br, 33.4.

***trans*-Bisethylenediaminedibromoplatinum(IV) Bromide, $[Pt(en)_2Br_2]Br_2$.**—This synthesis was effected by a procedure similar to that used by Schleicher, Henkel and Spies[9] for the preparation of $[Pt(en)_2Br_2]Cl_2$. Thus, 0.424 g. of $[Pt(en)_2]Br_2$ was dissolved in 25 ml. of water and treated with 0.2 ml. of bromine at 50°. After 15 min., the temperature was raised to 100° and air was blown over the surface of the solution to remove excess bromine. When the volume of the solution was reduced to 10 ml., it was cooled to room temperature, treated with 1 ml. of concentrated hydrobromic acid solution, and finally diluted with 100 ml. of 2:1 ethanol–acetone mixture. The fine yellow crystals that separated were filtered, washed with ethanol and acetone, and dried in air.[10] *Anal.* Calcd. for $[Pt(en)_2Br_2]Br_2$: Pt, 30.7. Found: Pt, 29.7.

Ethylenediaminetetrabromoplatinum(IV), $[Pt(en)Br_4]$.—Although this compound was formed successfully by the oxidation of $[Pt(en)Br_2]$ with bromine, this procedure[7,9] was found to be much less satisfactory than that which follows. An excess of 50% aqueous ethylenediamine was added to 2.99 g. of K_2PtBr_6 in 100 ml. of water at room temperature. After 3 hr., the solution was acidified with hydrobromic acid, heated to 90°, then cooled to 10°. The orange-colored powder that separated was filtered, washed with water followed by ethanol and ether, and dried in air. The yield was 1.78 g. or 78% based on K_2PtBr_6. *Anal.* Calcd. for $[Pt(en)Br_4]$: Pt, 34.0; Br, 55.6. Found: Pt, 34.0; Br, 55.3. This substance is soluble in both N,N'-dimethylformamide and γ-butyrolactone, and dissolves in liquid ammonia owing to the occurrence of reactions described elsewhere.[2]

Ethylenediaminedichloroplatinum(II), $[Pt(en)Cl_2]$.—Although another method of synthesis has been reported,[7] the following procedure is both simple and efficient. To 1.30 g. (0.0013 mole) of $[Pt(en)Br_2]$ suspended in 75 ml. of water was added to 1.064 g. (0.00626 mole) of silver nitrate and the mixture was acidified with 1 ml. of 6 *N* nitric acid. After heating the reaction mixture at 90° for 2 hr., the precipitated silver bromide was filtered off, and the filtrate was treated with excess potassium chloride solution. Golden yellow needles of the desired chloride separated after about 5 min., whereupon the solution was cooled to 0° and filtered. The product was washed with water, ethanol, and dried for 12 hr. at 110°. The yield was 0.93 g. or 91% based on $[Pt(en)Br_2]$. *Anal.* Calcd. for $[Pt(en)Cl_2]$: Pt, 59.8; Cl, 21.7. Found: Pt, 59.6; Cl, 21.7.

Ethylenediaminediiodoplatinum(II), $[Pt(en)I_2]$.—This substance was prepared by a method analogous to that used by Schleicher, *et al.*[9] Thus, 1.4445 g. (0.0035 mole) of $[Pt(en)Br_2]$ slurried in 150 ml. of water was treated with 1.1913 g. (0.0070 mole) of silver nitrate for 1 hr. at 90°. The precipitated silver bromide was removed by filtration and excess potassium iodide was added to the filtrate. The fluffy yellow solid that separated immediately was filtered, washed with water and with ethanol and dried in air. The yield was 1.73 g. or 96.7% based on $[Pt(en)Br_2]$. *Anal.* Calcd. for $[Pt(en)I_2]$: Pt, 38.3; I, 49.8. Found: Pt, 38.4; I, 49.5.

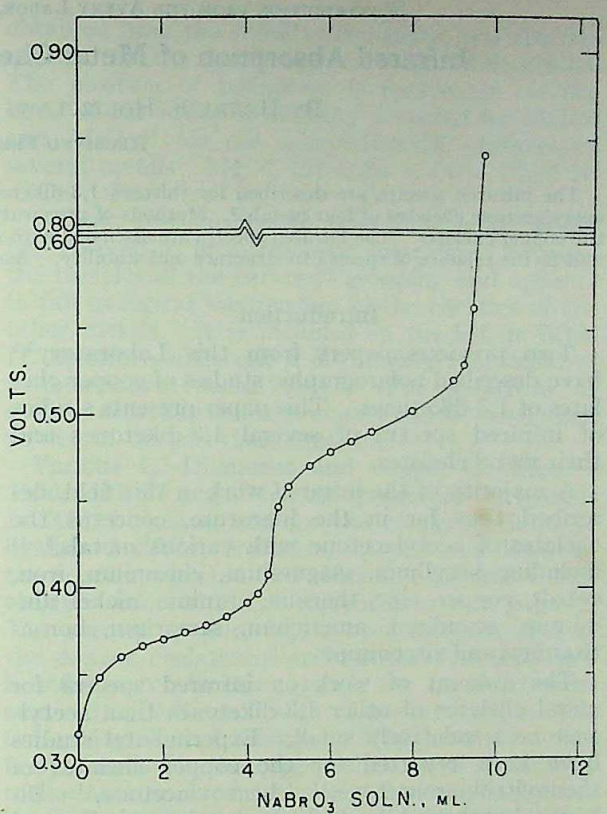

Fig. 1.—Potentiometric titration of $[Pt(en)_2]PtBr_4$ with sodium bromate.

Platinum(IV) Iodide, PtI_4.—In accordance with the procedure described by Pigeon,[11] PtI_4 was prepared in quantitative yield by heating 5.54 g. of platinum as H_2PtCl_6 with 19 g. of KI at 80°. *Anal.* Calcd. for PtI_4: Pt, 27.8. Found: Pt, 27.8.

Ethylenediaminetetraiodoplatinum(IV), $[Pt(en)I_4]$.—Approximately 1 g. of PtI_4 was dissolved in a slight excess of aqueous potassium iodide solution to provide a solution of K_2PtI_6 which was treated dropwise with 50% aqueous ethylenediamine. A very fine maroon-red precipitate separated at once and continued to form until the solution was colorless. Since analysis showed that this product was impure, it was treated with 100 ml. of γ-butyrolactone at room temperature; this resulted in a deep red solution and a bronze colored solid that was removed and discarded. The filtrate was diluted fivefold with water and fine glistening black crystals separated. This product was filtered, washed with water and with ethanol and dried in air; the yield was *ca.* 1 g. *Anal.* Calcd. for $[Pt(en)I_4]$: Pt, 25.6; I, 66.5. Found: Pt, 25.5; I, 66.5.

Infrared Absorption of Metal Chelate Compounds of 1,3-Diketones[1]

BY HENRY F. HOLTZCLAW, JR., AND JAMES P. COLLMAN

RECEIVED FEBRUARY 11, 1957

The infrared spectra are described for thirteen 1,3-diketones, the copper chelates of seventeen 1,3-diketones, and the acetylacetone chelates of four metals.[2] Methods of preparation are described, including an improved method of preparing the copper chelates. The infrared spectra are discussed with respect to a comparison with spectra reported in the literature and to the relation of spectra to structure and stability. Assignments are made for several absorption frequencies.

Introduction

Two previous papers from this Laboratory[3,4] have described polarographic studies of copper chelates of 1,3-diketones. This paper presents studies of infrared spectra of several 1,3-diketones and their metal chelates.

A majority of the infrared work in this field, described thus far in the literature, concerns the chelates of acetylacetone with various metals,[5-11] including beryllium, magnesium, chromium, iron, cobalt, copper, zinc, thorium, uranium, nickel, aluminum, scandium, americium, samarium, borontitanium and zirconium.

The amount of work on infrared spectra for metal chelates of other 1,3-diketones than acetylacetone is relatively small. Experimental studies have been reported for the copper chelates of thenoyltrifluoroacetone,[11] benzoylacetone,[11] dibenzoylmethane,[9,11] trifluoroacetylacetone[12] and hexafluoroacetylacetone.[12]

A few studies have been made of the infrared spectra of unchelated 1,3-diketones, including acetylacetone,[13] dibenzoylmethane,[13] and several fluorinated 1,3-diketones.[14]

The present paper describes preparation and infrared studies of thirteen 1,3-diketones, the copper chelates of seventeen 1,3-diketones, and the acetylacetone chelates of several metals.

Results and Discussion

The wave numbers of bands in the infrared spectra for the ligands and chelates studied are given in Tables I, III, IV and V.[2] Infrared intensity abbreviations used in the tables are: s, strong; m, medium; w, weak; b, broad; sh, shoulder. Bands in the Nujol region are not listed. Exact information on the origin of bands for metal coördination compounds is still relatively meager. Several of the assignments made in the tables and in the discussion, therefore, should be considered as tentative.

The following key to the Roman numeral designations used in Tables III, IV and V lists the ligand molecules

I. 3-Ethyl-2,4-pentanedione
II. 3-*n*-Propyl-2,4-pentanedione
III. 3-Chloro-2,4-pentanedione
IV. 3-Phenyl-2,4-pentanedione
V. 3-Benzyl-2,4-pentanedione
VI. Isovalerylacetone (6-methyl-2,4-heptanedione)
VII. Benzoylacetone (1-phenyl-1,3-butanedione)
VIII. Dibenzoylmethane (1,3-diphenyl-1,3-propanedione)
IX. 2-Furoyltrifluoroacetone [1-(2-furyl)-4,4,4-trifluoro-1,3-butanedione]
X. 2-Furoylperfluorobutyrylmethane [1-(2-furyl)-4,4,5,5,6,6,6-heptafluoro-1,3-hexanedione]
XI. 2-Thenoyltrifluoroacetone [1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedione]
XII. 2-Thenoylperfluorobutyrylmethane [1-(2-thienyl)-4,4,5,5,6,6,6-heptafluoro-1,3-hexanedione]
XIII. 3-Bromo-2,4-pentanedione
XIV. 3-Iodo-2,4-pentanedione
XV. 3-Methyl-2,4-pentanedione
XVI. Trifluoroacetylacetone (1,1,1-trifluoro-2,4-pentanedione)
XVII. Hexafluoroacetylacetone (1,1,1,5,5,5-hexafluoro-2,4-pentanedione)

Metal Chelates of Acetylacetone.—The infrared spectra of the acetylacetone (2,4-pentanedione) chelates of copper(II), palladium(II), nickel(II), cobalt(II), manganese(II), magnesium(II), cadmium(II), aluminum(III), chromium(III), iron(III) and sodium(I) were determined. Of the 11, only the four not previously reported in the literature (palladium, manganese, cadmium and sodium) are listed in Table I.[2]

Although the spectrum of acetylacetone contains no intense bands in the 1500 cm.$^{-1}$ region, metal chelates of acetylacetone do absorb strongly in this region. Following the assigment of Lecompte,[5] the uppermost band is assigned to a perturbed (or chelated) carbonyl and the lower band to a perturbed carbon–carbon double bond. In the conjugated chelate ring, the carbonyl and carbon–carbon double bonds have less double bond character and more single bond character, accounting for

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the large frequency shifts of the carbon–carbon double bond adsorption band and the carbonyl absorption band upon chelation.

The position of the perturbed carbonyl band, usually the strongest band found in the spectrum of a given chelate, is perhaps largely dependent upon three factors: (1) the masses of the groups attached, at the ends of the ligand molecule, to the carbonyl groups, (2) interaction of the carbonyl with neighboring π or d-orbitals, and (3) the relative electron density of the σ bonds. The latter factor is, for the most part, controlled by the electronegativity of the groups attached to the carbon atom of the carbonyl group. For chelates of different metals but the same ligand, the mass effect probably has very little relation to the strength of the metal–oxygen bond. If more conjugation between the metal ion and the carbonyl exists in one metal acetylacetonate than another, this might be expected to result in a stronger metal–oxygen bond, less double bond character in the carbonyl group, and a lowering of the frequency of the perturbed carbonyl band.

Previous attempts to find a band or bands related to the stability of the chelates have met with only partial success. Bellamy and Branch[11] found that for bivalent metal complexes of salicylaldehyde, the shift of the carbonyl band followed the usual order of stabilities. A rough measure of stability was obtained from the positions of this band with bivalent metal chelates of 2-thenoyltrifluoroacetone. They reported, however, that there was no apparent relation between chelate stability and position of the carbonyl band for the bivalent metal chelates of acetylacetone.

The bands selected by Bellamy and Branch appear to have been, in each case, the most intense band found in the 1500 cm.$^{-1}$ region rather than the first or uppermost band in each case. Selection of the uppermost of the two bands seems to yield a significant relationship. The uppermost band in this region, from the spectra measured in the present work, is listed for several metals in Table II in order of decreasing frequency.

Van Uitert, Fernelius and Douglas,[15] from stability constants calculated from *p*H measurements, have reported the order of increasing stability of several metal chelates of acetylacetone to be: Mg(II) < Cd(II) < Mn(II) < Co(II) < Zn(II) < Ni(II) < Cu(II).

TABLE II

FREQUENCIES OF PERTURBED CARBONYL BANDS IN ACETYLACETONE CHELATES OF SEVERAL METALS

Metal	Frequency, cm.$^{-1}$	Metal	Frequency, cm.$^{-1}$
Na(I)	1630	Mn(II)	1607
Ni(II)	1618	Co(II)	1595
Mg(II)	1615	Cu(II)	1580
Cd(II)	1613	Pd(II)	1577

A comparison of these two series indicates, with nickel an exception, a qualitative relationship between the strength of the metal–oxygen bond, as obtained from the stability constants, and the frequency of the perturbed carbonyl absorptions. The position of palladium is reasonable on the basis of the order of stability reported by Mellor and Maley[16] for the salicylaldehyde chelates of several metals: Mg < Cd < Zn < Co < Pb < Ni < Cu < Pd.

Sodium acetylacetonate, essentially ionic, would be expected to have the least interaction between the metal and the carbonyl grouping and appears to fall in logical relationship to the chelates of the other metals. It is included in the list in Table II, therefore, although it is the only compound of a monovalent metal listed. The spectrum of sodium acetylacetonate probably can be considered as that of the acetylacetonate ion.

Various 1,3-Diketones and Copper Chelates.—Tables III, IV and V[2] list the spectra for the ligands I—XII, inclusive, and for the copper chelates of ligands I–XVII, inclusive. Agreement between the spectra reported in Tables III, IV and V and the few reported in the current literature is good. The spectra of pure liquid acetylacetone and of the copper chelates of trifluoroacetylacetone and hexafluoroacetylacetone agree, for most frequencies, within 0–3 cm.$^{-1}$ with values reported by Belford, Martell and Calvin.[12] The perturbed carbonyl bands for the copper chelates of 2-thenoyltrifluoroacetone and 1-phenyl-1,3-butanedione correspond closely with the values reported by Bellamy and Branch,[11] but that for the copper chelate of dibenzoylmethane (1552 cm.$^{-1}$) does not agree with the value of Bellamy (1524 cm.$^{-1}$). The discrepancy may be explained by the choice of the most intense band by Bellamy rather than the first strong band in the 1500 cm.$^{-1}$ region. Some other values reported by Bellamy vary a few wave numbers from those reported in this work. These differences are thought to be accounted for by the use of dilute chloroform solution by Bellamy, whereas Nujol suspensions were used in the present work. Bellamy reports a free carbonyl band for benzoylacetone which was not found in this work. His spectrum of dibenzoylmethane agrees with that reported in Table IV.

4000-1650 Cm.$^{-1}$ Region.—Very few copper chelates of 1,3-diketones absorb in this region. The origin of the weak absorption bands for the copper chelates of 2-thenoyltrifluoroacetone and 2-furoylperfluorobutyrylmethane at 3110 and 3140 cm.$^{-1}$, respectively, and the moderate band for the copper chelate of hexafluoroacetylacetone at 3550 cm.$^{-1}$ is uncertain.

Seven out of the thirteen 1,3-diketones examined show one or more hydroxyl bands in the 3600 to 3000 cm.$^{-1}$ region. The diketones in which such bands are not found may perhaps have absorptions in this region which are weak or poorly resolved. The molecules containing electronegative groups such as trifluoromethyl or perfluoropropyl are found to have hydroxyl bands at a lower frequency than the other 1,3-diketones in agreement with Belford, who in a recent study of fluorinated copper chelates[12] attributed the lowering of the hydroxyl frequency to the presence of a more acidic hydrogen.

These bands are not sharp enough to provide more quantitative information about the acidity.

The next important absorption bands are the sharp, usually strong bands thought to be caused by free carbonyl absorptions of the keto form of the 1,3-diketone. These bands, present in the spectra of six of the thirteen diketones studied, disappear upon chelation. Except for 3-chloro-2,4-pentanedione, which has only one band centered at about 1725 cm.$^{-1}$, the diketones exhibit two such bands, one centered around 1700 cm.$^{-1}$ and the other around 1725 cm.$^{-1}$.

1650 to 1500 Cm.$^{-1}$ Region.—A strong, usually broad, band around 1610 cm.$^{-1}$, which disappears upon chelation, was observed in all of the diketones studied. The position of this band, which is characteristic of 1,3-diketones and which has been referred to as the "enol-chelate" band by Bellamy and Beecher,[17] does not seem to be related to the inductive or resonance effects of the group attached to the hydrogen-bonded, six-membered ring of the enol form.

The most important chelate band is the perturbed carbonyl band, usually the first strong band found in the spectrum of a copper chelate of a 1,3-diketone and ordinarily located around 1580 cm.$^{-1}$. In 11 of the 12 copper chelates for which the free diketone is also reported, the perturbed carbonyl bands of the chelate are at a lower frequency than the hydrogen-bonded carbonyl (enol chelate) band of the unchelated ligand. An exception is the copper chelate of 2-furoylperfluorobutyrylmethane, in which there are three bands which might conceivably be assigned to the perturbed carbonyl absorption, 1615 cm.$^{-1}$, 1598 cm.$^{-1}$ and 1580 cm.$^{-1}$. The 1598 band is probably caused by absorption of the furan ring. The 1615 band has been arbitrarily designated as the perturbed carbonyl band, because it is the first strong absorption and is higher than the expected furan absorption. The two bands at 1615 and 1598 cm.$^{-1}$ may, alternatively, both arise from furan absorptions, with the strong band at 1580 cm.$^{-1}$ originating from the chelated carbonyl group.

In contrast to the acetylacetonates of the various metals reported above, a comparison of the perturbed carbonyl bands of the copper chelates of the seventeen 1,3-diketones shows no apparent relationship to the stability of the chelates. Neither does the difference between the enol–chelate band of the ligand and the perturbed carbonyl band of the chelate, nor the difference between the perturbed carbonyl band and the perturbed carbon–carbon double bond, seem to have a direct relation to stability of the metal chelate. The absence of a relationship is not entirely unexpected. In comparing the acetylacetonates of various metals, the action of the ligand is essentially the same in each case and, except for the differences in the masses of the metals, any effect which strengthens the metal–oxygen bond weakens the carbon–oxygen carbonyl bond. For the copper chelates of various 1,3-diketones, on the other hand, the differences in resonance, inductive, and mass effects between the various chelates must be attributed essentially all to the ligand, the metal remaining the same, and may differ in their relative effects upon the metal–oxygen bond and the carbonyl bond. For example, a phenyl group attached to a carbonyl group in the ligand might set up an interfering conjugation through a quinoid-like structure, thereby decreasing the double bond character of the adjacent carbonyl group, lowering the frequency of the perturbed carbonyl band, and decreasing the strength of the copper–oxygen bond. This is illustrated by the spectrum of bis-(1-phenyl-1,3-butanediono)-copper(II), which has a perturbed carbonyl band at 1561 cm.$^{-1}$, compared to 1580 cm.$^{-1}$ for bis-(2,4-pentanediono)-copper(II) which is known to have a stronger copper–oxygen bond.[4] On the other hand, strong electronegative groups attached to the chelate ring cause a decrease in the stability of the chelate[4] but an increase in the strength of the carbon–oxygen carbonyl bond and therefore an increase in the frequency of the perturbed carbonyl absorption band. This is exemplified by bis-(hexafluoroacetylacetone)-copper(II) in which there are two strong bands at 1645 and 1615 cm.$^{-1}$ (either or both of which could be perturbed carbonyl absorptions). The increase in the first strong absorption band of the spectra of fluorinated copper chelates may be caused by the electron-attracting group increasing the force constant of the carbonyl bond.

Further, if a group capable of acting as an electron sink through resonance were attached to one of the carbonyls of a 1,3-diketone, and a strongly electronegative group were attached to the other carbonyl, the spectrum of the resulting chelate might contain two different perturbed carbonyl absorptions. The 1608 and 1568 cm.$^{-1}$ bands of bis-(2-furoyltrifluoroacetono)-copper(II) and the 1615 and 1580 cm.$^{-1}$ bands of bis-(2-furoylperfluorobutyrylmethane)-copper(II) may be explained in this manner. The analogous 2-thenoyl compounds are complicated by the presence of thiophene bands which may be at the same frequency as the second perturbed carbonyl band. In the furan-containing compounds, three bands were found, one of which logically is assigned to the furan ring.

The perturbed carbonyl band seems to be at a lower frequency for each of the copper chelates in which the carbon between the two carbonyl groups is substituted. This may be in part a mass effect. Although the information concerning mass effects upon absorption bands is meager at present, it is interesting to note that for chelates of 3-substituted 2,4-pentanedione a comparison of perturbed carbonyl frequencies with the masses of the substituted groups produces a reasonably good inverse relationship

Substituted group	Relative mass of group	Frequency of perturbed carbonyl
(Hydrogen)	1	1580
Methyl	15	1577
Ethyl	30	1571
Chloro	35.5	1577
n-Propyl	43	1575
Phenyl	77	1558
Bromo	80	1570
Benzyl	91	1547
Iodo	127

The additional factor of positive inductive effect of groups such as benzyl further complicates the factors controlling the position of the perturbed carbonyl absorption band.

Other bands in the 1650 to 1500 cm.$^{-1}$ region in either the free ligand or the chelate can be attributed to vibrations of functional groups, such as phenyl, furan and thiophene rings.

1500-800 Cm.$^{-1}$ Region.—A band centered around 1425 cm.$^{-1}$ in many of the 1,3-diketones and their chelates is probably caused by a methyl deformation. Similar assignments have been given by other workers, including Belford, Martell and Calvin[12] who have assigned the 1425 cm.$^{-1}$ band in acetylacetone to a methyl deformation. The compounds which have no methyl group substituted in the chelate ring fail to absorb in the 1425 cm.$^{-1}$ region.

Strong carbon–fluorine bands appear from 1300 to 1000 cm.$^{-1}$.

A range of additional perturbed carbonyl absorption has been reported by Lecompte[5] and by Bellamy and Branch[11] in the 1400 to 1300 cm.$^{-1}$ region. A comparison of several of the ligand and chelate spectra studied in the present work reveals a band which could, perhaps, be an additional perturbed carbonyl.

800-650 Cm.$^{-1}$ Region.—Strong bands occur in the upper 700 cm.$^{-1}$ region in the 1,3-diketones and their metal chelates. Ueno and Martell[18] ascribe similar bands in the range 779 to 740 cm.$^{-1}$ for metal chelates of bisacetylacetone–ethylenediimine and related compounds to C–H out-of-plane deformation vibrations. In compounds of the type $R'R''C{=}CHCH_3$, such vibrations are usually in the range 840-800 cm.$^{-1}$. Ueno and Martell reasoned that the aromatic nature of the six-membered hydrogen-bonded ring of the enol form of the ligand or of the conjugated chelate ring explains the lowering of these absorptions.

The 1,3-diketones which are substituted at the methylene carbon between the two carbonyl groups could have no hydrogen on the carbon–carbon double bond of the ligand enol form nor on the carbon–carbon double bond of the chelated ligand. The spectra of the chelates and free ligands are listed in Table III for compounds in which ethyl, *n*-propyl, chloro, phenyl and benzyl groups have been substituted at the number three carbon of 2,4-pentanedione. In Table V, the spectra of chelates are listed in which bromo, iodo and methyl groups have been substituted. The spectra of several of these ligands and chelates show bands in the 700 cm.$^{-1}$ region which cannot be attributed to a hydrogen out-of-plane deformation. The origin of this absorption is the more puzzling, inasmuch as the absorption band, in agreement with the observations of Ueno and Martell for the ethylenediimine compounds, seems to be almost unaffected by chelation of the ligand or by drastic alteration of the metal used in chelating the ligand.

Below 700 cm.$^{-1}$, absorption bands are expected which are caused by metal–oxygen vibrations.[5] Such bands, however, are conspicuously absent down to 650 cm.$^{-1}$ in most of the spectra of copper chelates of 1,3-diketones studied in the present work. In only a few instances (the copper chelates of 2,4-pentanedione, isovalerylacetone, 3-benzyl-2,4-pentanedione and 3-*n*-propyl-2,4-pentanedione) were bands found in this region which could be so assigned after comparing the spectra of the chelate and of the corresponding free 1,3-diketone. The possibility exists that an examination of the frequency region below 650 cm.$^{-1}$ might reveal additional bands which could be assigned to metal–oxygen vibrations.

Acknowledgment.—The authors wish to thank the Research Council of the University of Nebraska for a grant which partially supported this investigation.

Experimental

Spectra.—All spectra were determined in the frequency range 4000-650 cm.$^{-1}$ with a Perkin–Elmer Model 21 recording spectrophotometer, using sodium chloride optics.[19] Compounds usually were examined as solids in Nujol mulls. A few samples, as indicated in the tables, were studied as pure liquid films.

Preparation and Purification of Compounds. Metal Chelates.—1. The acetylacetonates of palladium(II), manganese(II) and cadmium(II) were prepared and analyzed by Wenz.[20] The copper chelates of hexafluoroacetylacetone and trifluoroacetylacetone were obtained from Professor A. L. Henne of The Ohio State University. Preparation and analysis of the copper chelates of acetylacetone, 1-phenyl-1,3-butanedione, 1,3-diphenyl-1,3-propanedione, 3-methyl-2,4-pentanedione, 3-ethyl-2,4-pentanedione, 3-*n*-propyl-2,4-pentanedione and 3-phenyl-2,4-pentanedione and the respective ligands are described in previous articles.[3,4]

2. **Sodium Acetylacetonate.**—The method of Morgan and Rawson[21] was used. The white precipitate was filtered, washed successively with cold, absolute ethanol and cold ether, dried and weighed; yield 23.0 g. (78%).

3. **Bis-(isovalerylacetono)-copper(II).**—A dioxane solution of the diketone was added slowly, with stirring, to an ammoniacal water solution of copper nitrate. The precipitate was filtered, washed with water, dioxane and ether, and dried. The sample was recrystallized from chloroform and sublimed at 110° at 0.005 mm. *Anal.* Calcd.: Cu, 19.87. Found: Cu, 19.25, 19.30.

4. **Bis-(2-thenoyltrifluoroacetono)-copper(II).**—An improved procedure was developed and was used in the preparation of several of the chelates.

A slurry of 11.1 g. of thenoyltrifluoroacetone (0.05 mole), 5.0 g. of copper acetate monohydrate (0.025 mole) and 100 ml. of 80% acetone–water solution was stirred for 24 hours, after which the acetone was removed on a steam-bath. The precipitate, after successive washing with ice-cold 50% water–ethanol solution, cold 5% aqueous ammonia (to remove excess copper acetate) and ice-water, was dried under vacuum and extracted in a Soxhlet extractor with 150 ml. of chloroform until the liquid extract became colorless. The chloroform solution was allowed to stand for 12 hours at room temperature and then was cooled to 0° and filtered. The dark-green crystals, superior to those produced without the extraction technique, were dried in a vacuum desiccator; yield 11.1 g. (88.7%). The compound would not sublime without decomposition. *Anal.* Calcd.: Cu, 12.56; C, 37.98; H, 1.58. Found: Cu, 12.72, 12.67; C, 38.34; H, 1.76.

5. **Bis-(2-furoyltrifluoroacetono)-copper(II).**—This compound was prepared and purified in the same manner as bis-(2-thenoyltrifluoroacetono)-copper(II). The green, crystalline compound decomposes upon sublimation; yield 99%. *Anal.* Calcd.: Cu, 13.41; C, 40.55; H, 1.69. Found: Cu, 13.87, 13.92; C, 40.07; H, 2.10.

6. **Bis-(2-thenoylperfluorobutyrylmethane)-copper(II).**—The method described for bis-(2-thenoyltrifluoroacetono)-copper(II) was used. The green, crystalline compound decomposes with sublimation; yield 99%. *Anal.* Calcd.: C, 33.92; H, 1.41. Found: C, 34.20; H, 1.43.

7. **Bis-(2-furoylperfluorobutyrylmethane)-copper(II).**—The compound was prepared and purified by the method described for bis-(2-thenoyltrifluoroacetono)-copper(II). The green, crystalline compound decomposes with sublimation; yield 98%. *Anal.*: Calcd. C, 35.53; H, 1.48. Found: C, 35.63; H, 1.32.

8. **Bis-(3-chloro-2,4-pentanediono)-copper(II).**—The method was similar to that described for bis-(2-thenoyltrifluoroacetono)-copper(II). A mixture of 44.6 g. of crude 3-chloro-2,4-pentanedione[22] (0.318 mole), 33.3 g. of copper acetate monohydrate (0.166 mole) and 200 ml. of acetone was allowed to stand in a stoppered flask for 24 hours. The crude precipitate, which was filtered from the slurry after cooling to 0°, was three times stirred with 200 ml. of water, filtered and dried on a fritted disc; yield 60 g. (80%). A small sample was recrystallized successively from benzene and chloroform and dried 48 hours in a vacuum desiccator. The green crystals decompose with sublimation and are unstable in alcohol and dilute, aqueous ammonia. *Anal.* Calcd.: Cu, 19.21; C, 36.31; H, 3.63. Found: Cu, 19.42; C, 35.93; H, 3.69.

9. **Bis-(3-bromo-2,4-pentanediono)-copper(II).**—A mixture of 25 g. of acetylacetone (0.25 mole) and 25 ml. of chloroform was placed in a 500-ml. three-neck, round-bottom flask fitted with a dropping funnel, stirrer and a tube leading to an aspirator (to remove hydrogen bromide). The aspirator was adjusted so that pressure inside the flask was approximately 50 mm. less than atmospheric pressure. The flask was immersed in an ice-bath and stirring commenced. A solution of 44 g. of bromine (0.275 mole) in 115 ml. of chloroform was added through the dropping funnel during a period of one-half hour, after which stirring was continued for an additional one-half hour. The solution was washed in a separatory funnel (good hood required) with eight 100-ml. portions of cold tap water. The last portion of wash water had a *p*H over 5. After removal of the chloroform under reduced pressure at room temperature, the remaining liquid was combined with 25 g. of copper(II) acetate monohydrate (0.125 mole) and 200 ml. of a 90% acetone–water mixture. After the slurry had stood for 24 hours, it was cooled to 0° and filtered. The green powder was washed by stirring three times with 200 ml. of water and dried; yield 60 g. (75%, calculated from acetylacetone). A sample was recrystallized twice from benzene and dried 48 hours in a vacuum desiccator. The compound decomposes upon sublimation and is unstable in alcohol and in dilute, aqueous ammonia. *Anal.* Calcd.: Cu, 15.14; C, 28.64; H, 2.86. Found: Cu, 15.37; C, 28.61; H, 3.04.

10. **Bis-(3-iodo-2,4-pentanediono)-copper(II).**—The chelate was precipitated by adding a water solution of copper(II) acetate monohydrate to an acetone solution of 3-iodo-2,4-pentanedione prepared by the method of Kumler.[23] Inasmuch as every attempt to recrystallize the chelate resulted in decomposition, the product never was obtained in really pure form. *Anal.* Calcd.: C, 23.37; H, 2.34. Found: C, 20.58; H, 2.17.

11. **Bis-(3-benzyl-2,4-pentanediono)-copper(II).**—A method used in previous work in this Laboratory[4] involved refluxing the sodium salt of acetylacetone with benzyl chloride, followed by fractional distillation under reduced pressure. The following new procedure represents some improvement over the former procedure. A mixture of 10 g. of sodium acetylacetonate (0.082 mole) and 14 g. of benzyl bromide (0.082 mole) was placed in a 250-ml. flask fitted with a reflux condenser. Approximately 150 ml. of nitrobenzene was added to raise the boiling temperature of the solution and for convenience in later separation of the product (soluble in nitrobenzene) from excess sodium acetylacetonate (relatively insoluble). The mixture was refluxed for eight hours and filtered. The filtrate was distilled at 90° and 10 mm. pressure until no more distillate came over. The solution obtained by dissolving the residue in 80 ml. of acetone was mixed with 10 g. of copper(II) acetate monohydrate (0.05 mole) and 20 ml. of water. After the mixture had stood for 24 hours, the precipitate was filtered off and washed four times by stirring in water and filtering. The dark grey compound, after drying, weighed 8 g. (25%). A small sample was recrystallized four times from 95% ethanol. The infrared spectrum of this sample was the same as the spectrum of a sample previously prepared by the other method and characterized by analysis.

1,3-Diketones.—Samples of 3-chloro-2,4-pentanedione, 3-ethyl-2,4-pentanedione, 3-*n*-propyl-2,4-pentanedione, 3-phenyl-2,4-pentanedione and 3-benzyl-2,4-pentanedione were prepared in our laboratories subsequent to preparing the copper chelates.[3,4] Purified samples of these diketones were recovered from the pure copper chelates by the following procedure. Approximately 1.5 g. of the copper chelate was decomposed by stirring for two hours in 100 ml. of 20% sulfuric acid, followed by washing the acid solution with three 10-ml. portions of ether. The ether washings were dried over 10 g. of anhydrous sodium sulfate for 24 hours and filtered. The sodium sulfate was washed with 10 additional ml. of dry ether and the washing added to the original ether filtrate. After removal of the ether under reduced pressure, the remaining oil was transferred to a vacuum, microdistillation apparatus and distilled. For 3-phenyl-2,4-pentanedione, which is a solid at room temperature, recrystallization from petroleum ether was used in place of the distillation step.

Samples of 1,3-diphenyl-1,3-propanedione and 1-phenyl-1,3-butanedione, purchased from Eastman Kodak Company, were recrystallized three times from 95% ethanol. Samples of 2-furoyltrifluoroacetone, 2-thenoyltrifluoroacetone, 2-furoylperfluorobutyrylmethane and 2-thenoylperfluorobutyrylmethane, purchased from the Midcontinent Chemical Company, were purified by vacuum distillation. Acetylacetone, purchased from Eastman Kodak Company, was purified by distillation.

Efforts to prepare sufficiently pure samples of 3-bromo-2,4-pentanedione and 3-iodo-2,4-pentanedione failed because of their instability. An attempt to alkylate acetylacetone by refluxing a solution of sodium acetylacetonate and methyl iodide in ethylene glycol likewise was unsuccessful.

Methods of Analysis.—Analysis for copper was made by means of a standard potassium iodide–sodium thiosulfate titration, using a starch indicator. Prior to titration, the chelates were decomposed (1) with 20% sulfuric acid, or (2) by heating followed by treatment with concentrated nitric and sulfuric acids, or (3) by precipitation with hydrogen sulfide followed by treatment of the precipitated sulfide with concentrated nitric and sulfuric acids.

Carbon–hydrogen analyses were performed by the Micro-Tech Laboratories, Skokie, Illinois.

Hydrogen Bonding and Electronic Transitions: The Role of the Franck–Condon Principle

BY GEORGE C. PIMENTEL

RECEIVED MARCH 11, 1957

The influence of hydrogen bond formation on electronic transitions (including the $n \rightarrow \pi^*$ blue shift phenomenon) is discussed in terms of the Franck–Condon principle. The resultant frequency shift in absorption is equal to $W_0 - W_1 + w_1$ where W_0 and W_1 are the energies of hydrogen bond formation in the ground and excited states, respectively, and w_1 is the excitation implied by the Franck–Condon principle. The necessity of combining absorption and emission data to determine $W_0 - W_1$ is noted. The available absorption data indicate that the spectral shifts caused by water are usually about twice as big as those caused by methanol, suggesting that the hydrogen bond energy of water exceeds that of methanol to a given base.

Several studies have been made of the effect of hydrogen bonding (hereafter called H-bonding) on electronic transitions. For example, the absorption of phenol near 36,000 cm.$^{-1}$ has been observed for solutions containing phenol and one of several bases.[1-4] Another large body of applicable data relates to electronic transitions of bases dissolved in either alcohol or water. These data established an empirical correlation among solution spectra (apparently first suggested by Kasha[5] and substantiated by a compilation of data by McConnell[6]) called the "$n \rightarrow \pi^*$ blue shift phenomenon." In this correlation the absorption maximum of an $n \rightarrow \pi^*$ electronic transition is found to shift toward higher frequency if the solvent is changed from an alkane to an alcohol (this direction of shift being defined as a blue-shift). Recently Brealey and Kasha[7] recognized and established the importance of H-bonding in this solvent effect. Yet their discussion does not recognize the role of the Franck–Condon principle. Consequently their detailed interpretations are indeed oversimplified. We shall examine this role to determine the relationship between H-bond formation and the resultant spectral changes. The present discussion applies to all electronic transitions, including but not restricted to the $n \rightarrow \pi^*$ type.

The Franck–Condon Principle and Hydrogen Bonding.—Both McConnell[6] and Bayliss and McRae[8] have discussed in terms of the Franck–Condon principle the effect of solvation on an electronic transition. The equilibrium distances and orientations of solvent molecules around a solute molecule are dictated by the energetics of solvation. If this solute molecule makes an electronic transition, the solvation arrangement of the initial state is not necessarily the most stable for the new electronic distribution and, indeed, could be energetically repulsive. Since the solvent molecules cannot reorient during the transition (Franck–Condon principle) such a change in solvation energetics would result in a change in the energy separation of the two states (*i.e.*, there would be a solvent shift).

Bayliss and McRae[8] have attempted to enumerate the contributing factors to the solvation effects. Their treatment does not give adequate attention to the H-bonding interaction which, when present, dominates such forces as are usually described in terms of dispersion, dipole-polarizability and dipole–dipole forces. The dispersion effects are of the order of the van der Waals energy and the change of this term during an electronic transition is likely to be even smaller (as is assumed by Bayliss and McRae[8]). The comparison of dipolar and H-bonding effects is more subtle. We are here concerned with that part of the solute–solvent interaction which is attributed to the presence of permanent dipole moments in some or all of the molecular species present but which is *not* part of the specific interaction designated the H-bond. Most often, the functional groups possessing high bond dipoles will be involved in H-bond formation and any residual capacity for dipolar interactions of a non-H-bonding type will be small indeed. Experimental confirmation of these views is evident in the spectra of pyridazine in hexane–ethanol mixtures, as presented by Brealey and Kasha (their Fig. 3). This figure shows frequency invariance of band features of the pyridazine (not H-bonded) during a solvent change from pure hexane to a mixture of about 2 *M* ethanol in hexane. This indicates that this transition is little influenced by the dispersive and non-H-bonding dipolar effects that accompanied the drastic solvent change.[9] A further indication that the orientation effects associated with H-bonding far exceed those of dipolar interactions is given by the Trouton's rule constants. These constants, which contrast entropies of vaporization, are relatively close to a "normal" value (near 20–21) for polar compounds (*e.g.*, diethyl ether, 20.2; acetone, 21.9; 1,1,2,2-tetrachloroethane, 22.1) compared to the high values for H-bonding compounds (*e.g.*, methanol, 24.9; water, 26.0; ethanol, 26.9). Consequently the following discussion will ignore the dispersive and dipolar interactions. In any particular system where these neglected terms are unusually large and the H-bonding terms are small, the present treatment will then account for only that portion of the spectral perturbation due to the H-bonding.

In an H-bonding system, the interaction is localized at functional groups with either proton donor or acceptor properties. A solvent shift then indicates that the H-bonding properties of these functional groups in the initial state differ from the H-bonding properties of these same groups in the final state. The magnitude of the shift must be evaluated, however, in terms of the Franck–Condon principle.

Figure 1 portrays potential functions for formation of an H-bond A-H· · ·B where R is the A· · ·B distance. Figure 1a portrays the situation

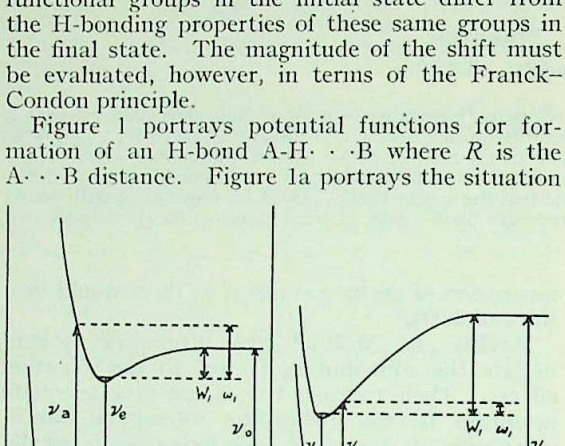

Fig. 1.—Hypothetical potential curves: energy *vs.* H-bond length: A–H. . .B; R = (A. . .B) distance; a, left, $W_0 > W_1$; b, right, $W_0 < W_1$.

when the excited state forms a weaker H-bond and in Fig. 1b the excited state forms the stronger H-bond. In each case the energy separation of the non-H-bonded species ($R = \infty$) is assumed to be identical to ν_0, the energy separation in a non-H-bonding solvent of the same refractive index. The H-bond energy is designated W ($W = -\Delta H$) and the excitation energy implied by the Franck–Condon principle is labeled w. (By these definitions, W and w are always positive numbers. Of course either W_0 or W_1 could be zero.)

There are three quantities of interest which might be experimentally accessible, ν_a, ν_e and ν_{0-0}, the frequencies appropriate to maximum of absorption, maximum of emission (*e.g.*, in a fluorescence spectrum), and the O–O transition, respectively.[10] These frequencies are related to the quantity ν_0 by the relations

$$\nu_a - \nu_0 = \Delta\nu_a = W_0 - W_1 + w_1 \quad (1)$$

$$\nu_e - \nu_0 = \Delta\nu_e = W_0 - W_1 - w_0 \quad (2)$$

$$\nu_{0-0} - \nu_0 = \Delta\nu_{0-0} = W_0 - W_1 \quad (3)$$

Clearly the most interesting quantity is $\Delta\nu_{O-O}$, which gives directly the difference in H-bond energies of ground and excited states. Since the quantity W_0 (for the ground state) usually can be determined by conventional methods and is known for many systems, eq. 3 offers a measure of W_1. The determination of $\Delta\nu_{O-O}$ requires both absorption and fluorescence studies. Although such studies do not involve any new techniques, they are subject to the usual difficulties (particularly the interference of overlapping bands).[11] None of the data recorded so far give $\Delta\nu_{O-O}$ but there are a number of measurements of values of $\Delta\nu_a$'s. It is notable that w_1 and w_0 are determined if all three data, $\Delta\nu_a$, $\Delta\nu_e$ and $\Delta\nu_{O-O}$, are measured (with the reservation expressed in footnote 10).

In Fig. 1a ($W_0 > W_1$) we see that the usual expectations of potential form predict that $W_0 > w_0$ and $w_1 > w_0$. No upper limit can be set on w_1 since the steep side of the potential function could rise sufficiently fast to make $w_1 > W_1$ (as is pictured in Fig. 1a). In any event, it will only be a coincidence if $w_1 = W_1$ and we see that $\Delta\nu_a$ cannot be expected, *a priori*, to measure W_0. Since w_1 is positive, eq. 1 predicts that if $W_0 > W_1$ then $\Delta\nu_a > 0$, *i.e.*, a blue-shift which exceeds the difference $W_0 - W_1$ by w_1 will be observed in absorption. Similarly, in emission, a shift will be observed which is less than $W_0 - W_1$ by w_0 (*i.e.*, either a red shift or blue shift may be observed; in either case, the shift will be small compared to W_0). If $W_1 = 0$, no shift will be observed in emission since then $W_0 = w_0$.

In Fig. 1b ($W_0 < W_1$) the anharmonicity expectations predict that $W_1 > w_1$ and $w_0 > w_1$. Now the absorption spectrum will show a shift which is less by w_1 than the red shift implied by the negative value of $W_0 - W_1$. The emission spectrum will show a red shift exceeding $|W_0 - W_1|$ by w_0.

Turning now to the interpretation of observations, a blue shift in absorption which is comparable in magnitude to W_0 implies Fig. 1a is applicable ($W_0 > W_1$) and the blue shift *exceeds* the difference $W_0 - W_1$. If a red shift is observed in absorption then Fig. 1b is applicable ($W_0 < W_1$) and the red shift is *less than* the difference $W_1 - W_0$. If only a small blue shift is observed in absorption, either of Figs. 1a or 1b could be applicable. Similarly, in emission, a blue shift implies Fig. 1a, a large red shift implies Fig. 1b, and a small red shift is ambiguous. Under any circumstances, $\Delta\nu_a$ and $\Delta\nu_e$ bracket the quantity $\Delta\nu_{O-O} = W_0 - W_1$.

The Expected Magnitude of Spectral Shifts.—The well characterized H-bonds have energies in the range 1–7 kcal. per bond (350–2500 cm.$^{-1}$). As mentioned above, a blue shift in absorption may exceed the ground state H-bond energy, hence blue shifts are expected in the range 350–2500 cm.$^{-1}$ and occasionally larger than 2500 cm.$^{-1}$. A red shift (in absorption) should never be as large as W_0, hence should not exceed 2500 cm.$^{-1}$. Even if a much stronger H-bond is formed in the excited state, the red shift reflects only the *difference* in energies of the ground and excited state H-bonds *at an H-bond distance optimum for the ground state but not for the excited state.*

The number of H-bonds influenced by the transition is, of course, an important factor. A monobasic proton donor can form only a single H-bond,

(10) The following discussion assumes "vertical" transitions for ν_0, ν_a and ν_e, without any consideration of transition probability as a function of configuration. It is difficult to assess this assumption, particularly for forbidden transitions which specifically depend upon vibration–electronic interaction. It is probably not drastically unsound for absorption in most cases.

(11) Kasha has pointed out that "fluorescence for $n \rightarrow \pi^*$ transitions) is characteristically non-existent; or, in rare cases, is extremely ..." [illegible] Communication from Dr. M. Kasha, Florida State University.

but a base molecule can form H-bonded complexes with two or more acid molecules. Thus Barrow and Yerger[12] identified the species A_2B in the system A = acetic acid, B = triethylamine. Similarly, complexes including several HX molecules have been proposed in HX–ether systems.[13] The solvent shift would be larger in a multiple H-bond complex in accordance with the number of H-bonds affected. Similarly, more than one H-bonding functional group may be present. If these groups are equivalent because of molecular symmetry, the electron distribution must necessarily change similarly at these sites. Again the observed shift would reflect the energies of all of the H-bonds affected. For strongly bonding systems (such as a dilute solution of pyridazine in ethanol) most of the pyridazine is expected to be in the 1:2 complex form and the blue shift will be determined by the sum of the changes of the first and second H-bond energies.

Experimental Data.—For electronic transitions of bases, the expectations concerning the magnitudes of H-bonding shifts are corroborated, as is revealed in the compilation of McConnell.[6] Except for glyoxal, all shifts induced by water or alcohol are in the range -1700 to $+4000$ cm.$^{-1}$ (20 examples). Furthermore, the red (negative) shifts are generally smaller than the blue (positive) shifts, again as expected. Tables I and II list a portion of these data, those systems for which both methanol and water solvents have been studied. Table III lists the available data for transitions in proton donors. All shifts are given as $\Delta\nu_a = \nu - \nu_0$ where ν is the frequency of maximum absorption in the H-bonding solvent and ν_0 is the corresponding frequency in a suitable reference solvent. Unless noted otherwise, the data in Tables I and II are from ref. 6 and the reference solvent is in every case a paraffin hydrocarbon.

It is interesting that the shifts caused by water are invariably higher than those in methanol and in six of eight examples, roughly double. Two possible explanations are suggested: more H-bonds may be formed between solvent and solute in water than in methanol; and/or the H-bonds with water may be stronger than those with methanol. The infrared spectral data provide support for the second proposal. The shifts in the stretching frequencies of water and alcohol in basic solvents are generally considered to be related to the corresponding H-bond energies. The shifts observed for water are usually about one and a half times those for methanol, as is evident in the compilation of data presented by Gordy.[15] Thus the infrared shifts also suggest that water forms stronger H-bonds to a given base than does methanol.

TABLE I

H-BOND SOLVENT SHIFTS FOR TRANSITIONS IN CARBONYL BASES

Base	ν_0 (cm.$^{-1}$)	Methanol $\Delta\nu_a$ (cm.$^{-1}$)	Water $\Delta\nu_a$ (cm.$^{-1}$)	Transition
Diazoacetic ester	25,500	+ 800	+1500	n-π
Acetone	35,960	+ 900	+1900	n–π
Mesityl oxide	30,760	+1200[a,7]		
		+1000	+3200	n–π
Diazoacetic ester	41,000	+1180[a,7]		
Mesityl oxide	43,000	− 550	− 600	π–π
		−1000	−1700	π–π

[a] Ethanol solvent.

TABLE II

H-BOND SOLVENT SHIFTS IN MISCELLANEOUS BASES

Base	ν_0 (cm.$^{-1}$)	Methanol $\Delta\nu_a$ (cm.$^{-1}$)	Water $\Delta\nu_a$ (cm.$^{-1}$)	Transition
Nitrosobenzene	13,000	+ 50	+ 450	n–π
Pyrazine	31,500	+ 700	+1800	n–π

Discussion

The Franck–Condon argument presented here implies a more complicated interpretation of the magnitude of the n $\rightarrow \pi^*$ "blue-shift" than the interpretation of Brealey and Kasha. Their comparison of the blue shift to the quantity W_0 is presumably based on the expectation that $W_1 = 0$ and no consideration is given to the large value of w_1 implied by the short interatomic distances of the H-bonded ground state. This suggests that the agreement between blue shift and H-bond energy found for each of the two systems pyridazine–ethanol and benzophenone–ethanol is fortuitous. This possibility is strengthened by noting that the blue shift used for pyridazine applies to a mixture containing about 25% uncomplexed pyridazine (using the K given by Brealey and Kasha), that the blue shift for benzophenone was corrected by about 20% because of overlap of an adjacent transition, and that the infrared shifts give only a coarse indication of the H-bond energy, possibly in error by as much as one kcal. On the other hand, their qualitative discussion seems to be correct. If a non-bonding electron localized on the basic functional group is transferred to an anti-bonding orbital, the change of electron density undoubtedly reduces base strength. Hence it is expected that $W_1 < W_0$ (though W_1 is not necessarily zero).

The red shifts of the π–π transitions indicate that the base strengths have been increased. This is no doubt to be attributed to a transition involving electron redistribution in the same space but

with enhanced electron density in the more peripheral portions. This is a characteristic difference of bonding and anti-bonding orbitals. Although this may be the expected behavior, again it is not necessary that every $\pi-\pi$ redistribution give a red shift since the basic functional groups may not be affected or the nodal properties may actually deplete the electron density at the basic sites.

The red shifts observed for the proton donors may be rationalized. All of these data refer to the transitions corresponding to the $A_{1g} \rightarrow B_{2u}$ transition of benzene, a transition to an excited state containing nodal planes perpendicular to the plane of the ring. The red shift suggests that this orbital places a nodal plane through the H-bonding functional group, so as to reduce the electron density at this site. This would cause an acidic group to become a better proton donor. Aromatic acids (phenol, aniline) should display red shifts whereas aromatic bases (anisole, dimethylaniline) should display no shift in basic solvents (as is observed, see ref. 1) and a blue shift in acidic solvents (no data available).

Conclusions

It seems clear that the solvent shifts caused by H-bonding solvents contain interesting information. In addition to empirical correlations which may aid in establishing the type of transition, these solvent shifts provide clues to the locale and nature of electron redistribution in the electronic transition. Perhaps the unique aspect is the promise for understanding the electronic distribution and H-bonding properties of excited states. For this purpose absorption and emission studies should be combined, if possible, to give the shift corresponding to the O–O transition.

Equations for the Limiting Current at the Rotated Dropping Mercury Electrode[1]

BY YUTAKA OKINAKA AND I. M. KOLTHOFF

RECEIVED JANUARY 26, 1957

This paper describes results of a theoretical and experimental study of the relationship between the limiting current at the rotated dropping mercury electrode on the one hand and the diffusion coefficient of the electroactive species, the kinematic viscosity of the solution, and the characteristics of the electrode on the other. Two theoretical equations are derived on the basis of hydrodynamics, one for the case when no surface-active substance is present and the other for the case when such substances are present. In view of the fact that the presence of a suitable surface-active substance is necessary for most practical purposes, the relations in the presence of a capillary-active substance were studied more extensively than those in its absence. The proposed equation in the presence of surface-active compounds involves an experimentally determined numerical constant and yields satisfactory agreement between observed and calculated limiting currents in the range of 75 to 210 r.p.m., provided that an electrode of the proper dimensions is employed. At a suitable speed of rotation in the presence of a surface-active substance, the limiting current at the rotated dropping mercury electrode, as a first approximation, is proportional to $D^{2/3}(mt)^{1/2}$, while at the unrotated conventional dropping mercury electrode it is proportional to $D^{1/2}m^{2/3}t^{1/6}$. Limitations of the derived equations are discussed both from theoretical and practical viewpoints.

The rotated dropping mercury electrode (R.D.M.E.) recently developed in this Laboratory[2] is of practical importance because it allows polarographic determinations at concentrations of an order of magnitude of one smaller than with the conventional dropping mercury electrode (D.M.E.). The quantitative dependence of the limiting current upon various factors is quite different at these two electrodes. In the present paper the results of a theoretical and a systematic practical study of the factors which affect the limiting current at the R.D.M.E. are described. In order to determine the effect of the height of mercury on the limiting current, it was necessary to revise the construction of the electrode previously described.[2] The expressions derived at 25° for the average limiting current in the absence (eq. 1) and presence of a surface-active compound which completely suppresses stirring at the mercury surface (eq. 2) are

$$i_l = 230nCD^{1/2}\{m^{2/3}t^{1/6} + 103D^{1/2}(mt)^{1/3} + 7.45U_0^{1/2}(mt)^{1/2}\} \quad (1)$$

$$i_l = 230nCD^{1/2}\{m^{2/3}t^{1/6} + 103D^{1/2}(mt)^{1/3} + 5.76U^{1/2}\nu^{-1/6}D^{1/6}(mt)^{1/2}\} \quad (2)$$

where i_l is the average limiting current in $\mu a.$, n the number of electrons involved in the electrochemical reaction, C the concentration of the electroactive species in mM, D the diffusion coefficient in cm.^{2}/sec., m the rate of flow of mercury in mg./sec., t the drop time in sec., U_0 the uniform velocity of the solution at the surface of the mercury drop in cm./sec., U the speed of rotation of the electrode in cm./sec. and ν the kinematic viscosity of the solution in cm.^{2}/sec. In the presence of surface-active substances satisfactory agreement between calculated (eq. 2) and observed limiting currents was found only when the electrode has a relatively small orifice (<0.75 mm. in diameter) and a small distance between the orifice and center of rotation (<8.5 mm.).

As shown in this paper, the first and second

terms are much smaller than the third term in the brackets of both equations 1 and 2 when U_0 or U is not very small. Therefore, as a rough approximation, we can write

$$i_l \sim nCD^{1/2}U_0^{1/2}(mt)^{1/2} \quad (1a)$$

$$i_l \sim nCD^{2/3}U^{1/2}\nu^{-1/6}(mt)^{1/2} \quad (2a)$$

If we compare these relationships with the Ilkovic equation at the D.M.E.

$$i_d = 607nCD^{1/2}m^{2/3}t^{1/6}$$

the following noticeable differences between the two types of electrodes are evident: (1) the effect of the height of mercury is much smaller at the R.D.M.E. than at the D.M.E., because at the former the product mt is practically constant with varying height of mercury, (2) the effect of applied potential and hence drop time t is much larger at the R.D.M.E. ($\sim t^{1/2}$) than at the D.M.E. ($t^{1/6}$), (3) in the presence of a surface-active substance i_l is not proportional to $D^{1/2}$ at the R.D.M.E., but closely to $D^{2/3}$.

Theoretical

When the current is controlled by diffusion and the effect of electrical migration is eliminated, the current at an instant, t, in the reduction (or oxidation) of an electroreducible (or oxidizable) substance is generally expressible by

$$i_t = nFD\iint_S \left(\frac{\partial c}{\partial x}\right)_{x=0,\,t} dS \quad (3)$$

where F is the faraday, S the area of the electrode, c the concentration at distance x from the electrode surface. As far as mass transfer is the only process controlling the current, the above fundamental equation is applicable to the R.D.M.E. if the concentration gradient at the surface of the electrode is explicitly expressible. According to the so-called "Nernst diffusion layer" concept,[3] when an electrode is placed in a stirred solution, there exists at the surface of the electrode a thin diffusion layer in which there is no motion of the solution. In view of the known fact that this simple assumption is not generally justified in stirred solutions,[3] it is necessary to apply hydrodynamic principles in order to take into account the effect of convection on mass transfer. Assuming that a mercury drop is a perfect sphere at any instant, the general equation of mass transfer[3] is given by

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{2}{r}\frac{\partial c}{\partial r} + \frac{1}{r^2}\Delta c\right) - \left(v\frac{\partial c}{\partial r} + \frac{u}{r}\frac{\partial c}{\partial \theta} + \frac{w}{r\sin\theta}\frac{\partial c}{\partial \phi}\right) \quad (4)$$

where

$$\Delta = \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\,\frac{\partial}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}$$

v, u and w are the velocity components in r, θ and ϕ directions, respectively. The spherical coördinates were chosen as shown in Fig. 1. Making suitable assumptions to obtain the concentration gradient at the mercury surface, equation 4 was

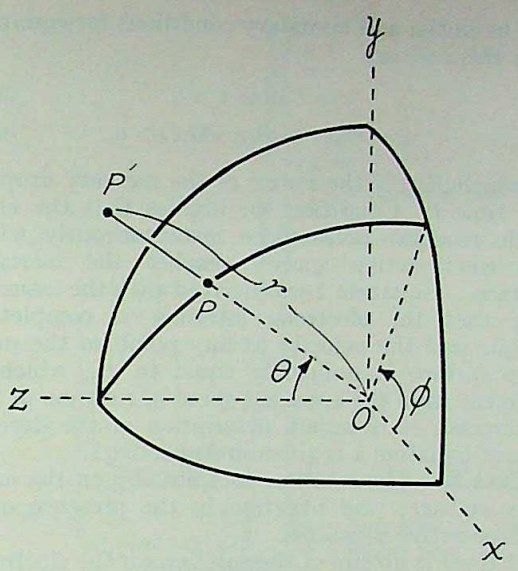

Fig. 1.—Spherical coördinates for equation 4.

solved, which allowed the calculation of the current using equation 3.

When a mercury drop is moved in an aqueous solution, two extreme situations can be considered at the mercury surface. One is the case in which flow velocities do not vanish; in other words, the solution slips on the mercury surface. This phenomenon occurs when the solution does not contain surface-active substances.[4] The other is the case in which flow velocities vanish on the mercury surface. Frumkin and Levich[5] showed that when a mercury drop falls into a solution containing a surface-active substance, the slip of the solution on the mercury surface is partly or completely inhibited by the formation of an elastic film of the surface-active substance on the mercury drop. These two different situations on the mercury surface are relevant to the experimental results at the rotated dropping amalgam electrode introduced by Stricks and Kolthoff.[2] They found that the limiting anodic current at a rotated dropping thallium amalgam electrode increases with rate of rotation in the absence of gelatin but remains unaffected by the speed of rotation in its presence. The larger current at higher speeds of rotation in the absence of gelatin is considered to be caused by the fact that the tangential flow on the amalgam surface enhances a motion within the amalgam drop, whereas in the presence of gelatin this motion does not occur since there are no flow velocities on the amalgam surface. We shall deal with these two cases separately, for they are entirely different from the hydrodynamic viewpoint. The following theoretical statements are made by considering for the sake of convenience that the electrode is placed in a solution flowing at a speed of U, instead of considering that the electrode is moved at this speed in the solution.

Case A.—The solution slips on the mercury surface, the situation in the absence of a surface-active substance.

The initial and boundary conditions for equation 4 in this case are

$$c = C \text{ when } t = 0 \quad (5)$$

$$c = 0 \text{ at } r = R(t) \text{ when } t > 0 \quad (6)$$

in which $R(t)$ is the radius of the mercury drop at the time t. Condition (6) implies that the electrode reaction takes place instantaneously when the electroactive species reaches the mercury surface. Equation 1 was derived with the assumption that the electrode interface is completely mobile and the velocity at any point on the mercury surface is uniformly equal to U_0, which is different from the apparent speed of rotation of the electrode. A complete description of the derivation of equation 1 is given in Appendix 1.

Case B.—The solution does not slip on the mercury surface; the situation in the presence of a surface-active substance.

If there is no slip of the solution on the electrode surface as in the case of a solid placed in a moving fluid, there must be a velocity gradient between the surface of the electrode and the bulk of the solution. The type of flow around the mercury drop can be estimated by evaluating the Reynolds number, $Re = Ul/\nu$, where l is the length representing the dimension of the electrode, which may be taken to be equal to the diameter of the mercury drop. For example, for one of our suitable electrodes the distance between the orifice and the center of rotation, d, was 0.74 cm. and the weight of a drop of mercury 0.037 g. at 210 r.p.m. The linear speed of rotation, U, of this electrode is calculated to be about 16 cm./sec., and the diameter of a mercury drop 0.13 cm. just before it is ejected from the orifice. Putting these values and 0.9×10^{-2} cm.^{2}/sec. as ν of water at 25° in the Reynolds number expression, Re is calculated to be equal to 230. Provided that there is no significant disturbance in the character of flow caused by the part of the glass end tube of the electrode dipped in the solution, it is considered from this Reynolds number that there will be a laminar boundary layer around the mercury drop, at least after it has grown to some extent.[6] However, at the very beginning of the growth of a mercury drop, when its size is small, the Reynolds number is certainly very small and the type of flow is considered to be rather close to Stokes' motion. This stage is of short duration and the type of flow will soon become laminar with a boundary layer. For example, the Reynolds number of the above electrode becomes 100 at 0.9 sec. with a drop life of 3.1 sec. Thus it is reasonable to assume that the type of flow is that with a laminar boundary layer during most of the drop life.

In order to solve equation 4 with this assumption, it is necessary to have expressions for the velocity distribution in the boundary layer and for its thickness, δ. Assuming a curvilinear system of coordinates (Fig. 2), whose x-axis is in the direction of the wall, the y-axis being perpendicular to it, the Prandtl boundary layer equations for steady flow[7] generally are given by

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{dp}{dx} + \nu\frac{\partial^2 u}{\partial y^2} \quad (7)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (8)$$

where u and v are the velocity components in x- and y-directions, respectively, ρ the density of the solution and p the pressure. Assuming that the velocity of flow outside the boundary layer around the small mercury drop is uniformly equal to the speed of rotation of the electrode, U, equations 7 and 8 can be solved by analogy to the case of a flat plate.[8] In view of the known fact that the tangential velocity distribution can be successfully approximated by a parabolic or polynomial function with respect to δ and y,[8] we shall make the further assumption that it is given by a polynomial of nth degree, which can be written as

$$u = U - U(\delta - y)^n/\delta^n \quad (9)$$

Prescribing the boundary conditions

$$u = 0, v = 0 \text{ where } y = 0 \quad (10)$$

$$u = U \text{ where } y = \delta \quad (11)$$

$$\delta = 0 \text{ where } x = 0 \quad (12)$$

we obtain the following expression for δ from (7), (8) and (9) (the mathematical process follows the case of a flat plat[8])

$$\delta = \sqrt{2(2n+1)(n+1)\nu x/U} \quad (13)$$

Thus if a parabolic distribution is assumed, *i.e.*, $n = 2$, we obtain

$$\delta = \sqrt{30\nu x/U} \quad (14)$$

The numerical constant of 30 in equation 14 must be determined experimentally because there is no theoretical support for the above velocity distribution. Somewhat arbitrarily we adopt the value of 30 in the mathematical treatment, a complete description of which is given in Appendix 2.

For case B the initial and boundary conditions for equation 4 are

$$c = C \text{ when } t = 0 \quad (15)$$

$$c = 0 \text{ at } r = R(t) \text{ when } t > 0 \quad (16)$$

$$c = C \text{ at } r = R(t) + \delta \text{ when } t > 0 \quad (17)$$

in which conditions 15 and 16 are the same as in case A and condition 17 implies that the concentration outside the boundary layer is always kept equal to the bulk concentration. Under these conditions we obtain the following equation for the limiting current at 25° in the presence of a surface active substance

$$i_l = 230nCD^{1/2}\{m^{2/3}t^{1/6} + 103D^{1/2}(mt)^{1/3} + KU^{1/2}\nu^{-1/6}D^{1/6}(mt)^{1/2}\} \quad (18)$$

where K becomes equal to 5.38, 5.82, 6.00 or 6.10 depending on whether the tangential velocity distribution is assumed to be a linear, a parabolic, a third or a fourth degree polynomial.

Experimental

Materials.—Conductivity water and 99.99% pure Linde nitrogen and C.P. chemicals were used without further puri-

(6) The transition from laminar to turbulent flow takes place at $Re = 3 \times 10^5$ in the case of a sphere. See, for example, H. Schlichting, "Boundary Layer Theory," translated by J. Kestin, McGraw-Hill Book Co., Inc., New York, N. Y., 1955, p. 31.

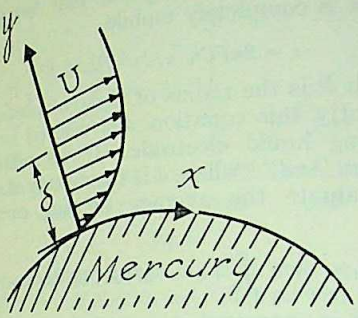

Fig. 2.—Curvilinear coördinates for equations 7 and 8.

feration except thallous chloride, which was purified by recrystallization. Solutions of known concentration of thallium and lead were prepared by dissolving weighed amounts of thallous chloride or lead nitrate in the appropriate amount of water. A zinc solution of known concentration was prepared by dissolving a weighed amount of pure zinc in dilute sulfuric acid and adjusting the volume. A solution of known cadmium concentration was obtained by dissolving an approximately weighed amount of cadmium sulfate in water and weighing as anhydrous salt after evaporation of an appropriate volume of the solution and drying. Nickel(II) perchlorate was prepared by adding an excess perchloric acid to the nitrate and evaporating to dryness. The nickel content of a solution of the perchlorate was determined gravimetrically by weighing as nickel dimethyl glyoxime.

Current Measurements.—Limiting currents were measured with a Leeds and Northrup Electrochemograph Type E with damping switch in a suitable position,[2] and with a manual apparatus as described by Lingane and Kolthoff.[9] All experiments were carried out at 25.0 ± 0.1°. All reported values of limiting currents have been corrected for residual currents.

Measurements of Kinematic Viscosity.—In the experiments in the presence of glycerol and sucrose the kinematic viscosity was measured with Ubbelohde suspended level viscometers, which had been calibrated with standard glycerol-water mixtures.

Electrode.—The R.D.M.E. described by Stricks and Kolthoff[2] was modified so that the height of the mercury column could be varied. The construction and manipulation of the modified R.D.M.E. are similar to those of the original one. The top and bottom of the plunger of a 2-ml. syringe are cut off (see Fig. 3) and the resulting tube is connected by Tygon tubing to a top tube as used with a D.M.E.; this constitutes the upper part of the electrode. The lower part consists of two units. One of these is made by connecting an end tube to a capillary. The other unit consists of the outer tube of the syringe, the bottom of which has been cut off, joined to the wide end of the glass tube A (Fig. 3). The lower part of the electrode is assembled by placing the mercury filled end tube and capillary in the holder of the rotating apparatus, and by connecting the small end of the glass tube A to the capillary. After this part is positioned properly, it is filled with mercury up to the top and the upper part of the electrode is connected through the two syringe pieces. The syringe is so well ground that the rotation is completely smooth; the height of mercury can be raised to about 100 cm. from the tip of the end tube without leakage of mercury. A detailed description concerning the treatment of the end tube with Silicone Dri Film and the rotating device is in the previous paper.[2] Eccentric rotation must be avoided.

The lower part of the end tube was 50 mm. in length and had an outside diameter of 3.5 to 4 mm. (see Fig. 3). The distance between the orifice and the bottom of the end tube was about 10 to 12 mm. for all electrodes used in the present experiments. The diameter of the orifice varied from 0.4 to 1.1 mm.; the distance between the orifice and center of rotation, d, was from 5 to 16 mm.

The electrolysis vessel used was a beaker of 250 ml. capacity. The volume of the solution was 100 ml. in all experiments.

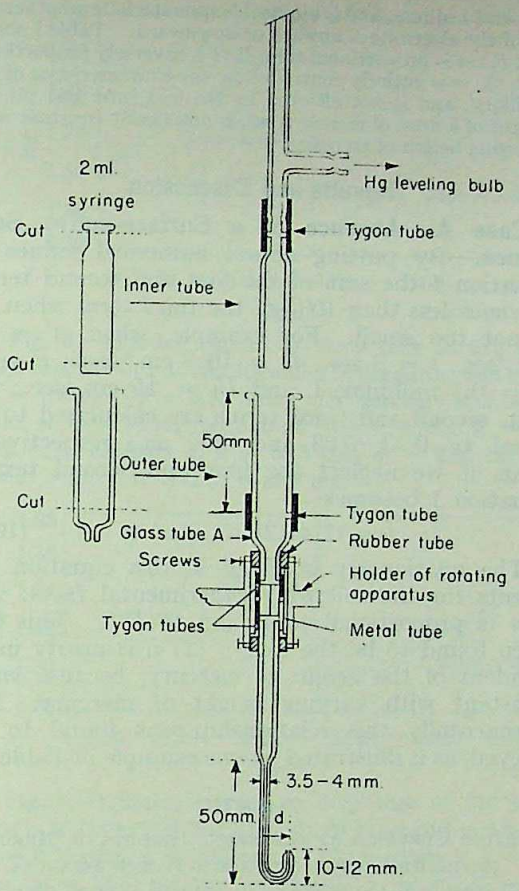

Fig. 3.—Assembly of the modified R.D.M.E.

General Characteristics of the Modified R.D.M.E. Relationship between the Height of Mercury, h, and m and t.—The general characteristics of the electrode were determined by using the same capillary with three different end tubes. The capillary used was 3.5 cm. in length of Sargent's capillary for D.M.E., the drop time of which was specified as 2 to 5 sec. The diameter of the orifice ϕ was measured with a microscope provided with an eye-piece micrometer. The distance between the orifice and center of rotation, d, was measured with a micrometer caliper. The results are listed in Table I, in which h is the height of mercury corrected for back pressure,[10] $h_{back} = 3.1/(mt)^{1/3}$ cm. This expression was derived from the fundamental formula $P_{back} = 2\sigma/r$ which gives the difference in pressure between outside and inside of a spherical surface of a liquid whose surface tension

is σ and radius r, and is applicable immaterially whether the tip of the electrode is upward or downward. Table I shows that (1) m is proportional to h, (2) t is inversely proportional to h, (3) m is entirely controlled by the characteristics of the capillary, and is not affected by the end tube and (4) the weight of a drop of mercury, mt, is practically constant with changing height of mercury.

Results and Discussion

Case A. Absence of a Surface-active Substance.—By putting actual numerical values in equation 1 the sum of the first and second terms becomes less than 10% of the third term when U_0 is not too small. For example, when $m = 15$ mg./sec., $t = 3$ sec., $D = 10^{-5}$ cm.^{2}/sec., $n = 1$, $C = 0.1$ millimole/l. and $U_0 = 15$ cm./sec., the first, second and third terms are calculated to be equal to 0.53, 0.03 and 9.59 μa., respectively. Thus if we neglect the first and second terms, equation 1 becomes

$$i_l = 1714nCD^{1/2}U_0^{1/2}(mt)^{1/2} \qquad (19)$$

The relationship involved in this equation accounts for the following experimental facts: (1) i_l/n is proportional to C and to $D^{1/2}$. This has been found to be the case[2]; (2) i_l is nearly independent of the height of mercury, because mt is constant with varying height of mercury. Experimentally this relationship was found to be obeyed, as is illustrated by one example in Table II.

TABLE II

LIMITING CURRENTS AT DIFFERENT HEIGHTS OF MERCURY IN THE ABSENCE OF SURFACE-ACTIVE SUBSTANCES

(End tube 3, 0.400 millimole/l., Tl^+ in 1 M $NaClO_4$, 210 r.p.m.)

V (*vs.* S.C.E.)	i_l (μa.) h = 93.5 cm.	h = 63.5 cm.
−0.7	44.0	43.2
−0.9	43.3	43.1
−1.1	42.8	42.8
−1.3	41.0	41.4
−1.5	38.0	38.5
−1.7	34.5	34.5

In the derivation of equation 1, we made an assumption that the velocity of flow on the mercury surface is uniformly equal to U_0. This surface velocity is not simply equal to the speed of rotation of the electrode, U, as there are complications caused by the viscosity of a real fluid, which exerts frictional forces on the mercury–solution interface, and by the mutual interaction between the motion inside the mercury drop and the tangential motion of the solution on the mercury surface. The presence of even trace amounts of surface active substances in the solution lowers the limiting current. At potentials other than the electrocapillary zero, the existence of an electrical double layer exerts a viscous drag resulting from the forces acting on the two sheets of the double layer and decreases the mobility of the interface.[11] Since the actual surface velocity is unknown, a direct comparison between calculated and observed limiting currents cannot be made.

Levich[4] derived the following equation for currents involving maxima of the second kind at the D.M.E. with the assumption that the electrode interface is completely mobile

$$i = 8nFC\sqrt{\pi/2}\sqrt{DU_0/R}\,R^2$$

in which R is the radius of a given spherical drop. Apparently this equation was derived for an unexpanding liquid electrode. If we substitute R with $(3mt/4\pi d)^{1/3}$ where d is the density of mercury, and evaluate the average limiting current, we obtain

$$i_l = (1/t)\int_0^t i\,dt = 2710nCD^{1/2}U_0^{1/2}(mt)^{1/2}$$

where i_l is expressed in terms of μa. This equation is identical with equation 19 except for the numerical constant.

Case B. Presence of a Surface-active Substance. Relation between i_l and t.—A number of experiments were carried out with several different end tubes and capillaries at various heights of mercury at 210 r.p.m. in solutions of 0.400 mM in thallous ion and 1 M sodium perchlorate in the presence of 0.01% gelatin. Some typical examples of plots of log i_l *vs.* log t using different end tubes and different capillaries are given in Figs. 4 to 6. The limiting currents were measured at various applied potentials, and hence at various drop times, the other conditions being kept constant. The points obtained with end tube 2 (Fig. 4) were scattered in a somewhat irregular way, but with the other end tubes reasonably good straight lines were obtained at voltages between −0.7 and −1.6 v. *vs.* S.C.E. It is seen that the slope increases with the diameter ϕ of the orifice, and hence with the drop weight mt. Equation 2 or 18 predicts that the slope should be close to 0.5, because under our experimental conditions the sum of the first and second terms is of the order of only 15% or less of the third term (for some numerical examples, see Table IV). The theoretical relationship is obeyed approximately with end tube 3 which has a relatively small orifice. The deviation in the slope from 0.5 for the other end tubes with larger orifice must be attributed to the deformation of the shape of a mercury drop from a sphere.

Experimental Determination of K in Equation 18.—As mentioned in the theoretical part, we made the assumption that the tangential velocity distribution is parabolic or polynomial in the boundary layer. Since this assumption affects only the numerical constant K, we must find the proper value of K experimentally. This was performed by comparing experimental values of limiting currents with theoretical values calculated from equation 18 where K tentatively was put equal to 5.82 (corresponding to a parabolic distribution).

In the calculation of limiting currents, it is important to use correct D values which were determined under the actual experimental conditions. The D values at infinite dilution calculated from equivalent conductance data are often quite different from those under the working conditions in polarography, although they are frequently used with the original Ilkovic equation for the D.M.E. In connection with the development of revisions of the original Ilkovic equation, several

[i] Using the D value reported by Sanborn and Orlemann (Table III).

rents, 0.892×10^{-2} cm.²/sec. was used as the kinematic viscosity of 0.1 M potassium chloride and a value of $D = 1.827 \times 10^{-5}$ cm.²/sec. as reported by Wang and Polestra. This example shows that the factor x was practically constant with varying m and t. The same was found also when other D values were used. We repeated two more sets of experiments and determined K from a total of 56 measurements of limiting currents, all of which were obtained with the same end tube at 210 r.p.m., but with various capillaries at various heights of mercury. The average values of x were calculated to be 0.990 ± 0.021, 1.025 ± 0.021 and 1.059 ± 0.022 with D values of 1.827×10^{-5}, 1.744×10^{-5} and 1.67×10^{-5} cm.²/sec., respectively. By multiplying 5.82 by these x values, the average values of K became 5.76, 5.97 and 6.16, respectively. These K values are used in Table V for the calculations of the limiting currents of ions different from thallium.

Typical experimental data in Table IV also show that the effect of the height of mercury on the limiting current is much smaller than at the D.M.E. as predicted from the theoretical equation because $(mt)^{1/6}$ in the third (principal) term of the equation is constant with varying height of mercury.

Comparison of Observed and Calculated Limiting Currents of Several Metal Ions with Different Diffusion Coefficients.—In order to examine the validity of the proposed equation with respect to the relationship between i_l and D, several experiments were carried out with solutions of thallium, lead, cadmium, zinc and nickel at various concentrations of supporting electrolytes. The experiments were conducted with end tube 3 and capillary 4 at 210 r.p.m. In the experiments with heavy metal ions starch was used as a surface-active substance instead of gelatin because a small fraction of the heavy metals is bound by gelatin.[2] Starch is not bound by the heavy metal ions and 0.01% was found sufficient to suppress completely maxima of the second kind. The kinematic viscosities were calculated from densities and specific viscosities, which were taken from the International Critical Tables, or measured with an Ubbelohde viscometer.

The observed and calculated limiting currents are tabulated in Table V. Using the above three values of K the calculated values of limiting currents were obtained by employing the various values of D listed in Table III. The best agreement between calculated and observed values was obtained with diffusion coefficients determined by the radiotracer technique. This result lends support to the reliability of the D values determined by this technique and to the conclusion that reliable values of D can be derived from measurements with the R.D.M.E. The good agreement between the theoretical value of K of 5.82 and the experimental value of 5.76 indicates that the average tangential velocity distribution in the boundary layer is closely approximated by a parabolic function. v. Stackelberg, Pilgram and Toome[14] determined their values of D in the presence of gelatin for all of the ions used in the present experiments, while we did not use gelatin except for thallous ion. This accounts, in part at least, for the lower values of the limiting currents calculated with their D values.

Results Obtained with Various End Tubes at Various Speeds of Rotation.—The validity of the proposed equation 18 was further tested with respect to the correlation between i_l on the one hand and m, t and U on the other. Experiments were carried out with solutions of thallous ion in 1 M sodium perchlorate, 0.05 M potassium nitrate and 0.1 M potassium chloride in the presence of 0.01% gelatin.

The tracer diffusion coefficients of thallous ion in sodium perchlorate and potassium nitrate are not available in the literature. However Wang[12a] and Wang and Polestra[12b] concluded from experimental results that observed diffusion currents at a D.M.E. agree better with values calculated from the Strehlow–Stackelberg equation[16,17]

$$i_d = 607nCD^{1/2}\{m^{2/3}t^{1/6} + AD^{1/2}(mt)^{1/6}\}$$

where A is equal to 17, or more accurately 16.7, than with values calculated from the original

Ilkovic equation ($A = 0$)[18] and the Lingane–Loveridge equation ($A = 39$),[18] when tracer diffusion coefficients are used for D. In accordance with the above conclusion, we calculated the diffusion coefficient of thallous ion in the given media from the diffusion current data obtained with a D.M.E. and the Strehlow–Stackelberg equation. The D values of thallous ion in 1 M sodium perchlorate and in 0.05 M potassium nitrate thus calculated are 1.74×10^{-5} and 1.85×10^{-5} cm.²/sec., respectively.

Experimental and calculated limiting currents are listed in Table VI. With end tubes 2 and 4, which have a large orifice, the differences between the observed and calculated values at −1.3 v. were consistently more negative than those at −0.7 v. probably as a result of deviation from a sphere of a drop. The observed values with end tubes 3, 6, 5, 7 and 10 at 210, 150 and 75 r.p.m. are in agreement within a few per cent. with the calculated values at both of the applied potentials.

The diameter of the orifice of these end tubes varied between 0.35 and 0.75 mm., and the distance between the orifice and center of rotation varied between 5.2 and 8.5 mm. At 600 r.p.m. with end tube 3, the observed results failed to fit the equation. A possible reason for this discrepancy is that the fraction of the surface area of the mercury drop inside the orifice and therefore not in contact with the solution at a higher speed of rotation is greater than at a lower speed of rotation, because the ejected mercury drops are smaller at a higher speed of rotation than those at a lower speed of rotation because of centrifugal force effects. The main reason for the discrepancy found at high speeds of rotation is attributed to the effect of the motion of the solution caused by the vigorous rotation of the electrode. We assumed in the derivation of the proposed equation that the velocity of outer flow is equal to the apparent speed of rotation; in other words, the electrode rotates at a medium at rest. Actually, however, especially at a high speed of rotation, the

[a] The m value was constant within the viscosity range investigated.

end tube serves as a stirrer giving rise to a swirling of the solution, and the solution moves in the same direction as the rotation of the electrode. Thus the velocity of rotation *relative* to the solution becomes smaller than the apparent speed of rotation and accounts for the fact that the calculated value of the limiting current is considerably greater than the experimental one. A similar effect is observed at the lower speeds of rotation when the distance between the orifice and center of rotation of the electrode is increased; this results in an effective swirling motion of the liquid caused by the rotation of the end tube. The effect is particularly pronounced with end tube 8 (d = 16 mm.) even at 75 r.p.m. and is still observed with end tube 9 (d = 10.5 mm). It is clear that for theoretical studies it is essential to choose an end tube of proper dimensions so that more or less well-defined and reproducible hydrodynamic conditions can be obtained.

Influence of the Kinematic Viscosity on the Limiting Current.—It is known that the diffusion current at the D.M.E. is greatly affected by the change of viscosity of the solution to be electrolyzed because of the variation of diffusion coefficients of electroactive species. In the case of the R.D.M.E., the viscosity of the solution is expected to exert an effect on the hydrodynamic boundary layer thickness in addition to the variation of the diffusion coefficient. This effect is related to the term $\nu^{-1/6}$ in equation 2. In order to examine the validity of the expected relation, experiments were carried out with thallous ion in 0.1 M potassium chloride and in 0.05 M potassium nitrate in the presence of 0.01% gelatin, the viscosity being varied by adding glycerol or sucrose.

Experimental and calculated limiting currents are tabulated in Table VII in which the values of D were calculated with the aid of the Strehlow–Stackelberg equation from the data obtained with a D.M.E. The equation was found valid when ν was varied from 0.89 to 1.3 × 10^{-2} cm.²/sec., but at higher viscosities the apparent effect of viscosity tended to become greater than expected from the equation. This is a natural result of the fundamental assumptions underlying the boundary layer theory itself. Prandtl's boundary layer, equations 7 and 8, on which our theoretical treatment is based, are derived from the general Navier-Stokes equations with the aid of the simplifications which can be introduced as a consequence of the small values of viscosity. This corresponds to the condition that the boundary layer thickness should be very small as is clear from the relation that the thickness of the boundary layer, δ, is proportional to $\nu^{1/2}$. From equation 14 the boundary layer thickness in 30.9% sucrose solution under the present experimental conditions, for example, is computed to be 0.83 mm. at 90° from the forward stagnation point just before the mercury drop comes off. This amounts to about a half of the maximum diameter of the mercury drop, 1.7 mm., which is contrary to our original assumption that δ is very small compared with the size of a mercury drop. The boundary layer theory is a limiting theory at zero viscosity, and the assumptions made in the derivation of the boundary layer equations are satisfied with an increasing degree of accuracy as the Reynolds number increases, *i.e.*, the viscosity decreases.[19] Thus it is to be expected that the proposed equation will also give more satisfactory results as the viscosity decreases.

A theoretical treatment may be possible also for the other limiting case of a very large viscosity. However, as is known from hydrodynamics, the experimental results at intermediate viscosities cannot be interpreted by an interpolation between the two limiting cases. In addition, the quantitative effect of the viscosity on the diffusion current at the D.M.E. is still incompletely known. Because of such difficulties, a quantitative interpretation of experimental results at moderately high viscosities is at present impossible.

Current–Time Relation during Individual Drop Life.—From equation 2 it follows that the equation of the instantaneous limiting current in the presence of a surface-active substance is given by

$$i_t = 230nCD^{1/2}\{(7/6)m^{2/3}t^{1/6} + (4/3)103D^{1/3}(mt)^{1/6} + (3/2)5.76U^{1/2}\nu^{-1/6}D^{1/6}(mt)^{1/2}\} \quad (24)$$

A few experiments were conducted to examine the validity of this equation. The current was measured in terms of the iR drop across a 10,000 ohm

standard resistor in series with the R.D.M.E. cell by using a fast response Sanborn Industrial Recorder, Model 127, combined with a preamplifier, Model 126. The maximum sensitivity of this instrument is 50 mv. per cm., and the paper was driven at a speed of 25 mm./sec. A manual polarograph was used to apply the constant voltage to the cell circuit.

Although the total applied voltage can be kept constant, the actual potential of the R.D.M.E. decreases as the drop grows because of the iR loss across the standard resistor. In the example given here, the maximum current was 18.1 μa., so that the decrease of the actual potential of the R.D.M.E. amounted to 0.181 v. However, as shown by Lingane[20] with a D.M.E., this magnitude of the variation in potential causes no perturbation of the current–time curves provided the total applied voltage is large enough to keep the potential of the R.D.M.E. in the limiting current region during the lifetime of a drop.

The present experiments were carried out with a 0.201 mM thallium solution in 0.05 M potassium nitrate in the presence of 0.01% gelatin with end tube 3 at 210 r.p.m. The m value was equal to 12.05 mg./sec. The total applied potential was −0.9 v. *vs.* S.C.E., and hence the potential of the R.D.M.E. decreased to −0.719 v. at the end of the drop life. An example of the current–time curve is shown in Fig. 7.

The disagreement between the observed and calculated current–time curves was significant in the region of early drop life. This trend is also observed with the D.M.E. Lingane[20] attributed it mainly to the variability of m during the drop life caused by the larger back pressure exerted on the young drop and also to the non-sphericity in the early life of the drop. In the case of the R.D.M.E. the variation of m is much smaller because the lumen of the orifice is larger than that of the capillary used with a D.M.E. For example, for the end tube used in the present experiment whose diameter of orifice is 0.75 mm., the back pressure calculated from the formula $P_{back} = 2\sigma/r$[10] amounts to *ca.* 1.7 cm. at the beginning and *ca.* 0.8 cm. at the end of the drop life. Therefore, from the expression $m = k(h - h_{back})$, the variation of m is calculated to be only *ca.* 2.5% when the height of mercury is kept at 40 cm.; this variation is too small to account for the difference between the experimental and theoretical curves in Fig. 7. With reference to the non-sphericity of the mercury drop, the deviation of the shape from a sphere at the early life of the drop is considered to be greater at the R.D.M.E. than at the D.M.E. because of the larger lumen of the orifice at the R.D.M.E. As the most important reason for the discrepancy, however, one cannot overlook the variation of the hydrodynamic conditions during the drop life. As mentioned in the theoretical part, at the beginning of the growth of the mercury drop, the Reynolds number is so small that the boundary layer theory fails to account for the hydrodynamic situation at the very early drop life. There is no doubt that a few mathematical simplifications are also responsible which

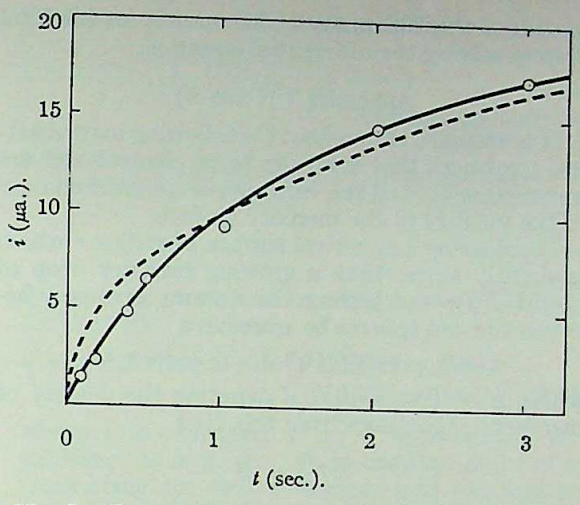

Fig. 7.—Current–time curve; end tube 3, capillary 4, 210 r.p.m., h = 78.5 cm., 0.201 mM, Tl^+ in 0.05 M KNO_3 and 0.01% gelatin; ———, experimental; – – –, theoretical.

were made for the purpose of obtaining a practical expression of the *average* limiting current.

We have discussed so far several aspects on the applicability of the proposed equation of the limiting current. Limitations of the equation are, of course, ascribed to the fact that some ideal situations were assumed which are somewhat different from the actual conditions. For example, the following assumptions are not fully justified even with an end tube whose dimension is in the recommended range; (1) the mercury drop is at any instant a perfect sphere which expands from its center outwards symmetrically, (2) the rotation of the electrode does not swirl the solution at all, (3) a laminar boundary layer is developed at any instant in the drop life, (4) the thickness of the boundary layer is expressed by the simple function (13). The fourth assumption is considered to be only a rough approximation from the purely hydrodynamic viewpoint, because it does not account for the separation of the boundary layer, which occurs on a body of revolution such as a sphere as a result of the acceleration in the front half and the deceleration in the rear half of the sphere. Since the expression for the boundary layer thickness was obtained by analogy with a flat plate, this assumption corresponds to a neglect of the curvature of the mercury drop as far as the boundary layer thickness is concerned. An attempt was made to make use of the expressions for the boundary layer thickness and the velocity distributions derived by taking the effect of curvature into consideration.[21] The final equation thus obtained is so involved and impractical that it is not given in this paper. At any rate, it is gratifying that only one numerical constant had to be determined empirically to obtain a satisfactory equation of the limiting current. It is considered that this empirical factor probably compensates on the average for the error resulting from the simplifications mentioned above.

matics of the University of Minnesota for his kind help in solving the differential equation.

Appendix 1 (Case A)

It is assumed throughout the following mathematical treatment that solutions to be electrolyzed are incompressible and the variation of c is marked only in the vicinity of the mercury surface.

Considering a spherical surface of radius r which is slightly larger than a growing mercury drop of radius $R(t)$, and letting the volume enclosed between the two spheres be ϵ, we have

$$4\pi r^3/3 = 4\pi\{R(t)\}^3/3 + \epsilon = 4\pi a^3 t/3 + \epsilon$$

where $a = (3m/4\pi d)^{1/3}$, d denoting the density of mercury. It follows from this that

$$3r^2 \frac{\mathrm{d}r}{\mathrm{d}t} = a^3$$

and hence

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{a^3}{3r^2} = \frac{1}{3r^2}\left(\frac{r^3 - 3\epsilon/4\pi}{t}\right)$$

When we consider the velocity of motion of a point on the spherical surface of radius r resulting from the growth of the mercury drop, it is clear that $r - R(t) << R(t)$ and $4\pi r^3/3 >> \epsilon$, and hence $\mathrm{d}r/\mathrm{d}t \cong r/3t$. Assuming that the r component of the flow velocity is negligible in comparison with the θ-component we get

$$v \cong r/3t \qquad \text{(A1)}$$

By putting $u = U_0$ and (A1) into equation 4 and neglecting w, we obtain

$$\frac{\partial c}{\partial t} = \mathrm{D}\left(\frac{\partial^2 c}{\partial r^2} + \frac{2}{r}\frac{\partial c}{\partial r} + \frac{1}{r^2}\Delta c\right) - \frac{r}{3t}\frac{\partial c}{\partial r} - \frac{U_0}{r}\frac{\partial c}{\partial \theta} \qquad \text{(A2)}$$

Substituting the variables r and t by

$$\sigma = 3t^{1/3} \text{ and } \eta = r/at^{1/3}$$

equation (A2) becomes

$$\frac{\partial c}{\partial \sigma} = \frac{D}{a^2}\left(\frac{\partial^2 c}{\partial \eta^2} + \frac{2}{\eta}\frac{\partial c}{\partial \eta} + \frac{1}{\eta^2}\Delta c\right) - \frac{U_0\sigma}{3a\eta}\frac{\partial c}{\partial \theta}$$

Putting $\tau = D\sigma/a^2$, $\xi = \eta - 1$ and $f = \eta c/C$, we get from the above equation

$$\frac{\partial f}{\partial \tau} = \frac{\partial^2 f}{\partial \xi^2} + \frac{\Delta f}{(1+\xi)^2} - \frac{a^3 U_0 \tau}{3D^2(1+\xi)}\frac{\partial f}{\partial \theta} \qquad \text{(A3)}$$

Since the condition $r - R(t) << R(t)$ is equivalent to $\xi << 1$, we can put $1 + \xi \cong 1$. For the sake of simplicity, we put $A = a^3 U_0/3D^2 = \text{const.}$ Then (A3) becomes

$$\frac{\partial f}{\partial \tau} = \frac{\partial^2 f}{\partial \xi^2} + \Delta f - A\tau\frac{\partial f}{\partial \theta} \qquad \text{(A4)}$$

By changing the variables as above, the initial and boundary conditions 5 and 6 become

$$f = 1 + \xi \text{ when } \tau = 0 \qquad \text{(A5)}$$

$$f = 0 \text{ when } \xi = 0;\ \tau > 0 \qquad \text{(A6)}$$

In order to solve (A4), we define the functions G and W as

$$G(\omega,\xi,\xi') = \frac{1}{2\sqrt{\pi\omega}}\left[\exp\left\{-\frac{(\xi-\xi')^2}{4\omega}\right\} - \exp\left\{-\frac{(\xi+\xi')^2}{4\omega}\right\}\right] \qquad \text{(A7)}$$

$$W(\tau,\theta,\theta',\varphi,\varphi') = \sum_{l,k}\exp\{-\tau l(l+1)\}\, Y_l^{(k)}(\theta,\varphi)\, Y_l^{(k)}(\theta'\varphi')$$

in which $Y_l^{(k)}$'s are spherical surface harmonics. Function (A7) has the properties

$$G(\omega,0,\xi') = G(\omega,\xi,0) = 0, \quad \frac{\partial G}{\partial \omega} = \frac{\partial^2 G}{\partial \xi^2} = \frac{\partial^2 G}{\partial \xi'^2} \text{ and}$$

$$\lim_{\omega\to 0}\int_0^\infty G(\omega,\xi,\xi')g(\omega,\xi')\mathrm{d}\xi' = g(0,\xi) \qquad \text{(A9)}$$

for any bounded continuous function $g(\omega, \xi)$ such as $g(\omega, 0) = 0$. Function (A8) is the fundamental solution of the following differential equation on the unit sphere

$$\frac{\partial H}{\partial \tau} = \Delta H$$

and W has the properties

$$\frac{\partial W}{\partial \tau} = \Delta W = \Delta' W \text{ where } \Delta' W = \frac{1}{\sin\theta'}\frac{\partial}{\partial \theta'}\left(\sin\theta'\frac{\partial W}{\partial \theta'}\right) + \frac{1}{\sin^2\theta'}\frac{\partial^2 W}{\partial \varphi'^2}$$

$$\lim_{\tau\to 0}\iint_S W(\tau,\theta,\theta',\varphi,\varphi')H(\tau,\theta',\varphi')\mathrm{d}S' = H(0,\theta,\varphi)$$

for any continuous function $H(\tau,\theta,\varphi)$, and

$$\iint_S W(\tau,\theta,\theta',\varphi,\varphi')\mathrm{d}S = \iint_S W(\tau,\theta,\theta',\varphi,\varphi')\mathrm{d}S' = 1 \qquad \text{(A10)}$$

where S is the unit sphere, $\mathrm{d}S = \sin\theta\mathrm{d}\theta\mathrm{d}\varphi$, and $\mathrm{d}S' = \sin\theta'\mathrm{d}\theta'\mathrm{d}\varphi'$ which is an area element on the unit sphere.

Now we consider the differential equation

$$\frac{\partial^2 h}{\partial \xi^2} - A\tau\frac{\partial h}{\partial \theta} = 0 \qquad \text{(A11)}$$

The solution of this equation, which satisfies the conditions $h = 1 + \xi$ when $\theta = 0$, and $h = 0$ when $\xi = 0$, $\theta \neq 0$, is given by

$$h = \int_0^\infty G\left(\sqrt{\frac{\theta}{A\tau}},\xi,\xi')(1+\xi')\mathrm{d}\xi' = \frac{2}{\sqrt{\pi}}\int_0^{\xi\sqrt{A\tau/\theta}/2}\exp(-\lambda^2)\mathrm{d}\lambda + \xi \qquad \text{(A12)}$$

If we put $g = f - h$, we obtain the following equation for g from (A4) and (A11)

$$\frac{\partial g}{\partial \tau} = \frac{\partial^2 g}{\partial \xi^2} + \Delta g - A\tau\frac{\partial g}{\partial \theta} + \Delta h - \frac{\partial h}{\partial \tau} \qquad \text{(A13)}$$

The initial and boundary conditions for this equation are

$$g = 1 \text{ when } \tau = 0 \qquad \text{(A14)}$$

$$g = 0 \text{ when } \xi = 0, \tau \neq 0 \text{ (except where } \theta = 0) \qquad \text{(A15)}$$

Now we consider the function

$$\frac{\partial}{\partial \tau'}\iint_S \mathrm{d}S'\int_0^\infty G(\tau-\tau',\xi,\xi')W(\tau-\tau',\theta,\theta',\varphi,\varphi')g(\tau',\xi',\theta',\varphi')\mathrm{d}\xi' =$$

$$\iint_S \mathrm{d}S'\int_0^\infty GW\left\{-A\tau'\frac{\partial g}{\partial \theta'} + \Delta' h(\tau',\xi',\varphi') - \frac{\partial h(\tau',\xi',\varphi')}{\partial \tau'}\right\}\mathrm{d}\xi'$$

By integrating both sides of the above expression from 0 to τ and using (A14), (A15) and the properties of G and W explained above, we obtain

$$g(\tau,\xi,\theta,\varphi) - \int_0^\infty G\mathrm{d}\xi' = \int_0^\tau \mathrm{d}\tau\iint_S \mathrm{d}S'\int_0^\infty\left(-GWA\tau'\frac{\partial g}{\partial \theta} + GW\Delta' h - GW\frac{\partial h}{\partial \tau'}\right)\mathrm{d}\xi' \qquad \text{(A16)}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and hence

$$\iint_S \frac{\partial g}{\partial \xi} dS = 4\pi \int_0^\infty \frac{\partial G}{\partial \xi} d\xi' + \iint_S dS \int_0^\tau d\tau \iint_S \int_0^\infty \left(-\frac{\partial G}{\partial \xi} WA\tau' \frac{\partial g}{\partial \theta'} + \frac{\partial G}{\partial \xi} W\Delta' h - \frac{\partial G}{\partial \xi} W \frac{\partial h}{\partial \tau'} \right) d\xi' dS' \quad (A17)$$

From (A10) the second term of the right-hand side of the above equation becomes

$$\int_0^\tau d\tau' \iint_S dS' \int_0^\infty \left(-\frac{\partial G}{\partial \xi} A\tau' \frac{\partial g}{\partial \theta'} + \frac{\partial G}{\partial \xi} \Delta' h - \frac{\partial G}{\partial \xi} \frac{\partial h}{\partial \tau'} \right) d\xi'$$

If we define $h(0, \xi) = 1 + \xi$ in (A12), then h is infinitely differentiable on the surface S. Thus $\iint_S \Delta' h \, dS' = 0$. From (A12) we obtain

$$\frac{\partial h}{\partial \tau'} = \frac{\xi}{2} \sqrt{\frac{A}{\pi \theta' \tau'}} \exp\left(-\frac{A\tau'\xi'}{4\theta'} \right) \quad (A18)$$

Except the region of very small τ', (A18) is small. Because we integrate the concentration gradient with respect to time to obtain the average limiting current expression, the effect of the contribution of (A18) at small values of τ' on the final expression can be neglected. Thus we neglect the third term in the brackets of (A17). It can be seen, furthermore, by applying the successive substitution method to equation (A16) that the first term in the brackets of equation (A17) is also small. Thus (A17) can be simplified as

$$\iint_S \frac{\partial g}{\partial \xi} dS = 4\pi \int_0^\infty \frac{\partial G(\tau, \xi, \xi')}{\partial \xi} d\xi' = 4\pi \left\{ \frac{2}{\sqrt{\pi}} \frac{1}{2\sqrt{\tau}} \exp\left(-\frac{\xi^2}{4\pi} \right) \right\}$$

and therefore

$$\iint_S \left(\frac{\partial g}{\partial \xi} \right)_{\xi=0} dS = 4 \sqrt{\frac{\pi}{\tau}} \quad (A19)$$

From equation (A12), we obtain

$$\iint_S \left(\frac{\partial h}{\partial \xi} \right)_{\xi=0} dS = \sqrt{\frac{A\tau}{\pi}} 2\pi \int_0^\pi \frac{\sin\theta}{\sqrt{\theta}} d\theta + 4\pi = 2(1.790)\sqrt{\pi A\tau} + 4\pi \quad (A20)$$

From (A19), (A20) and the relation $f = g + h$ it follows that

$$\iint_S \left(\frac{\partial f}{\partial \xi} \right)_{\xi=0} dS = \frac{4\pi^{1/2}}{\tau^{1/2}} + 4\pi + 3.580\, \pi^{1/2} A^{1/2} \tau^{1/2} = \frac{4\pi^{1/2} a}{D^{1/2} t^{1/2}} + 4\pi + \frac{3.580 \pi^{1/2} U_0^{1/2} a^{1/2} t^{1/4}}{3^{1/2} D^{1/2}} \quad (A21)$$

On the other hand, we have

$$\left(\frac{\partial c}{\partial r} \right)_{r=R(t)} = \left(\frac{\partial \xi}{\partial r} \right)_{r=at^{1/2}} \left[\frac{\partial \{ C(1+\xi)^{-1} f \}}{\partial \xi} \right]_{\xi=0} = \frac{C}{at^{1/2}} \left(\frac{\partial f}{\partial \xi} \right)_{\xi=0} \quad (A22)$$

Thus, from (A21) and (A22) we obtain the following expression for the concentration gradient in the radial direction on the surface of the electrode integrated over the total surface area

$$\iint_S \left(\frac{\partial c}{\partial r} \right)_{r=R(t)} \{R(t)\}^2 dS = \frac{C}{at^{1/2}} \iint_S \left(\frac{\partial f}{\partial \xi} \right)_{\xi=0} (at^{1/2})^2 dS = C \left(\frac{4\pi^{1/2} a^2 t^{1/4}}{3^{1/2} D^{1/2}} \right) + 4\pi a t^{1/2} + \frac{3.580 \pi^{1/2} U_0^{1/2} a^{3/2} t^{1/2}}{D^{1/2}} \Bigg)$$

Therefore the average limiting current is given by

$$i_l = nFCD \frac{1}{t} \int_0^t \left(\frac{4\pi^{1/2} a^2 t^{1/4}}{3^{1/2} D^{1/2}} + 4\pi a t^{1/2} + \frac{(3.580)\pi^{1/2} U_0^{1/2} a^{3/2} t^{1/2}}{D^{1/2}} \right) dt$$

$$= nFCD^{1/2} \left\{ \frac{(6) 4^{1/2} 3^{1/4} m^{2/3} t^{1/6}}{7\pi^{1/6} d^{2/3}} + \frac{3^{4/3} \pi^{2/3} D^{1/3} (mt)^{1/2}}{4^{1/3} d^{1/3}} + \frac{(3.580) U_0^{1/2} (mt)^{1/2}}{3^{1/2} d^{1/2}} \right\}$$

By putting numerical constants $\pi = 3.1416$, $d = 13.54$ at 25°, we obtain

$$i_l = nFCD^{1/2} \{ 0.238 m^{2/3} t^{1/6} + 2.452 D^{1/2} (mt)^{1/2} + 0.562 U_0^{1/2} (mt)^{1/2} \} \quad (A23)$$

where i_l is expressed in a., C in mole/ml., D in cm.^{2}/sec., m in g./sec., U_0 in cm./sec. and t in sec. Converting the unit of current into μa., and putting $F = 96500$ coulombs, equation 1 is obtained.

Appendix 2 (Case B)

The tangential velocity component in the boundary layer can be written as

$$u = U[2\{r - R(t)\}/\delta - \{r - R(t)\}^2/\delta^2] \quad (A24)$$

where $\delta = \sqrt{30\nu R(t)\theta/U}$. The velocity component, v, is given by (A1), and $w = 0$ as in Case A (Appendix 1).

Changing the variables r and t by $\eta = rt^{-1/3}$ and $s = 3t^{1/3}$, equation 4 can be written as

$$\frac{\partial c}{\partial s} = D \left(\frac{\partial^2 c}{\partial \eta^2} + \frac{2}{\eta} \frac{\partial c}{\partial \eta} + \frac{1}{\eta^2} \Delta c \right) - \left(\frac{sv}{3} - \frac{\eta}{s} \right) \frac{\partial c}{\partial \eta} - \frac{su}{3\eta} \frac{\partial c}{\partial \theta} \quad (A25)$$

From (A1), $v \cong 3\eta/s^2$ in the region $r - R(t) << R(t)$ and hence $\eta - a << a$, in which $a = (3m/4\pi d)^{1/3} = R(t)/t^{1/3}$. In addition, $\partial c/\partial t, \partial c/\partial r$, $\partial^2 c/\partial r^2$, Δc, $\partial c/\partial \theta \cong 0$ outside the range $r - R(t) << R(t)$, and therefore $\partial c/\partial \eta \cong 0$ outside the range $\eta - a << a$. Hence $\left(\frac{sv}{3} - \frac{\eta}{s} \right) \frac{\partial c}{\partial \eta} \cong 0$ in equation (A25). Putting $\eta c(s, \eta, \theta, \varphi) = f(s, \eta, \theta, \varphi)$, equation (A25) becomes

$$\frac{\partial f}{\partial s} = D \left(\frac{\partial^2 f}{\partial \eta^2} + \frac{1}{\eta^2} \Delta f \right) - \frac{su}{3\eta} \frac{\partial f}{\partial \theta}$$

In the vicinity of $r \cong R(t)$, $\eta \cong a$. If we put $\xi = \eta - a$, this equation becomes

$$\frac{\partial f}{\partial s} = D \left(\frac{\partial^2 f}{\partial \xi^2} + \frac{1}{a^2} \Delta f \right) - \frac{su}{3a} \frac{\partial f}{\partial \theta} \quad (A26)$$

By transforming the variables as above, the initial and boundary conditions 15, 16 and 17 can be written as

$$f(0, \xi, \theta, \varphi) = (a + \xi) C \quad (A27)$$

$$f(s, 0, \theta, \varphi) = 0 \text{ when } s > 0 \quad (A28)$$

$$f\{s, \delta(s,\theta), \theta, \varphi\} = \{a + \delta(s,\theta)\} C \quad (A29)$$

where

$$\delta(s, \theta) = \sqrt{90\nu a\theta/Us}$$

In order to obtain a solution of equation (A26), first we consider the differential equation

$$D \frac{\partial^2 h}{\partial \xi^2} - \frac{su}{3a} \frac{\partial h}{\partial \theta} = 0 \quad (A30)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A solution of this equation must satisfy the conditions

$$h(s,0,\theta) = 0 \tag{A31}$$

$$h\{s,\delta(s,\theta),0\} = \{a + \delta(s,\theta)\}C \tag{A32}$$

$$\frac{\partial h}{\partial \theta} \cong 0 \text{ except when } \xi << a \tag{A33}$$

When $\xi << a$, we obtain from (A24)

$$\frac{su}{3a} \cong \frac{s}{3a}\, U \frac{2U^{1/2}s^{1/2}\xi}{\sqrt{90\nu a\theta}} = \frac{2U^{3/2}s^{1/2}\xi}{\sqrt{810\nu a^3\theta}} = bs^{1/2}\theta^{-1/2}\xi$$

where

$$b = 2U^{3/2}/\sqrt{810\nu a^3} = \text{constant}$$

Therefore, (A30) becomes

$$D\frac{\partial^2 h}{\partial \xi^2} - bs^{1/2}\theta^{-1/2}\xi\frac{\partial h}{\partial \theta} = 0 \tag{A34}$$

Changing the variables by putting

$$z = (b/D)^{1/3}s^{1/2}\theta^{-1/2}\xi \text{ and } \omega = \theta \tag{A35}$$

(A34) becomes

$$D^{1/3}b^{2/3}s\omega^{-1}\left(\frac{\partial^2 h}{\partial z^2} + \frac{z^2}{2}\frac{\partial h}{\partial z}\right) - b^{2/3}D^{1/3}sz\frac{\partial h}{\partial \omega} = 0 \tag{A36}$$

A particular solution of (A36) can be obtained by substituting h, which satisfies the equation

$$\frac{\partial^2 h}{\partial z^2} + \frac{z^2}{2}\frac{\partial h}{\partial z} = 0$$

by z given by (A35). It is

$$h(s,\xi,\theta) = A\int_0^z \exp\left(-\frac{\zeta^3}{6}\right)d\zeta + B = A_1\gamma\,(1/3,\, bs^{2/3}\xi^3/6D\theta^{2/3}) + B \tag{A37}$$

where A, A_1 and B are constants, and

$$\gamma(X,Z) = \int_0^Z e^{-t}t^{X-1}\,dt$$

which is an incomplete gamma function. Since (A37) is a particular solution

$$h(s,\xi,\theta) = A_1\gamma(1/3,bs^{2/3}\xi^3/6D\theta^{2/3}) + A_2\xi + B \ (A_2\text{:const.}) \tag{A38}$$

is also the same. From (A31), (A32), (A33) and (A38), we obtain

$$B = 0$$

and $A_1\gamma(1/3,\, 30\nu/6D) + A_2\delta(s,\theta) = Ca + C\delta(s,\theta)$. Therefore

$$A_1 = Ca/\gamma(1/3,\, 30\nu/6D),\quad A_2 = C$$

Thus we obtain from (A38)

$$h(s,\xi,\theta) = \frac{Ca\gamma(1/3,bs^{2/3}\xi^3/6D\theta^{2/3})}{\gamma(1/3,\, 30\nu/6D)} + C\xi \tag{A39}$$

This is the unique solution of (A30) which satisfies the given conditions.

Next putting $f - h = g$, we can write the following equation from (A26), (A27), (A28) and (A29)

$$\frac{\partial g}{\partial s} = D\left(\frac{\partial^2 g}{\partial \xi^2} + \frac{1}{a^2}\Delta g\right) - \frac{su}{3a}\frac{\partial g}{\partial \theta} + \frac{D}{a^2}\Delta h - \frac{\partial h}{\partial s} \tag{A40}$$

with the boundary conditions

$$\left.\begin{aligned} &g(0,\xi,\theta,\varphi) = aC,\ (h(0,\xi,\theta) = C\xi \text{ from (A39)}) \\ &g(s,0,\theta,\varphi) = 0 \text{ when } s > 0 \\ &g\{s,\delta(s,\theta),\theta,\varphi\} = 0 \end{aligned}\right\} \tag{A41}$$

In order to solve equation (A40), we define the functions G and W as

$$G(s,\xi,\xi') = \frac{1}{2\sqrt{\pi Ds}}\left[\exp\left\{-\frac{(\xi-\xi')^2}{4Ds}\right\} - \exp\left\{-\frac{(\xi+\xi')^2}{4Ds}\right\}\right] \tag{A42}$$

$$W(s,\theta,\theta',\varphi,\varphi') = \sum_{l,k}\exp\left\{-\frac{Ds}{a^2}l(l+1)\right\} - Y_l^{(k)}(\theta,\varphi)\,Y_l^{(k)}(\theta',\varphi') \tag{A43}$$

in which $Y_l^{(k)}$'s are spherical surface harmonics. Functions (A42) and (A43) have the properties similar to (A7) and (A8) in Appendix 1.

With reference to f we can ignore the slight discontinuity at $\xi = \delta(s,\theta)$ when it is integrated to obtain (A44); and h is a smooth function over the whole region. Therefore, from $f - h = g$, g can be regarded as a function which can satisfy (A41). Thus

$$\frac{\partial}{\partial s'}\iint_S dS'\int_0^\infty G(s-s',\xi,\xi')W(s-s',\theta,\theta',\varphi,\varphi')g(s',\xi',\theta',\varphi')d\xi'$$
$$= \iint_S dS'\int_0^\infty GW\left\{-\frac{su(s',\xi'\theta')}{3a}\frac{\partial g}{\partial \theta'} + \frac{D}{a^2}\Delta' h(s',\xi',\theta') - \frac{\partial h(s'\xi',\theta')}{\partial s'}\right\}d\xi'$$

By integrating both sides of the above equation from 0 to s and using (A41) and the characteristic properties of G and W, we obtain

$$\iint_S g(s,\xi,\theta,\varphi)dS = 4\pi C\int_0^\infty G(s,\xi,\xi')a\,d\xi' + \int_0^s ds'\int_0^\infty G(s-s',\xi,\xi')d\xi'\iint_S\left\{-\frac{su}{3a}\frac{\partial g}{\partial \theta'} + \frac{D}{a^2}\Delta' h - \frac{\partial h}{\partial s'}\right\}dS' \tag{A44}$$

In (A44) the term

$$\iint_S\left(-\frac{su}{3a}\right)\frac{\partial g}{\partial \theta'}\,dS'$$

is negligibly small compared with the first term of the right-hand side, as can be seen by applying the successive substitution method. From the property of the Laplacian on a sphere it follows that

$$\iint_S \Delta' h\,dS' = 0$$

It can be seen that the value of

$$\int_0^s ds'\int_0^\infty G(s-s',\xi,\xi')d\xi'\iint_S\frac{\partial h}{\partial s'}\,dS'$$

is also negligible as is clear from the fact that the following expression is evaluated to be very small

$$\frac{\partial h}{\partial s} = \frac{C}{\gamma(1/3,\, 30\nu/6D)}\left\{\exp\left(-\frac{bs^{2/3}\xi^3}{6D\theta^{2/3}}\right)\right\}\frac{3^{2/3}b^{1/3}\xi}{2^{4/3}D^{1/3}s^{1/3}\theta^{1/3}}$$

Thus, (A44) can be simplified as

$$\iint_S g(s,\xi,\theta,\varphi)\,dS \cong 4\pi C\int_0^\infty G(s,\xi,\xi')a\,d\xi' = \frac{4\pi C}{2\sqrt{\pi Ds}}\int_0^\infty\left[\exp\left\{-\frac{(\xi-\xi')^2}{4Ds}\right\} - \exp\left\{-\frac{(\xi+\xi')^2}{4Ds}\right\}\right]a\,d\xi'$$

It follows from this that

$$\iint_S\frac{\partial g(s,0,\theta,\varphi)}{\partial \xi}\,dS = \frac{4\pi C}{2\sqrt{\pi D^2 s^3}}\int_0^\infty\left\{\exp\left(-\frac{\xi^2}{4Ds}\right)\right\}\xi a\,d\xi = 4\pi aC/\sqrt{\pi Ds} \tag{A45}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

On the other hand, we obtain from (A39)

$$\frac{\partial h(s,0,\theta,\varphi)}{\partial \xi} = \frac{Ca}{\gamma(1/3,\ 30\nu/6D)} \frac{3^{1/3}b^{1/3}s^{1/3}}{2^{1/3}D^{1/3}\theta^{1/3}} + C \quad \text{(A46)}$$

Generally, when Z is very large

$$\gamma(X,Z) \sim \Gamma(X) - Z^{X-1}e^{-Z}\{1 + O(1/Z)\}$$

where $\Gamma(X)$ is a gamma function. In our case, $Z = 30\nu/6D = 5 \times 10^{-2}/10^{-5} > 10^3$. Therefore

$$[\Gamma(1/3) - \gamma(1/3,Z)] \sim e^{-1000}$$

Accordingly we can put $\gamma(1/3,\ 30\nu/6D) = \Gamma(1/3)$. Thus from (A46) we obtain

$$\iint_S \frac{\partial h(s,0,\theta,\varphi)}{\partial \xi} dS = \frac{3^{1/3}b^{1/3}s^{1/3}aC}{2^{1/3}\Gamma(1/3)D^{1/3}} 2\pi \int_0^{\pi} \frac{\sin\theta}{\sqrt{\theta}} d\theta + 4\pi C$$

$$= \frac{2^{1/3}3^{1/3}(1.79)\pi b^{1/3}s^{1/3}Ca}{\Gamma(1/3)D^{1/3}} + 4\pi C \quad \text{(A47)}$$

From $c(t,r,\theta,\varphi) = \eta^{-1}f(s,\xi,\theta,\varphi) = (a + \xi)^{-1}f(s, \xi,\theta,\varphi)$ and $f(s,0,\theta,\varphi) = 0$ we can write the relation

$$\left(\frac{\partial c}{\partial r}\right)_{r=R(t)} = \frac{\partial f(s,0,\theta,\varphi)}{\partial \xi} \frac{1}{a} \left(\frac{\partial \xi}{\partial \eta}\right)_{\eta=a} \left(\frac{\partial \eta}{\partial r}\right)_{r=R(t)} =$$

$$a^{-1}t^{-1/3} \frac{\partial f(s,0,\theta,\varphi)}{\partial \xi} = a^{-1}t^{-1/3} \left\{\frac{\partial g(s,0,\theta,\varphi)}{\partial \xi} + \frac{\partial h(s,0,\theta,\varphi)}{\partial \xi}\right\} \quad \text{(A48)}$$

From (A45), (A47) and (A48) we obtain the following expression for the concentration gradient in the radial direction at the surface of the mercury drop integrated over the total surface area

$$\iint_S \left(\frac{\partial c}{\partial r}\right)_{r=R(t)} \{R(t)\}^2 dS = C\left\{\frac{4^{1/3}3^{1/3}m^{2/3}t^{1/3}}{\pi^{1/3}d^{2/3}D^{1/3}} + \frac{2^{1/3}3^{1/3}\pi^{2/3}(mt)^{1/3}}{d^{1/3}} + \frac{3^{1/3}(1.79)\pi^{1/3}U^{1/3}(mt)^{1/3}}{\Gamma(1/3)\ 30^{1/3}\nu^{1/3}d^{1/3}D^{1/3}}\right\} \quad \text{(A49)}$$

where $\Gamma(1/3)$ is equal to 2.680. Using the same numerical constants as for (A23) we obtain the following equation for the average limiting current expressed in terms of amp.

$$i_l = \frac{1}{t}\int_0^t \left[nFD \iint_S \left(\frac{\partial c}{\partial r}\right)_{r=R(t)} \{R(t)\}^2\, dS\right] dt$$

$$= nFCD^{1/3}\{0.238m^{2/3}t^{1/6} + 2.452D^{1/3}(mt)^{1/3} + 0.438U^{1/3}\nu^{-1/6}D^{1/6}(mt)^{1/3}\}$$

The numerical constant of the third term in the brackets corresponds to a parabolic velocity distribution. Converting the unit of current into μa. we obtain equation 18.

Addition of Methyl Radicals to Acetylenic Compounds

BY M. GAZITH AND M. SZWARC

RECEIVED JANUARY 5, 1957

The addition of methyl radicals to several acetylenic compounds was investigated. The activation energies of these addition reactions were found to be higher than those observed in the addition reactions involving the corresponding ethylenic compounds. At the same time it was observed that the entropies of activation are also higher in the additions to the acetylenic compounds. The following pair of compounds were compared: acetylene–ethylene, methylacetylene–propylene, dimethylacetylene–the butenes–2, phenylacetylene–styrene, and diphenylacetylene–the stilbenes. It is suggested that the difference in the reactivity of a C≡C triple bond as compared with a C=C double bond arises from two factors. The π electrons in the shorter C≡C bond interact more strongly and consequently higher activation energy is necessary for the addition process which utilizes one of these electrons. On the other hand, the cylindrical symmetry of the C≡C bond leads to higher entropy of activation than the planar symmetry of the C=C double bond.

During the last few years a considerable amount of work has been carried out in these laboratories on the addition of radicals to aromatic and olefinic compounds.[1-6] The reactions investigated are represented by the general equation

$$R + A \longrightarrow R.A$$

where R denotes a radical, A represents a molecule of an aromatic or an olefinic compound, and R.A represents the primary addition product which, of course, is also a radical. Most of these investigations dealt with the addition of methyl radicals, and the relative rate constants of such additions, denoted as methyl affinities, were measured by the ratios k_2/k_1, where the subscripts refer to the two reactions[7]

$$CH_3 + \text{solvent} \longrightarrow CH_4 + \text{solvent radical} \quad (1)$$

$$CH_3 + A \longrightarrow A.CH_3 \quad (2)$$

The investigation reported in the present communication deals with the addition of methyl radicals to acetylenic compounds. The main purpose of this study was to find how the reactivity of a C≡C triple bond differs from that of a C=C double bond, and to interpret this difference in terms of electronic structures of the respective compounds.

Experimental

The following acetylenic compounds were investigated: acetylene, methylacetylene, dimethylacetylene, phenylacetylene, diphenylacetylene, and dimethyl ester of acetylene dicarboxylic acid. Acetylene was purchased from Matheson Co. and was 99.5% pure. The gas was deaerated and then distilled from trap to trap, the middle portion being collected. In some experiments the gas used was twice distilled. This additional purification did not affect the results indicating that our rate constants for acetylene are genuine.

High purity grade methylacetylene and dimethylacetylene were obtained from Farchan Research Laboratories. These compounds were used without further purification. Phenylacetylene and diphenylacetylene were prepared and purified by Dr. Bader from Aldrich Chemicals.[8] Finally, the dimethyl ester of acetylene dicarboxylic acid was prepared in our laboratories from the respective dicarboxylic acid. The ester was purified by fractionation *in vacuo*.

Acetyl peroxide was prepared by the method described previously[9]; the compound was twice crystallized in an apparatus described by Mundy[10] and then dissolved in spectroscopically pure isoöctane. We used in our work 5×10^{-2} M and 5×10^{-3} M solutions of acetyl peroxide.

Experiments were carried out at four temperatures, namely, 55, 65, 75 and 85°. The experimental procedure and the method of analysis were described previously[1,11] and need not be repeated again. However, some modifications were introduced in the work involving gaseous compounds. For these compounds we used a reaction vessel shown in Fig. 1. The solution of acetyl peroxide in isoöctane was introduced into the spherical container, deaerated by the repeated freezing and thawing technique. Thereafter, the desirable amount of the gaseous compound was condensed in it by cooling the flask with liquid nitrogen. The stopcock leading to the vacuum line was then closed, and by turning the reaction flask round the ground joint No. 2, all the contents were transferred into ampoule A cooled now by liquid nitrogen.[12] Finally the ampoule was sealed off at constriction C, heated for a desired time at the required temperature, and then quickly cooled by immersion in a solid carbon dioxide–acetone bath. Eventually the ampoule was placed in a special device in which the tip of the ampoule could be broken *in vacuo*. Then the contents of the ampoule were analyzed in the usual way.

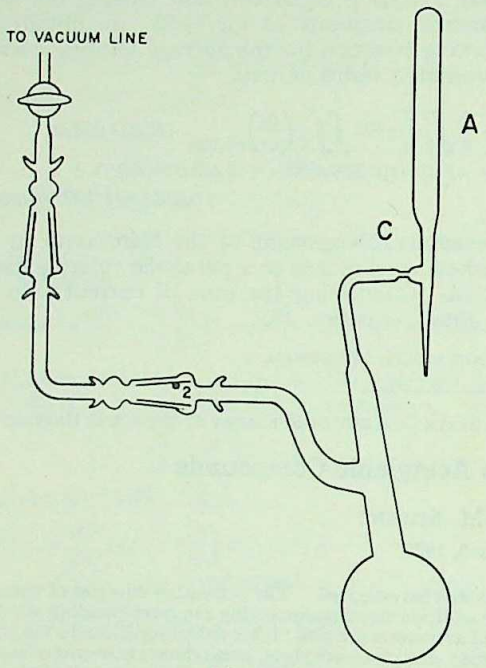

Fig. 1.

Results and their Evaluation

It was shown previously[1,2] that the ratio of the rate constants k_2/k_1 can be evaluated from the equation

$$k_2/k_1 = \{[A^0(CH_4) - A(CH_4)]/A(CH_4)\}(X_{HS}/X_A)$$

In this equation $A^0(CH_4)$ and $A(CH_4)$ denote the amounts of methane formed in two experiments carried out under identical conditions except that in one the olefinic or aromatic compound was present, while in the other was absent. The symbols X_{HS} and X_A denote the mole fractions of the solvent and the investigated olefinic or aromatic compound.

It was considered[4] that the substitution of $A^0(CH_4)$ and $A(CH_4)$ by $A^0(CH_4)/(CO_2)$ and $A(CH_4)/(CO_2)$ might be advantageous. While the former entities are dependent on the time of experiment, on the amount of the peroxide used, and are very sensitive to small changes in the temperature, the latter are independent of the amount of the peroxide used and the time of experiment, and only slightly affected by the temperature. The experimental advantage is therefore obvious.

On the other hand, the determination of $A^0(CH_4)$ and $A(CH_4)$ requires one measurement for each, while the ratios $A^0(CH_4)/(CO_2)$ and $A(CH_4)/(CO_2)$ are derived from two measurements for each ratio. Hence, the experimental errors are squared in the latter method and this drawback might outweight the advantages mentioned previously. In this investigation both methods were used in determining the k_2/k_1 ratios for phenylacetylene and diphenylacetylene in order to find which of these is more reliable. The results are given in Table I and they show that both methods lead to values which essentially are identical within their respective experimental errors. The only considerable deviation was observed in experiments involving diphenylacetylene and carried out at 85°. We believe that the value based on the $A(CH_4)/(CO_2)$ ratio obtained in this particular series of experiments is less reliable and it appears to be too high. It is also worth noticing that the scatter of the results appears to be nearly the same in both methods, indicating that both are equally reliable.

The reliability of these two methods was tested further by plotting the $\log(k_2/k_1)$ against the reciprocal of absolute temperature, as shown in Fig. 2.

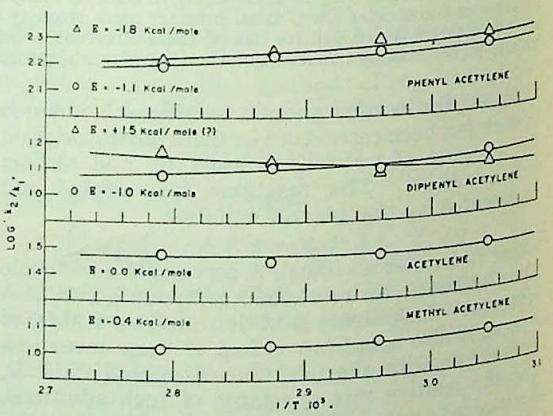

Fig. 2.

The differences in activation energies and A_2/A_1 factors calculated for the reaction involving phenylacetylene were well within the experimental errors (see Table III). However, the agreement does not seem as good for diphenylacetylene, apparently because of the high value of k_2/k_1 determined at 85° by the $A(CH_4)/(CO_2)$ method. We mentioned earlier that this determination seems to be inaccurate and if this result is discarded the respective E and A_2/A_1 values agree reasonably with those obtained by the alternative method.

(11) M. Levy and M. Szwarc, This Journal, **76**, 5981 (1954).
(12) The amount of solution used was chosen in such a way that the ampoule A was nearly full, thus the error caused by the volatility of the gaseous olefins was minimized.

[a] The amount of CH_4 formed in absence of acetylenes is the average of a few experiments carried out simultaneously with various runs. Such experiments were carried out at each of the temperatures used in this investigation. [b] The ratio CH_4/CO_2 is the average of *all* the experiments carried out at temperatures 55–85°. It appears that this ratio is temperature independent within the investigated range of temperature.

Discussion

Inspection of Tables I and II shows that the values of k_2/k_1 calculated for acetylene, methylacetylene, phenylacetylene and diphenylacetylene are constants independent of the concentration of the acetylenic compound. This means that the abstraction of hydrogen atoms by methyl radicals from these compounds is negligible as compared to the methyl radical addition reaction, a conclusion particularly significant for methylacetylene.

TABLE II

Compound	T, °C.	Range of concn., %	No. expt.	k_2/k_1
Acetylene	54.7	2.8–6.6	6	30.1 ± 1.63
	64.9	2.8–7.6	5	29.4 ± 3.26
	74.8	3.0–7.8	4	28.4 ± 0.70
	85.2	3.0–6.5	4	30.1 ± 1.66

	74.8	4.9–11.7	3	10.86 ± 0.69
	85.2	5.2–11.5	3	10.39 ± 0.70
				$(k_2/k_1)_{exp}$
Dimethylacetylene	54.7	5.6–19.1	3	1.26–0.44
	Extrapolated to 0%; k_2/k_1 = 4.7			
	64.9	7.8–22.0	3	0.8–0.4
	Extrapolated to 0%; k_2/k_1 = 1.4			
	74.8	9.2–20.9	3	1.16–0.21
	Extrapolated to 0%; k_2/k_1 = 2.0			

On the other hand, the same calculations applied to the results obtained for dimethylacetylene lead to a variable entity, denoted in Table II as $(k_2/k_1)_{exp}$ which decreases with the increasing mole fraction of the compound. It was shown elsewhere[13] that such a result is due to the abstraction of hydrogen atoms from the investigated compound by methyl radicals, and that the ratio k_2/k_1 is then obtained by plotting the reciprocal of $(k_2/k_1)_{exp}$ *versus* the mole fraction of the investigated compound. Such a plot results in a straight line, intercept of which gives the reciprocal of the k_2/k_1. Using this method we computed the respective k_2/k_1 listed in Table II. However the experimental data lead to considerable uncertainties and therefore the quoted values represent only the magnitude of the respective rate constants.

It is interesting to compare the addition of radicals to C≡C triple bonds and to the corresponding C=C double bonds. The addition of a radical leads eventually to the formation of a new C–C σ bond, and this process utilizes one of the π electrons of the multiple bond. Hence, whenever the interaction of the π electrons is stronger, *i.e.*, whenever the exchange integral β is more negative, the activation energy of the addition reaction should be larger. Since C≡C triple bonds are shorter than the C=C double bonds, the interaction between their π electrons is more powerful. Therefore, the activation energy of the addition reaction involving a C≡C bond should be larger than the activation energy of the reaction involving a corresponding C=C double bond, if our argument is correct. This conclusion seems to be confirmed by the data listed in Table III. All the activation energies quoted in this

table were calculated by the least square method. Although the differences which interest us are small, and in some cases their magnitude is comparable to the experimental errors, the consistency of the observed trends supports our suggestion that in the addition reaction a C≡C triple bond acts as a "compressed" C=C double bond.[14]

The cylindrical symmetry of a C≡C bond as compared to the planar symmetry of a C=C double bond implies that the A factors (*i.e.*, entropy of activation) should be greater for the addition of radicals to the acetylenic compounds. This conclusion seems also to be substantiated by the data listed in Table III.

Since the nature of the C≡C bond affects in the same direction the activation energy and the *A* factor, one cannot predict how the rate of addition to the C≡C bond would compare with the rate of addition to the C=C double bond. For example, the rate of addition of methyl radicals to acetylene is comparable with the rate of addition to ethylene; on the other hand, the rates of addition to the other investigated acetylenic compounds are lower than those observed for the respective olefinic compounds.

Finally, let us compare the rate of addition of methyl radicals to acetylenic compounds with those of addition of other radicals. The only quantitative data available came from the studies of copolymerization processes. Thus, Doak[15] investigated the copolymerization of methyl acrylate and acrylonitrile with phenylacetylene, diphenylacetylene and hexyne. From his data one derives the values listed in Table IV for the relative rate constants of the addition of methyl acrylate radicals and acrylonitrile radicals to the acetylenic compounds. The results show some similarities for all the three radicals investigated. The steric hindrance is probably responsible for lower reactivity of diphenylacetylene as compared with phenylacetylene, and the smallest effect is observed in the attack by the smallest radical, *i.e.*, methyl radical. On the other hand, the lower reactivity of hexyne (or propyne) as compared with phenylacetylene reflects the higher resonance stabilization of the radical formed from the latter molecule and therefore the effect is shown for each of the three radicals listed in Table IV.

TABLE IV

	Methyl acrylate radical		Acrylonitrile radical		Methyl radical at 65°
Acetylenic compd.	$1/r_1$ at 60°	Relative value of the addition constant	$1/r_1$ at 60°	Relative value of the addition constant	relative value of the addition constant
Phenylacetylene	1.6	(1.0)	3.85	(1.0)	(1.0)
Diphenylacetylene	0.018	0.011	0.074	0.019	0.071
Hexyne (or propyne)	0.09	0.056	0.018	0.0047	0.06

The data listed in Table IV can be compared in a different way, namely, by computing the ratio of the rates of addition of radicals to phenylacetylene and to styrene. The following results are obtained

	Methyl acrylate radical	Acrylonitrile radical	Methyl radical
$\frac{k \text{ for addition to styrene}}{k \text{ for addition to phenylacetylene}}$	~6	3.5	4.5

The higher reactivity of styrene as compared with phenylacetylene was discussed by Doak in terms of higher resonance energy of the radical Ph.CH.CH_2.X as compared with Ph.Ċ = CH.X. We believe, however, that our explanation is more correct, namely, the uncoupling of a π electron is more difficult in a short C≡C bond than in the longer C=C bond.

The fact that the ratios of the rate constants of addition to styrene and to phenylacetylene is approximately the same for three radicals of different polarities seems to indicate that the polarities of both styrene and phenylacetylene are close to zero.

After completion of this work, Mr. Buckley, working in our laboratories, investigated the addition of methyl radicals to pentyne-1 and hexyne-1. These results are summarized in Tables V and VI and Fig. 3. They lead to the following conclusions. Methyl radicals react with pentyne-1 and hexyne-1 in a dual fashion: add to the triple C≡C bond or abstract α hydrogen atom from the CH_2 group adjacent to the C≡C bond. The relevant rate constants are calculated from the plots of $(k_2/k_1)^{-1}_{exp}$ *versus* x_a/x_s (for the details of the method see ref. 10) by the least square method. These calculations show that k_2/k_1 for pentyne-1 and hexyne-1 at 65° are 13.7 and 17.5, respectively. Both these values

TABLE V

T = 65°C., SOLVENT ISOÖCTANE

Hydrocarbon	Mole, %	$(k_2/k_1)_{exp.}$
Pentyne-1	10.51	4.61
Pentyne-1	7.88	5.94
Pentyne-1	5.26	7.30
Pentyne-1	2.63	9.26
Pentyne-1; k_2/k_1 extrapolated to 0 mole % = 13.7		
Hexyne-1	10.45	6.00
Hexyne-1	7.84	7.00
Hexyne-1	5.24	8.86
Hexyne-1	2.62	12.50
Hexyne-1; k_2/k_1 extrapolated to 0 mole % = 17.5		

TABLE VI

T = 65°C., SOLVENT ISOÖCTANE

Hydrocarbon	k_2/k_1	k_1/k_2	k_5/k_1	k_5'/k_1
Pentyne-1	13.7	1.2	16.3	8.1
Hexyne-1	17.5	0.97	17.0	8.5

compare reasonably with the k_2/k_1 value determined for methylacetylene, namely, 10.85, and thus it appears that the rate of addition of methyl radicals to an acetylene of the type CH≡C—R is, at least approximately, independent of the length of the group R.

It is interesting to compare the rate of abstraction of hydrogen atoms from the CH_2 group α to C≡C triple bond with the rate of abstraction from the same group α to C=C double bond. The results arrived at from the study of reactions of pentyne and hexyne lead to values 8.1 and 8.5, respectively, for the ratio k_5'/k_1 (k_5' represents the rate constant of hydrogen abstraction reaction per active hydrogen, *i.e.*, $k_5/2$ for the discussed hydrocarbons). On the other hand, the work of Buckley and Szwarc[12] demonstrated that the corresponding values of k_5'/k_1 for butene-1, pentene-1, heptene-1, decene-1 and hexadecene-1 are 3.3, 4.1, 6.3, 6.4 and 6.4, respectively. It appears, therefore, that the rate of abstraction of a hydrogen atom from a CH_2 group adjacent to a C≡C triple bond is slightly higher than the corresponding rate for a reaction involving a CH_2 group adjacent to a C=C double bond. This point will be discussed further in a forthcoming publication.

Photochemical Exchange of Water between $Cr(H_2O)_6^{+3}$ and Solvent[1]

BY ROBERT A. PLANE AND JOHN P. HUNT

RECEIVED DECEMBER 3, 1956

Studies have been made on the rate of the reaction $Cr(H_2O)_6^{+3} + 6H_2O^{18} \rightarrow Cr(H_2O^{18})_6^{+3} + 6H_2O$ in the presence of light of various wave lengths. Quantum yields have been obtained for the three $Cr(H_2O)_6^{+3}$ absorption bands (2610, 4080, 5740 Å.) at three temperatures (0, 10, 27°). At 27°, the quantum yields for all bands are of the order of magnitude 10^{-2}, and decrease with decreasing temperature. Solutions of $Cr(H_2O)_6(ClO_4)_3$ were carefully checked for fluorescence which was found to be absent even at −196° in glasses prepared by dissolving $Cr(H_2O)_6(ClO_4)_3$ in isopropyl alcohol. In order to account for the low quantum yields and absence of fluorescence, it seems most likely that the electronically excited chromic species converts to the ground state by radiationless transitions to high vibrational states of the ground electronic level. Because of the large temperature dependence of the photochemical reaction, it appears more probable that reaction occurs from an excited electronic state rather than from an excited vibrational state. However, such an interpretation seems to demand that during deactivation, some of the chromic species must pass through a spin forbidden (doublet) state.

For many years it has been known that some substitution reactions of complex ions are hastened by light. Most such reactions seem to be particularly sensitive to ultraviolet radiation, and the mechanisms which have been proposed usually involve an electron transfer followed by rapid substitution. For example, for a series of complex ions of the type $[Co(NH_3)_5X]^{++}$ (in which X is F^-, Cl^-, Br^- or I^-)

Linhard and Weigel have proposed that the photodecomposition is due to an electron transfer from X^- to the Co atom forming the cobaltous complex ion which rapidly decomposes.[2] Recently, several authors have interpreted the ultraviolet and visible absorption spectra of a number of complex ions including $Cr(H_2O)_6^{+3}$.[3] The spectrum of $Cr(H_2O)_6^{+3}$ in solution was measured by the present authors using a calibrated Beckman DU spectrophotometer, and is reproduced in Fig. 1. The spectrum in Fig. 1 was obtained from a 0.04 *M* solution of $Cr(H_2O)_6(ClO_4)_3$ which contained 0.1 *M* $HClO_4$. The absorption follows Beer's law, is unaffected by addition of perchloric acid or sodium perchlorate, and is essentially temperature independent. At very short wave lengths (below 2400 Å.) there is a strong absorption which has been attributed to an electron transfer. However, the three weak absorption bands at longer wave lengths are assigned to forbidden electronic transitions within the 3d subshell of the chromium atom.[3] The present work was undertaken to determine whether irradiation of the three weak absorption bands of $Cr(H_2O)_6^{+3}$ might hasten its substitution reactions which normally are quite slow.[4]

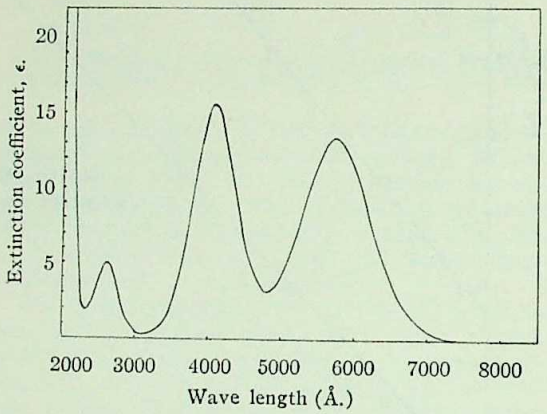

Fig. 1.—Absorption spectrum $Cr(H_2O)_6^{+++}$.

The particular substitution reaction chosen for study was the isotope exchange reaction

$$Cr(H_2O)_6^{+3} + 6H_2O^{18} \longrightarrow Cr(H_2O^{18})_6^{+3} + 6H_2O$$

It was chosen because considerable data already exist for the "dark" reaction,[4] there is no change in spectrum during the course of the reaction, and this reaction should be relatively simple in nature.

Experimental

The general procedure followed involved preparation of a solution of $Cr(ClO_4)_3$ and $HClO_4$ in which the solvent water (but not $Cr(H_2O)_6^{+3}$) was initially enriched in O^{18} by about a factor of 3. A portion of the solution was taken for analysis of the initial O^{18} content of the $Cr(H_2O)_6^{+3}$ and the remainder was then irradiated for a number of hours. After irradiation, the solution was again sampled and the remainder allowed to stand until isotopic equilibrium had been attained and then sampled again. The rate of the "dark" reaction was obtained either from the previous data,[4] or in some cases from new experiments run parallel with the photoreactions. In all cases, ClO_4^- was the only anion present.

The materials used were prepared by methods described previously,[4] and the sampling procedure was essentially the $Cr(H_2O)_6PO_4$ precipitation and ignition used earlier.[4] The only difference in sampling procedure was that the precipitate was ignited at 160° without the subsequent heating to 750° as done in earlier work. Despite the fact that this lower temperature ignition served to remove but *ca.* $4H_2O$/Cr, the elimination of oxygen exchange between water and phosphate seemed to allow slightly greater reproducibility of results.

For irradiations, a cylindrical cell was used with light filters serving as a cover. The light came from above the cell in a slightly divergent beam which did not strike the walls of the cell. In most experiments, nearly all of the light was absorbed in the solution. In cases where this condition did not obtain, appropriate corrections were applied to the results. During irradiation, solutions were thermostated and were stirred using a magnetic stirrer. Light sources were the General Electric Co. AH-4, AH-5 and 4-watt germicidal lamp. Appropriate Corning filters were used to select wave lengths such that each absorption band could be irradiated separately. The light was monitored during the experiments using a Weston Photronic cell and was found to be constant in intensity during an experiment to ±3%. Quantum fluxes were measured in the reaction cell, before and after a run, using the uranyl oxalate actinometer.[5] For wave lengths longer than 4500 Å., the photochemical experiment was run with one set of filters and the actinometer with another set. Results were then calculated from data supplied by the lamp manufacturer on the relative intensities of various spectral bands and by measuring the transmission of the various filters. This method was checked by direct measurement with a calibrated photronic cell giving good agreement.

Results

The data obtained and results calculated are summarized in Table I.

TABLE I

PHOTOCHEMICAL RESULTS

Range (Å.) irradiated	*t*, °C.	Moles quanta l.-hr.	Total rate (*M*/hr.) × 10^4	Dark rate (*M*/hr.) × 10^4	Quantum yield

exchange reaction is increased slightly on irradiation. The increase corresponds to a quite small quantum yield (molecules reacted per quantum absorbed) which is therefore subject to large experimental error. The probable limits of uncertainty placed on the resultant values of the quantum yield reflect, in most cases, only the ±5% uncertainty in measuring the reaction rates in the presence and absence of radiation. Within the rather large limits of error, there seems to be no dependence of quantum yield on wave length even though different absorption bands are irradiated.

It is seen from Table I that the quantum yield increases with increasing temperature. Although the results are too uncertain to permit accurate evaluation of the activation energy of the photochemical process, they are consistent with a value of 13 kcal. per mole for all three absorption bands. This value is about half of that found for the activation energy of the same reaction in the absence of light (26.7 kcal. per mole).[4]

In order to interpret the photochemical results, solutions of chromic perchlorate were checked for fluorescence.[6] Solutions of chromic concentrations 10^{-4} to 10^{-1} *M* were irradiated with a mercury arc lamp and observed (using either the eye or a photocell with photomultiplier) at right angles to the incident beam. Each of the three absorption bands was irradiated by using filters between the sample and the light source. When observed through a filter which passed only light of wave length longer than the incident beam, no light was detected even when the light source was very intense such as that obtained from the AH-5. Low temperature studies were made on solutions of $Cr(H_2O)_6(ClO_4)_3$ dissolved in isopropyl alcohol and frozen to a clear glass at liquid nitrogen temperature. Again no fluorescence was detected. It should be noted that the solutions in isopropyl alcohol must have a somewhat different absorption spectrum than the aqueous solutions since they appear green rather than violet.

Discussion

Although the rate of the exchange reaction of $Cr(H_2O)_6^{+3}$ is clearly increased by light absorption, the over-all quantum yield for reaction is quite small. The small yield might result from an extremely large "cage effect," but such an explanation does not seem probable for this particular reaction in which the solvent "cage" is itself a reactant. A more plausible explanation for the small quantum yield might involve a series of events somewhat similar to those described by Zimmerman to account for very small quantum yields (1.4×10^{-5} to 5.4×10^{-2}) for the photodecomposition of permanganate.[7] After excitation of $Cr(H_2O)_6^{+3}$ to any one of the three electronic states corresponding to the three absorption bands, it is expected that rapid radiationless transition should occur to the lowest lying of these, since all three are of the same spin multiplicity (quartet).[8] Since no fluorescence is observed for $Cr(H_2O)_6^{+3}$, it like MnO_4^- might well undergo further radiationless transition to a high vibrational level of the ground electronic state (also a quartet state). The question arises as to whether the exchange reaction occurs during the period of electronic excitation, or during the subsequent vibrational excitation. In the permanganate decomposition, it seems most probable that chemical reaction occurs during vibrational excitation. This conclusion is convincingly supported by the strong dependence of quantum yield on wave length of exciting radiation (5.4×10^{-2} molecules/quantum at 2537 Å. to 1.4×10^{-5} molecules/quantum at 5640 Å.) and the but slight dependence on temperature which increases with increasing wave length (at wave lengths below 4360 Å., no temperature dependence; at 5640 Å., activation energy 4 kcal. per mole).[7] Apparently for irradiation of MnO_4^- at shorter wave lengths, the greater amount of resultant vibrational energy is more efficient in bringing about reaction; at longer wave lengths, some thermal energy must be supplied. However, in the case of $Cr(H_2O)_6^{+3}$, essentially no dependence of quantum yield or activation energy on wave length could be detected. This fact together with the large activation energy observed seems to indicate a marked difference between the photoreactions of MnO_4^- and $Cr(H_2O)_6^{+3}$. In fact, the latter might well undergo reaction while in an electronically excited state.

That electronic excitation should affect reaction rate seems likely in terms of Taube's striking correlation of reaction rate and electronic configuration.[9] Whereas the normal $Cr(H_2O)_6^{+3}$ falls in Taube's class of "inert" complex ions, excitation of the 3d electrons, might be expected to produce a "labile" complex ion.[10] Furthermore, if the exchange reaction occurs while $Cr(H_2O)_6^{+3}$ is in an excited electronic state, the relatively large activation energy can be understood. This energy would correspond to the activation energy for the exchange of the excited species. In the case of other labile complex ion substitution reactions which have been studied by Bjerrum and Poulsen at very low temperatures,[11] activation energies are of the same magnitude. For example, an activation energy of 12.7 kcal./mole was determined for the reaction

$$Fe^{+3} + SCN^- \longrightarrow FeSCN^{+2}$$

However, if the temperature dependence of the present photochemical reaction is due to the excited species requiring activation energy for reaction, it is necessary that the excited species be relatively long lived. An activation energy of 13 kcal./mole would correspond, if the pre-exponential rate factor were the same as for the normal ion (5×10^{14} sec.$^{-1}$),[4] to a mean life for reaction of 6×10^{-6} sec. at 25°. This value should be compared with an estimate of the mean life of the excited state.

From the integrated intensity of absorption bands it is possible to obtain an estimate of the maximum mean lifetime of an excited state.[12]

Of the three absorption bands of $Cr(H_2O)_6^{+3}$ only the lowest energy state is considered, since it is assumed that there is quite rapid internal conversion from the higher states. This assumption is consistent both with previous fluorescence studies,[8] and with the observation that in the present case, the quantum yield does not depend upon which absorption band is irradiated. Such an estimate for the lowest energy band is 1.4×10^{-5} sec., which should correspond to the mean life of that state if the only mode for return to the ground state is direct fluorescence. The lack of fluorescence indicates that the actual lifetime of this state is many orders of magnitude less; in fact, too short for any detectable reaction to occur. However, the life time of electronic excitation may actually be much longer than the lifetime of the lowest excited quartet state. According to the spectral assignment of Finkelstein and Van Vleck for solid chrome alum,[13] there is a doublet state which lies fairly close to the lowest excited quartet state. If before conversion to the ground state, some of the excited $Cr(H_2O)_6^{+3}$ passed into such a spin forbidden state of long life time, it could well have sufficient time to undergo the chemical exchange reaction while still electronically excited.

The Mechanism of Chemisorption: Ethylene and Ethane on Nickel

BY P. W. SELWOOD

RECEIVED AUGUST 23, 1956

Magnetization–volume isotherms have been obtained for ethylene and for ethane on a commercial nickel–kieselguhr catalyst, and for ethylene on a coprecipitated nickel–silica catalyst. Isotherms have also been obtained for hydrogen on a nickel surface already covered in part with chemisorbed ethylene, and for ethane on a surface already covered with hydrogen. It has been shown that if the d-band of the nickel in these catalysts gains one electron per chemisorbed hydrogen atom, the d-band gains on the average a little over two electrons for each ethylene molecule chemisorbed at room temperature. Admission of ethylene to nickel at higher temperatures is followed by dissociative adsorption or fragmentation. On a coprecipitated catalyst at 100° this fragmentation yields approximately a six-electron transfer per molecule of chemisorbed ethylene. Ethane at room temperature is chemisorbed on a bare nickel surface with somewhat more than a six-electron gain by the nickel per molecule of ethane. Ethane is not chemisorbed on a nickel surface already covered with hydrogen. In these catalyst systems there are three or four times as many nickel sites available to hydrogen as to ethylene, and over six times as many to hydrogen as to ethane. Admission of hydrogen to a nickel surface already covered with ethylene leads both to the formation of ethane and to the chemisorption of hydrogen.

The purpose of this work was to extend the method of magnetization–volume isotherms to ethylene, to ethane, and to certain aspects of the ethylene hydrogenation reaction.[1]

Experimental

All the results reported below were obtained by the induction method previously described.[1] Adsorptions were made and magnetizations were measured at 27° except as otherwise stated.

Two catalyst samples were used. One was Universal Oil Products Company nickel–kieselguhr hydrogenation catalyst, containing 52.8% nickel. This catalyst has an approximate surface area (B.E.T., N_2) of 175 sq. m. per g. The other catalyst was a coprecipitated nickel–silica prepared as described by Van Eyk Van Voorthuisjen and Franzen,[2] and designated by them CLA 5421. This sample contained 37.5% nickel, and had a surface area of about 200 sq. m. per g. Specific magnetization *vs.* temperature for samples similar to these already have been published.[1]

Each sample was reduced in flowing hydrogen before each series of measurements. Reduction was at 360° for 12 hr., followed by evacuation at 10^{-6} mm. for 1 hr. at 360°, and cooling *in vacuo* to 27°.

Hydrogen used for reduction and for adsorption measurements was purified as previously described,[1] as was the helium used for dead-space determination. The ethylene was Phillips Research Grade guaranteed to be 99.9+% pure. The ethane was Mathieson Technical Grade.

The results reported below were obtained on samples weighing 6 to 8 g.

Results

Figure 1 shows automatically recorded changes of magnetization observed when ethylene was flushed over evacuated U. O. P. catalyst, up to atmospheric pressure. The change is negative, that is, in the same direction as that caused by chemisorbed hydrogen on nickel at room temperature. The effect is, however, considerably smaller than that for hydrogen. This accounts for our failure to observe the effect for ethylene at room temperature in our first experiments in which the less sensitive Faraday method was used.[3] We did observe and report the effect of ethylene at higher temperatures, as described below.

It will be seen that there is a fairly large thermal transient caused by the heat of chemisorption. After temperature equilibrium had been reached the sample was evacuated with the result shown, namely, a small positive transient appeared. No permanent change of magnetization was produced by evacuation even though, as will be shown below, over half the ethylene was thus removed. This result merely shows, as is well known, that a large fraction of the ethylene adsorbed on nickel–silica at room temperature is held by van der Waals forces.

Figure 2 shows both magnetization–volume isotherms and, the more familiar, pressure–volume iso-

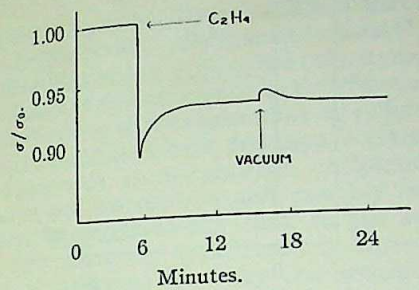

Fig. 1.—Automatic recording of magnetization changes during admission and evacuation of ethylene on nickel–kieselguhr.

therms for hydrogen on a U. O. P. catalyst sample. The result is similar to that already described for hydrogen on nickel,[1] but is needed here in connection with interpretation of the new results on ethylene hydrogenation.

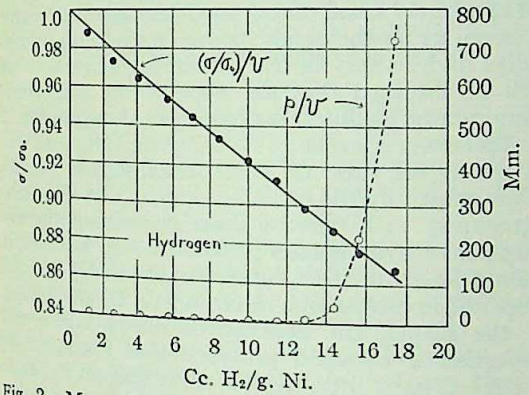

Fig. 2.—Magnetization–volume and pressure–volume adsorption isotherms for hydrogen on nickel–kieselguhr at 27°.

In Fig. 3 there are shown the results for ethylene adsorption on U. O. P. catalyst. After atmospheric pressure had been reached the sample was evacuated for 15 minutes. This resulted in the removal of considerable gas but with no change of magnetization. After a few minutes pumping no further gas could be removed, at room temperature. The volume of residual ethylene was then found by adding ethylene again up to atmospheric pressure. The total volume of ethylene first adsorbed was 10.8 cc. (S. C.) per g. of nickel. The volume taken up in the second addition was 6.0 cc. This was taken to mean that 4.8 cc. of ethylene remained chemisorbed on the sample. The second addition of ethylene caused no change of magnetization and was thereby proved to be all physical adsorption.

This procedure for finding the volume of residual chemisorbed ethylene ignores the fact that certain reactions may take place in this system at room temperature. One possibility is that of polymerization. But under the conditions and short time (15 min.) of the experiment it is hard to believe that polymerization could have introduced any serious error. Another possibility is that of self-hydrogenation. This, if occurring to any appreciable degree, could seriously impair the interpretations given below. The desorbed gas was therefore analyzed by absorption in bromine water. It was found

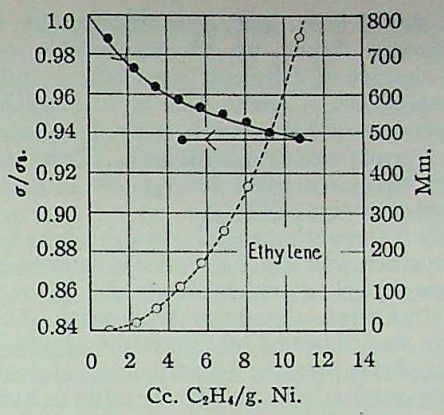

Fig. 3.—Magnetization–volume and pressure–volume adsorption isotherms for ethylene on nickel–kieselguhr at 27°.

found that no saturated hydrocarbon was present in sufficient amount to warrant consideration for the purposes of this work.

Two further points may be mentioned. All the adsorption results reported here are given for convenience in cc. of gas adsorbed (S. C.) per g. of nickel. It will be understood that the silica support must contribute to the van der Waals part of the total adsorption. The other point is that one may wonder why more ethylene cannot be pumped off if the pressure at 4.8 cc. residual ethylene is actually over 100 mm. as seems to be indicated in Fig. 3. But this was doubtless due to hysteresis in the desorption isotherm. The actual pressure at 4.8 cc. ethylene after desorption was very small.

Figure 4 shows the results for a hydrogen isotherm *over* the 4.8 cc. of chemisorbed ethylene, on the same sample as for Fig. 3.

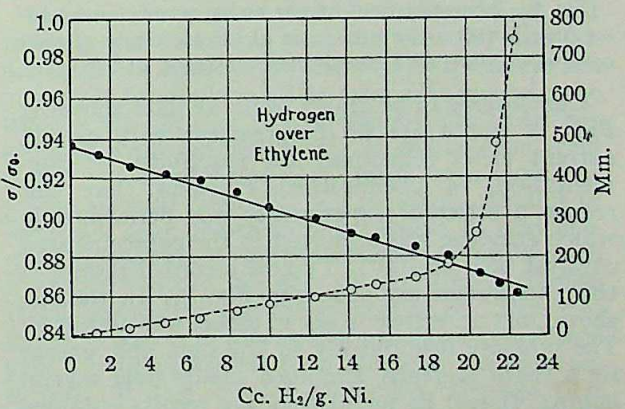

Fig. 4.—Magnetization–volume and pressure–volume isotherms for hydrogen on nickel–kieselguhr already partially covered with chemisorbed ethylene at 27°. The p–v isotherm shown has not been corrected for the modest amount of ethane present in the gas phase at the higher pressures.

In view of the rather unexpected result shown in Fig. 4, namely, that hydrogen may in fact be chemisorbed on a nickel surface already covered (so far as possible) with chemisorbed ethylene, this experiment was repeated on the coprecipitated catalyst. The results were qualitatively the same as shown in Fig. 4. The volume of chemisorbed ethylene, being in this case determined by removal of the excess by exhaustion through a Toepler

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

pump, was 5.0 cc. per g. of nickel, the volume of hydrogen taken up to atmospheric pressure in the absence of ethylene was 22.0 cc., and in the presence of the ethylene 27.0 cc. Coprecipitated catalysts are subject to a very large magnetic change on exposure to hydrogen. For this catalyst the effect for hydrogen was the largest so far observed, namely, 48%.

Figure 5 gives ethane isotherms on a bare U. O. P. nickel surface, and Fig. 6 shows ethane isotherms on the same nickel on which about 12.5 cc. of chemisorbed hydrogen already was present. This last isotherm was obtained by first adding hydrogen up to atmospheric pressure over the bare catalyst, then pumping out for 15 min., that is, until the hydrogen pressure was a fraction of a mm. The ethane was then added in successive increments in the usual way.

Fig. 5. Fig. 6.

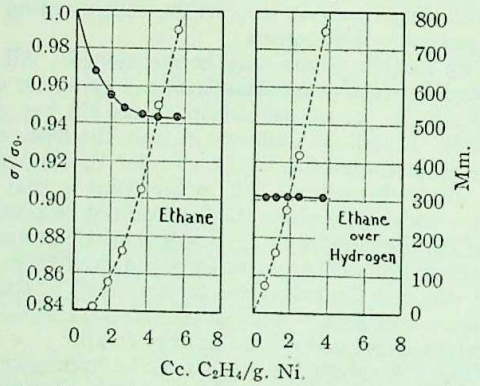

Fig. 5.—Magnetization–volume and pressure–volume adsorption isotherms for ethane on nickel–kieselguhr at 27°.

Fig. 6.—Magnetization–volume and pressure–volume adsorption isotherms for ethane on nickel–kieselguhr already covered (in part) with chemisorbed hydrogen, at 27°.

Conclusions to be drawn from the data shown in Figs. 3 and 4 are in disagreement with certain current views concerning the reactivity, or fragmentation, of chemisorbed ethylene. For this reason a series of experiments was performed in which ethylene was admitted to the coprecipitated catalyst held at 100°. Typical recorded results of this experiment are shown in Fig. 7. In the run shown, 6.2 cc. ethylene per g. nickel was admitted. The pressure rose quickly to 159 mm. and, except for a slight increase, remained steady over several hours. It will be noted that the results obtained in this experiment are in sharp contrast to those in which the ethylene is admitted to the nickel at room temperature, even though the quantity of ethylene chemisorbed in these cases is very nearly the same.

At the conclusion of the run shown in Fig. 7 the sample was cooled to 27°, evacuated to remove excess ethylene, and treated with hydrogen. The hydrogen uptake to atmospheric pressure was only 20.6 cc. and the magnetization fell to $\sigma/\sigma_0 = 0.58$.

Discussion

In a previous paper[4] we showed that the magnetization results are, in general, consistent with

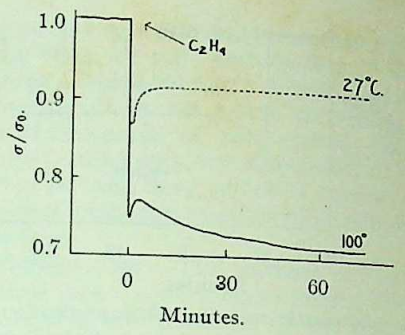

Fig. 7.—Automatic recording of magnetization changes during admission of ethylene on nickel–silica at 100°, as compared with admission at 27°.

the idea, often expressed, that each chemisorbed hydrogen atom contributes one electron to the nickel particle to which it becomes attached. The possible complication that hydride ions are formed on extremely small nickel particles does not greatly concern us on the catalysts and in the temperature range under study in the present investigation. It will be assumed that the slope of the magnetization-volume isotherm for hydrogen shown in Fig. 2 is, therefore, a measure of the adsorption condition in which the ratio of atoms chemisorbed to electrons gained by the nickel is unity. This view is in agreement with current ideas concerning the adsorption of hydrogen on palladium. If, however, it should be shown that formation of the Ni–H bond does not involve a one-electron gain by the d-band of the nickel, the conclusions drawn below will nevertheless be valid provided that formation of the Ni–C bond produces the same magnetic change as does the Ni–H bond. That this is a reasonable assumption is supported by consideration of the magnetic properties of coördination complexes involving metal–carbon bonds.

It will be noted that the initial slope of the magnetization isotherm shown for ethylene in Fig. 3 is a little larger than that for hydrogen. This is to say that the nickel gains on the average a little more than two electrons for every ethylene molecule chemisorbed. This is clear confirmation for the view that ethylene is, in the system studied, held principally by two-site attachment,[5] and that a moderate fraction of the ethylene dissociates hydrogen to occupy four or more sites—two for the dissociated hydrogen and two or more for the acetylenic residue.

One sees, however, that additional increments of ethylene have a smaller effect on the magnetization. It might be surmised that this is due to one-site attachment, but the easy removal of over half of the ethylene with no attendant change of magnetization shows clearly that a substantial fraction of the ethylene is held by van der Waals forces. The actual fraction of physically adsorbed ethylene at one atmosphere pressure is 55.5%.

It will be noted that the volume of chemisorbed ethylene is much smaller than the volume of hydrogen which may be adsorbed on the same catalyst. This observation has been made several

times in the past, as has the implication that there are at least two kinds of nickel surface sites.[6,7] One class of sites is accessible to ethylene or to hydrogen, another class of sites is accessible to hydrogen alone. The actual fraction of sites accessible to ethylene is not readily determined with precision because hydrogen apparently is chemisorbed completely at pressures of one atmosphere and possibly higher. We believe it correct to say that, in the system studied here, there are approximately three sites accessible to hydrogen for every one accessible to ethylene. All the conclusions drawn for the U. O. P. catalyst are equally valid for the coprecipitated catalyst except that for the latter there are three and a half to four sites accessible to hydrogen for every site accessible to ethylene.

Turning now to the hydrogen isotherms obtained on a nickel surface already saturated with chemisorbed ethylene, as shown in Fig. 4, it will be seen that a very large volume of hydrogen is taken up. But, the total hydrogen taken up at one atmosphere pressure is 4.9 cc. greater than the volume of hydrogen adsorbed on a bare nickel surface at one atmosphere. This excess volume of hydrogen is the same as the volume of chemisorbed ethylene present. There can be little doubt that the excess hydrogen is used in the expected fashion to hydrogenate the ethylene, and this is confirmed by the appearance of ethane in the gas phase.

It is, of course, far from surprising to find that hydrogen reacts with ethylene to form ethane over a nickel catalyst. But if the fraction of hydrogen used in hydrogenation is actually 4.9/22.2 as indicated in Figs. 2 and 4, then after the addition of, say, 12 cc. of hydrogen the volume of ethane liberated should be 12 cc. $\times$ 4.9/22.2 = 2.6 cc. In a dead-space of 8.6 cc. this should exert a pressure of 230 mm., whereas the actual pressure was only 100 mm.

In the above calculation it has been assumed that the product ethane is not adsorbed. Turning to Figs. 5 and 6, one sees that while ethane is chemisorbed on a bare nickel surface it is not chemisorbed at room temperature in the presence of an adsorbed layer of hydrogen. Ethane is, however, physically adsorbed on such a catalyst surface at room temperature to the extent of almost 4 cc. per g. of nickel at one atmosphere. We have then a complete explanation for the pressure–volume isotherm shown in Fig. 4. After the addition of 12 cc. of hydrogen there has been formed 2.6 cc. of ethane. At a partial pressure of 100 mm. almost 1 cc. of this would be physically adsorbed. The remaining 1.6 cc. of ethane in 8.6 cc. dead space would exert a pressure of 140 mm., which is fairly close to that actually observed.

The above reasoning involves two assumptions: first, that the hydrogen is chemisorbed in more or less normal fashion in spite of the presence of ethylene and ethane and, second, that the hydrogen neither hydrogenates the ethylene preferentially nor is it adsorbed preferentially but rather that it reacts purely according to chance impact on the surface. Justification for these two assumptions follows.

The magnetization isotherm in Fig. 4 is a straight line with a negative slope. Yet replacement of a chemisorbed ethylene molecule by two atoms of hydrogen would produce either no change or a slight positive change of magnetization. There can, therefore, be no question that hydrogen is chemisorbed in the presence of ethylene. On the other hand, the regular increase of pressure with added hydrogen in Fig. 4 shows that the generation of ethane is linear with each increment of hydrogen. There seems little doubt that for approximately every four molecules of hydrogen taken up under the conditions of Fig. 4, one molecule is used to hydrogenate the ethylene.

Another observation in connection with Fig. 4 is that the slope of the magnetization isotherm is much less than that for the corresponding hydrogen isotherm shown in Fig. 2. It requires 2.4 atoms of hydrogen on a nickel–ethylene surface to lower the magnetization the same fraction as may be achieved by one hydrogen atom on a bare nickel surface. To express this in another way: if one electron is gained by the bare nickel for each hydrogen atom adsorbed, then one electron is gained by the nickel–ethylene surface for each 2.4 hydrogen atoms taken up.

The problem of interpretation now resolves itself into finding a structural relationship that will account for the following two observations: (1) the number of sites accessible to ethylene is only one-third of the number accessible to hydrogen, and (2) a net gain of one electron by the nickel during hydrogenation of ethylene requires 2.4 atoms of hydrogen.

Table I shows some possible configurations and mechanisms. Class (A) sites and class (B) sites are accessible to hydrogen; Class (A) sites alone are accessible to ethylene. The ratio e/H given in the table is the net gain of electrons by the nickel per atom of hydrogen taken up. It will be clear from Table I that situation (III) must be a close approximation to the truth. Of the sites accessible to hydrogen only one-third is accessible to ethylene, and the addition of eight atoms of hydrogen to such a surface yields a net gain of only four electrons. It will be recalled that the adsorption of ethylene as in Fig. 3 results in a little more than a two-electron gain by the nickel for each ethylene molecule adsorbed. If this modest correction is made then the ratio e/H for situation (III) in Table I is found to be almost exactly 1/2.4, as observed experimentally.

For the coprecipitated catalyst the corresponding figures for e/H are (before correction for some dissociation of the ethylene): calcd. 1.7 to 1.8; found, 2.2.

The conclusions drawn above are in sharp disagreement with the fact that the hydrogen–deuterium exchange reaction is strongly inhibited by the presence of chemisorbed ethylene on nickel, and the inference that hydrogen is not chemisorbed as atoms under these conditions.[6,8] None of the situa-

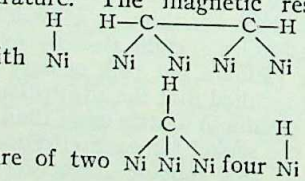
(III)	$H_2C{-}CH_2$ (A) + H H (B) + H H (B) + $4H_2$ → H H (B) + H H (B) + H H (B) + C_2H_6	1/2

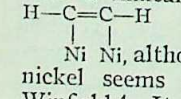
tions represented in Table I could be expected to poison the nickel surface for the hydrogen–deuterium exchange.

Our results for the mode of attachment of ethylene on a bare nickel surface are also in apparent disagreement with those reported by Pliskin and Eischens,[9] who on the basis of infrared absorption studies found extensive fragmentation of the ethylene. These workers did, however, find results in agreement with those reported here for ethylene adsorbed on a nickel surface containing some chemisorbed hydrogen.

A clue to these discrepancies is found in the paper of Turkevich, *et al.*,[10] who found no poisoning by ethylene on nickel–kieselguhr at −78°, but marked poisoning on a nickel wire at 90°. This result suggests that some secondary reaction of the ethylene is responsible for the poisoning and this view is supported strongly by the results shown in Fig. 7. When ethylene is admitted to the catalyst at 100° the loss of magnetization is much greater than when admission is at room temperature. Furthermore, progressive fragmentation of the ethylene is readily followed for an hour or more until a steady state is reached corresponding to over six bonds to the nickel for every ethylene molecule adsorbed, instead of the two bonds found at room temperature. We have insufficient information to determine the nature of the adsorption complex formed at the higher temperature. The magnetic results are consistent with



with a mixture of two



four Ni and one

Ni, although carbon bonding to more than one nickel seems not to have been considered by Winfield.[4] It will be noted that after the fragmentation process had taken place the catalyst had lost some of its ability to adsorb hydrogen.

These results which demonstrate progressive fragmentation of the adsorbed ethylene clear up most of the difficulty mentioned above. When ethylene is admitted to bare nickel at low temperature it is adsorbed primarily by the familiar two-site attachment and in this way can exert little or no poisoning effect on the hydrogen–deuterium exchange reaction. As the temperature is raised fragmentation of the ethylene occurs; this results in increased occupation of nickel sites, and poisoning becomes marked. Whether or not poisoning becomes complete doubtless will depend on the initial ratio of sites accessible to hydrogen and to ethylene. The lower this ratio the more effective, it may be predicted, will poisoning become. Actually the coprecipitated catalyst on which fragmentation was demonstrated above was not the best choice to show this effect because the H_2/C_2H_4 ratio of accessible sites is fairly high.

In the work described here slight fragmentation of the ethylene was observed at room temperature, while extensive fragmentation is implied by the work of Eischens and by others. There is no real conflict here because the fragmentation process which is rapid at 100° must certainly occur also at room temperature. How much fragmentation occurs will depend on the intrinsic activity of the surface, on the time elapsed between admission of the ethylene and further testing of the surface (all room temperature experiments reported here were completed in less than one hour), and also on the rate of admission of the ethylene, the adsorption of which heats the nickel appreciably.

Pliskin and Eischens report evidence for the presence of adsorbed ethyl radicals on a sample to which first ethylene and then hydrogen was admitted. The results reported here do not deny this possibility. They do, however, require the added hydrogen to be used at random for hydrogenation and for chemisorption, and not for hydrogenation before chemisorption or *vice versa*. The results reported here are also not inconsistent with the view that ethylene is hydrogenated from the gas phase.

A few further conclusions may be drawn. From Fig. 5 it will be seen that the initial magnetization slope for ethane on bare nickel is twice that observed for ethylene and over four times that for hydrogen. The chemisorption of a molecule of ethane clearly involves a minimum four-site attachment, thus confirming the well-established dissociative mechanism for paraffin–deuterium exchange.[11] Actually the dissociation probably preceeds even further with some ethane molecules requiring six or more sites.

The total volume of ethane which may be chemisorbed appears (by comparison of Figs. 3 and 5) to be a little under half the volume of ethylene which may be chemisorbed. This result suggests that hydrogen dissociated during the chemisorption of ethane cannot (at room temperature) migrate to class (B) sites.

Figure 6 confirms the view that the relatively slow exchange reaction of paraffins with deuterium is due to the strong chemisorption of hydrogen on all sites which might otherwise be accessible to the paraffin molecules.[12]

Preparation and Characterization of a New Crystalline Form of Molybdenum Disulfide

BY RONALD E. BELL AND ROBERT E. HERFERT

RECEIVED FEBRUARY 26, 1957

During an investigation involving preparation of a quantity of synthetic molybdenum disulfide, X-ray techniques were applied to evaluate purity where ordinary wet chemical methods could not be used. The X-ray examinations indicated diffraction patterns differing from the pattern of natural molybdenite. An intensive study by single crystal X-ray techniques revealed that instead of the customary hexagonal molybdenum disulfide structure a hitherto unreported rhombohedral form of the compound had been prepared.

Introduction

The synthesis of molybdenum disulfide by chemical means has been described by a number of early researchers.[1-9] Such various methods of preparation as that proposed by Berzelius,[1] wherein molybdenum trisulfide is decomposed by vacuum heating; or the method of Svanberg and Struve,[2] involving reaction of molybdenum trioxide with hydrogen sulfide gas at red heat; the procedure of heating molybdenum and sulfur in an iron tube as proposed by van Arkel[3]; the procedure of de Schulten,[4] in which molybdenum trioxide, sulfur and potassium carbonate are fused together; the method used by Milbauer,[5] wherein molybdenum dioxide reacted with molten potassium thiocyanate; finally, Lander and Germer deposited molybdenum disulfide coatings from molybdenum carbonyl in atmospheres containing rather critical ratios of hydrogen sulfide and carbon monoxide; are among those listed in the literature.

In these earlier experiments evidence that molybdenum disulfide had been prepared synthetically was based on chemical analysis and, in some cases, also on microscopic examination. Van Arkel[3] reported Debye–Scherrer patterns identical to those obtained with natural molybdenum disulfide for his synthetic product. Other than this, there are no references in which the crystal structure of synthetic molybdenum disulfide has been established by modern crystallographic techniques.

A quantity of molybdenum disulfide of a purity that was not readily obtained by purification of the natural product was required at the authors' laboratory for standardization as to physical, chemical and mechanical properties; therefore, it was proposed to prepare the material by chemical synthesis.

As will be shown, it developed that the material eventually prepared differed from natural molybdenum disulfide in that the crystal structure was not the same.

Experimental

Preparation.—After experimenting with several of the procedures described in the literature and finding them to yield products unsatisfactory for this investigation, the procedure described by de Schulten[4] was applied to the preparation of the subject material. Briefly, this procedure is as follows: four parts by weight of potassium carbonate (reagent grade) are fused with six parts by weight of flowers of sulfur in a 250-ml. covered porcelain crucible at 675°, the reaction being conducted in a gas-fired furnace until evolution of sulfur dioxide is complete. The crucible and contents are removed from the furnace (taking precaution to avoid thermal shock) and allowed to cool. One part of sublimed molybdenum trioxide is added and the crucible is reheated at 900° for 30 minutes. Additional molybdenum trioxide is added in the same manner and the contents of the crucible are reheated at 900° after each addition, until a total of six parts by weight of molybdenum trioxide has been added. The entire mass is solidified, and the excess reagents and impurities are removed from the molybdenum disulfide by prolonged boiling with dilute ammonia, followed by washing with distilled water, boiling for a short time (20 to 30 min.) in dilute hydrochloric acid, and finally, by thorough washing with water, alcohol and ether. The material is then vacuum dried at 75°. The above treatment will not remove the MoO_2 impurity.

Purification.—The chemical reaction involved in de Schulten's method for synthesizing molybdenum disulfide is believed to proceed in two steps

$$2MoO_3 + S \longrightarrow 2MoO_2 + SO_2 \quad (1)$$

$$MoO_2 + 3S \longrightarrow MoS_2 + SO_2 \quad (2)$$

(It is assumed that potassium carbonate merely acts as a flux without actually entering into the reaction.)

The procedure just described includes measures which were intended to remove all ammonia and acid-soluble impurities. Upon X-ray diffraction examination of the product, the only detectable impurity not removed by this treatment was molybdenum dioxide.

The presence of molybdenum dioxide as an impurity in the product may be attributed to inhomogeneities in the fusion mass which result in local deficiencies of available

sulfur with subsequent failure of the reaction to go to completion.

A satisfactory method was not developed, despite many attempts, which would result in complete reaction of the MoO_2 with sulfur (eq. 2) to form MoS_2. The products of all the experiments contained various amounts of molybdenum dioxide with the molybdenum disulfide product.

No suitable method was found for detecting and estimating the molybdenum dioxide content by chemical means. However, by means of X-ray diffraction examination, the presence of molybdenum dioxide was determined readily (Fig. 2A).

In order to utilize X-ray methods for quantitative determinations of molybdenum dioxide in molybdenum disulfide, mixtures of known molybdenum dioxide and molybdenum disulfide contents were prepared. A direct reading X-ray spectrometer with copper radiation at 50 kvp.-16 ma. and a nickel filter was used to obtain X-ray diffraction patterns for samples containing 2.135, 5.31 and 9.36% molybdenum dioxide by weight. The X-ray intensity for the molybdenum dioxide phase was based on the absolute intensity of the (110) reflection from the molybdenum dioxide phase.

To reduce the lower limit of detection of the molybdenum dioxide phase in a mixture with molybdenum disulfide, specimens containing known amounts of the dioxide and the disulfide were compressed into pellets at a stress of 12,000 p.s.i. The application of stress to the powder mixture resulted in preferred orientation of the phases present. Preferred orientation of the dioxide phase resulted in greater intensity of the (110) planes compared to that of the randomly distributed powder. The development of preferred orientation in the powder mixture is, of course, highly dependent upon such factors as powder particle size, purity, method of compression and the total stress exerted on the mixture.

X-Ray diffraction data on pellets containing preferredly oriented molybdenum dioxide yielded a sensitivity of 325 counts per second per per cent. molybdenum dioxide contained in the mixture. Thus, the lower limit of detection was placed at about 3.25 counts per second, or 0.01% molybdenum dioxide. Figure 1 represents a plot of the absolute intensity of the (110) reflection from molybdenum dioxide as a function of concentration of molybdenum dioxide in a mixture with molybdenum disulfide.

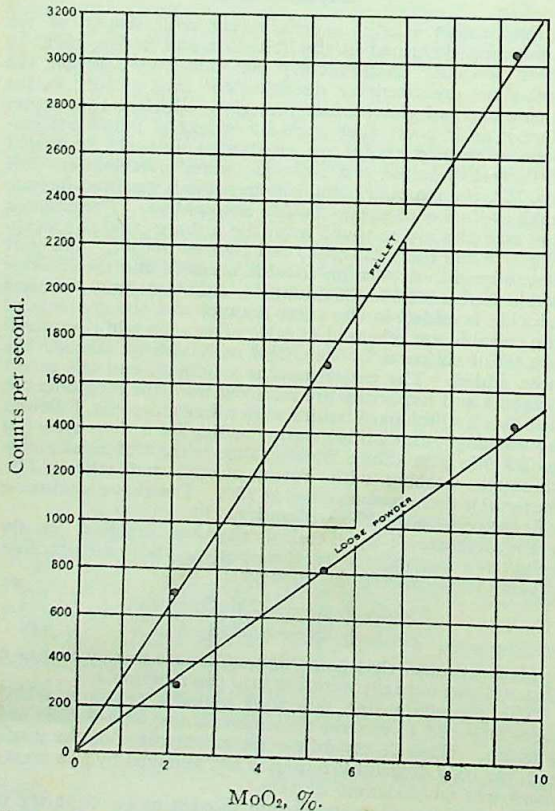

Fig. 1.—X-Ray calibration curve for determination of MoO_2 in MoS_2.

In order to remove the molybdenum dioxide present as impurity in the synthetic product, a procedure similar to that developed by Milbauer[5] was employed. Briefly, this consists of digesting the synthetic molybdenum disulfide in molten potassium thiocyanate, followed by digestion with dilute aqueous ammonia and dilute hydrochloric acid as previously described. This method was successful in decreasing the molybdenum dioxide content to a level below 0.01%, the limit of X-ray diffraction analysis. This treatment did not affect the crystallinity of the product.

Chemical Analysis of the Product.—A total of about 1500 g. of synthetic molybdenum disulfide was prepared and purified as described above. On the basis of the amount of molybdenum trioxide used, this represents a recovery of about 45%.

The product was analyzed by quantitative chemical methods for total molybdenum, total sulfur, carbon, titanium, insolubles and silica. The titanium was believed to result from the decomposition of the glaze on the porcelain crucibles. The results of these analyses are summarized in Table I.

TABLE I

CHEMICAL ANALYSIS OF SYNTHETIC MOLYBDENUM DISULFIDE

	Assay, %
Total molybdenum	60.17
Total sulfur	39.87
Carbon	0.04
Titanium	.005
Insolubles (including Ti as TiO_2 and most of the SiO_2)	.16
Silica	.10

X-Ray fluorescence analysis of the synthetic molybdenum disulfide showed the material to contain 59.9% molybdenum, which is in close agreement with the value obtained by chemical analysis as shown above.

Silicon and titanium in small amounts were the only impurities revealed by a semi-quantitative optical spectrographic analysis.

Crystallographic Examination.—During the processes of verifying the purity of product and determining of crystallinity by X-ray diffraction techniques, a marked difference was noted between the diffraction patterns obtained from the natural molybdenum disulfide and the synthetic molybdenum disulfide. The synthetic molybdenum disulfide exhibited differences in the reflections occurring in the vicinity of the $(10\,l + 2)$ reflections of the natural material (Figs. 2B and 2C). Instead of the (103), (105) and (107) reflections characteristic of the natural MoS_2, the synthetic material had doublets centered about the normal reflection position for the (103), (105) and (107) planes.

Crystallographic data describe natural molybdenum disulfide as a hexagonal layered structure. It has a dihexagonal dipyramidal unit cell with two molecules per unit cell. It is further characterized as a "P" Bravis lattice with a $P6_3/mmc$. symmetry. Under these limitations no reflections could occur at the positions found in the diffraction pattern from the synthetic molybdenum disulfide. Either an abnormality exists in the atomic positions of the unit cell or there is an entirely different crystal structure present. Due to the complexity of the diffraction pattern, structure determination from the powder patterns was not attempted.

Since crystal structure is determined most readily by single crystal X-ray techniques, an attempt was made to obtain crystals large enough for analysis. A single crystal platelet with a trigonal outline was obtained from one of the melts. A transmission Laue pattern was obtained from this crystal. This showed a threefold symmetry, instead of the sixfold symmetry characteristic of the naturally occurring molybdenum disulfide. This same crystal was used for obtaining both 0-level and 1-level Weissenberg photographs with rotation about an axis parallel to one of the edges of the three-sided crystal and also a rotation and 0-level Weissenberg photograph about an axis normal to one of the edges.

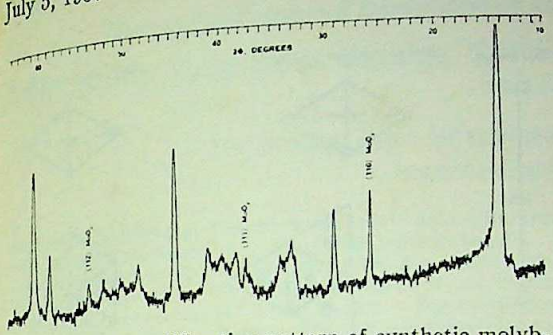

Fig. 2A.—X-Ray diffraction pattern of synthetic molybdenum disulfide containing molybdenum dioxide (copper radiation, 50 kvp-16 ma. nickel filter).

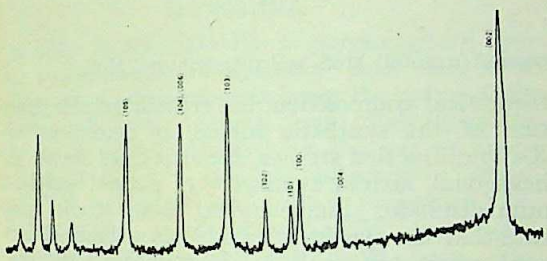

Fig. 2B.—X-Ray diffraction pattern of purified naturally occurring molybdenum disulfide.

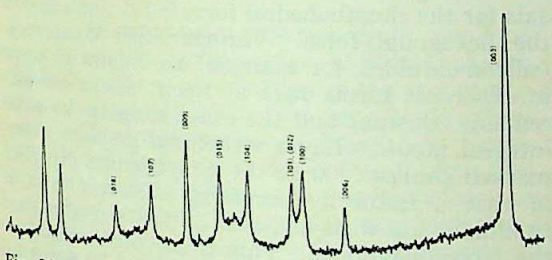

Fig. 2C.—X-Ray diffraction pattern of synthetic molybdenum disulfide with (*hkl*) as designated.

Indexing of these photographs showed that only reflections with $h + k + l = 3n$ were present. This indicated the presence of a rhombohedral lattice which is also in harmony with the threefold axis symmetry of the Laue photograph. Therefore, the crystal was assigned an "R" Bravis lattice with a "3m" symmetry. Referred to the hexagonal lattice, the *a*-axis was found to be identical with that of natural molybdenum disulfide. However, the *c*-axis of the rhombohedral was found to be 1.5 times greater. This means that the (002), (004) and (006) reflections of the hexagonal type would now correspond to (003), (006) and (009) for the rhombohedral lattice. The transformation from hexagonal to rhombohedral axis is H = *h*, K = *k* and L = 3/2 *l*.

The appearance of the doublets in the Debye–Scherrer pattern for the (103), (105) and (107) reflections of the natural molybdenum disulfide are now fully explained by the rhombohedral symmetry. The (101) plane of the hexagonal symmetry now becomes the (101) and (012) reflections of the rhombohedral planes. Similarly, the (103) is replaced by (104) and (015), and the (105) by (107) and (018). The (001) reflections of the rhombohedral type show a very slight displacement away from the zero beam. Positional measurements of the powder photograph peaks of hexagonal (008) and rhombohedral (0012) reflections are, respectively, 1.540 and 1.533 Å.

The unit cell of the molybdenum disulfide has two molybdenum atoms at $^2/_3$, $^1/_3$, 0; and $^1/_3$, $^2/_3$, $^1/_2$, which places them on the two vertical axes. Pairs of sulfur atoms are on these same vertical axes, one above and one below each molybdenum atom at a distance of $^1/_8$ (equivalent to 4.61 Å.), as shown in Fig. 3. The three molybdenum atoms in the rhombohedral unit would have to lie on three vertical threefold axes and could be placed at 000; $^2/_3$, $^1/_3$, $^1/_3$; and $^1/_3$, $^2/_3$, $^2/_3$, with a sulfur atom above and below each molybdenum atom at a distance of $^1/_4$ (equivalent to 4.61 Å.). Both types would have the same interatomic distances, but in the hexagonal form the molybdenum atom would lie at the center of a trigonal prism, with the three upper sulfur atoms directly above the three lower sulfur atoms. In the rhombohedral form, the three sulfur atoms above would be in alternate positions with respect to the three below, that is, rotated 60°.

There is also an alternative description possible for the hexagonal molybdenum disulfide atoms. The molybdenum atoms could be located on the threefold symmetry axes alternating with pairs of sulfur atoms 3.08 Å. apart. However, this description does not apply to the rhombohedral form—there are no sulfur pairs.

In order to compare the relative intensities obtained from the powder patterns, theoretical determinations were made for the atomic contributors to the (00 *l*) reflections. Using the parameter ($^1/_4$) for the sulfur atoms the contributors to the (00 *l*) reflections of the synthetic molybdenum disulfide would be

(003)	Mo
(006)	Mo − 2S
(009)	Mo
(0012)	Mo + 2S
(0015)	Mo
(0018)	Mo − 2S
(0021)	Mo

There is reasonably good correlation between the theoretical values obtained from the structure factor determinations for intensities and those observed on the powder patterns. A comparison of the "*d*-values" and relative intensities for the natural and synthetic molybdenum disulfides is presented in Table II.

TABLE II

theoretical density of the newly discovered crystallographic form was computed from X-ray measurement of the interplanar spacings. Computation of the theoretical density is based on the relation

$$\rho = \frac{1.6602 \times M \times \text{at. wt.}}{\text{volume}}$$

where $M = 3$, the number of atoms per unit cell. Lattice parameter measurements permit determination of the volume of the unit cell. The lattice parameters and theoretical density of rhombohedral molybdenum disulfide are presented in Table III.

Conclusion

In the course of preparing molybdenum disulfide by synthetic methods, a product has been made which resembles natural molybdenum disulfide, but is of higher chemical purity. However, the synthetic sulfide has a crystal form different from that of the natural sulfide. Although the chemical composition of the synthetic sulfide coincides with the theoretical composition, the crystallographic structure of the synthetic sulfide, as determined by X-ray diffraction studies, does not have the normal hexagonal, sixfold symmetry of natural molybdenum disulfide. Single-crystal X-ray studies indicate that the synthetic sulfide has a threefold trigonal symmetry with a rhombohedral unit cell. The lattice parameter of the *a*-axis is identical for the two crystal forms, but the parameter of the *c*-axis for the rhombohedral form is 1.5 times that of the hexagonal form. Various other compounds (silicon carbides, for example) are known to occur in allotropic forms such as these, where one axis remains constant and the other increases by some integral factor. Layer structured graphite shows marked similarity with the molybdenum disulfide, in that a naturally occurring allotropic form is rhombohedral with its *c*-axis 1.5 times greater than the hexagonal form. This is the first indication, however, of the existence of allotropic forms of molybdenum disulfide.

In view of the crystal structure, it is suggested that other crystallographic forms of the sulfide could exist, depending upon the mode of preparation.

The various lubrication studies performed in an attempt to compare naturally occurring molybdenum disulfide and synthetic molybdenum disulfide showed the two had essentially the same lubricating qualities.

For all practical purposes, the theoretical densities of the synthetic disulfide and the natural hexagonal disulfide are equal.

Acknowledgments.—Our appreciation is due Dr. L. S. Ramsdell, Department of Mineralogy, University of Michigan, for the single crystal Weissenberg photographs and interpretations.

Studies of the Tungsten-containing Species Present in Acidified Sodium Tungstate Solutions[1]

BY DONALD JOHN BETTINGER[2] AND S. YOUNG TYREE, JR.

RECEIVED DECEMBER 19, 1956

Rayleigh turbidities and differential indices of refraction were measured and weight average ionic weights were calculated for sodium tungstate solutions acidified with perchloric acid. Aggregation or polymerization of the tungstate species as the solution is acidified is verified by this technique. Although the degree of polymerization does not change suddenly at certain H^+/WO_4^{2-} ratios, the change in degree of polymerization is not so uniform as to exclude the possibility of predominant species at certain H^+/WO_4^{2-} ratios. Some evidence for an intermediate predominant species between the monomer and hexamer is cited. Definite evidence is obtained for continued polymerization beyond the hexamer toward a possible dodecamer. The extent of polymerization beyond the hexamer is dependent both on H^+/WO_4^{2-} ratio and total tungsten concentration. It appears to be possible to use the light scattering technique to study the rate of polymerization of freshly prepared tungstic acid up to the point where precipitation commences.

Introduction

In order to elucidate the isopolytungstate system measurements of diffusion[3] and dialysis[4,5,6] coefficients of solutions containing the polyanionic species have been carried out. Polytungstate solutions have been studied by the use of spectrophotometric,[3,7-9] conductometric,[7,9,10] cryoscopic,[11,12] isopiestic[13] and pH[9,14] measurements. Thermometric,[7] conductometric,[7-9,15] and potentiometric[6,8,9,11,15,16] titrations have been employed in studies of these solutions. Self-diffusion[17] studies have been made over a limited range of concentrations.

It may be regarded as certain from the forementioned studies that as acid is added to a solution of $Na_2WO_4 \cdot 2H_2O$ polymerization of the monotungstate ion commences. The first very predominant species is the hexatungstate although, as Jander predicted and Anderson's, Biehler's and Pan and Hseu's data indicate there is reason to believe an intermediate predominant species may exist between the monotungstate and the hexatungstate. According to Jander depending on the concentration of the tungstate solution and the hydrogen ion concentration an equilibrium either between $HW_6O_{21}^{5-}$ and $H_3W_6O_{21}^{3-}$ or between $HW_6O_{21}^{5-}$ and a dodecatungstate apparently exists.

The question arises as to whether there are rather sharp lines of demarcation between the point where a given species is predominant and another species is predominant or whether there are no predominant species at any time. Also if predominant species exist the question arises as to what factors cause a change in the species predominant at a given time. Jander[4] has set ranges of pH and concentration in which he believes a given species to be very predominant.

This paper deals with the application of the light scattering and related techniques to a study of sodium tungstate solutions of several concentrations to which various amounts of perchloric acid are added. If polymerization of monotungstate does take place with increase in hydrogen ion concentration it should prove possible to follow the change in weight average ionic weight of the isopolytungstate species with change in H^+/WO_4^{2-} ratio. Likewise some indication as to the effect of tungstate concentration on the degree of polymerization at a given H^+/WO_4^{2-} ratio may be available from these studies.

Experimental

Instruments.—A standard Phoenix Precision Instrument Company differential refractometer designed according to Brice[18] was used to obtain differences between the refractive indices of the solution and solvent as the concentration of the solution was varied. This instrument was standardized using standard sucrose solutions and light of wave length 589 mμ from a sodium lamp source.

Turbidity measurements were made using a light scattering photometer fabricated in this Laboratory, similar in design to that described by Brice,[19] and calibrated using purified thiophene-free benzene, the absolute turbidity of which is given by the National Bureau of Standards[20] as 46×10^{-6} cm.$^{-1}$. Carbon tetrachloride, as would be expected if the instrument were functioning correctly, showed no dissymmetry.

Since the light scattering photometer was standardized using benzene and employed for aqueous solutions the usual correction was applied to account for the difference between the refractive index of benzene and that of water.[21,22]

A Leeds and Northrup line operated pH meter was used for potentiometric titrations, while a Beckman Model G pH meter was used to determine the pH of the polytungstate solutions. The meters were standardized against known buffer solutions.

Chemicals.—The chemicals were C.P. or reagent grade except for the sodium tungstate which in addition to being reagent grade met the specifications according to Dr. Folin.[23]

Results and Calculations

Debye[24,25] has derived the expression for the turbidity of dilute solutions. It can be expressed as

$$\tau = \frac{32\pi^3 Mcn_0^2}{3\lambda^4 N}\left(\frac{n - n_0}{c}\right)^2 \quad (1)$$

where M equals the weight average ionic or molecular weight of the solute. Let

$$H = \frac{32\pi^3 n_0^2}{3\lambda^4 N}\left(\frac{\Delta n}{\Delta c}\right)^2 \quad (2)$$

Then

$$\tau = HMc \text{ or } Hc/\tau = 1/M \quad (3)$$

Equation 3 is for ideal solutions. The addition of the term $2Bc/RT$, where B is an empirical constant which expresses the interaction between the solvent and the individual segments of dissolved polymer molecules, gives an equation for non-ideal solutions.

$$Hc/\tau = 1/M + 2Bc/RT \text{ or } c/\tau = 1/MH + 2Bc/RTH \quad (4)$$

If c/τ is plotted against c and a straight line is drawn through the points and extrapolated to zero concentration then the intercept represents the value of c/τ at infinite dilution and is equal to $1/MH$ or in other words

$$(c/\tau)_{c=0} = 1/MH \text{ or } M = 1/H\,(c/\tau)_{c=0} \quad (5)$$

Thus by plotting two graphs (1) Δn *versus* c in order to obtain the slope and thus $\Delta n/\Delta c$ so that H can be calculated and (2) c/τ *versus* c and extrapolate to $c = 0$ to obtain $(c/\tau)_{c=0}$ it is possible to calculate M, the weight average molecular or ionic weight of the solute.

Δn for a given sodium tungstate solution to which a certain amount of perchloric acid has been added is corrected by subtracting a Δn for the sodium perchlorate formed assuming complete consumption of the acid to form sodium perchlorate. The corrected Δn is divided by the appropriate Δc expressed in g./cc. and the value is squared to obtain $(\Delta n/\Delta c)^2$ which is used in the equation for M.

The τ value used in the equation for M is obtained from the τ value for the solution, determined experimentally for a given sodium tungstate solution to which a certain amount of perchloric acid is added, by subtracting a τ value for the sodium perchlorate formed assuming complete conversion of acid to salt. The tungstate concentration expressed in g./cc. is divided by the corresponding corrected τ value to obtain c/τ for a given concentration and H^+/WO_4^{2-} ratio. c/τ values are obtained for concentrations ranging from 0.5 to 0.025 molar in sodium tungstate and 1/2 to 3/2 H^+/WO_4^{2-} ratio. For a given H^+/WO_4^{2-} ratio these values are plotted against c in g./cc. A straight line is drawn through the points and extrapolated to zero concentration to obtain $(c/\tau)_{c=0}$ needed in the equation for M.

The assumption as to what constitutes the solute is important. The two extreme cases would be (1) to calculate c/τ as if the solute were WO_4^{2-} neglecting the excess Na^+ over and above that accounted for in the $NaClO_4$ or (2) to calculate c/τ as if the solute were Na_2WO_4 neglecting the Na^+ accounted for in the $NaClO_4$. The true value of the solute is somewhere between these extremes. In all cases the H^+ is neglected. This is justified since in many cases the solutions are approximately neutral. In those cases where the H^+/WO_4^{2-} ratio is 7/6 or more and the pH of the solution is in the acid region the hydrogen ion concentration is still negligibly small as compared to the tungstate ion and sodium ion concentrations. Any hydration of the tungstate ion is neglected as being too uncertain to incorporate in these calculations.

Determinations of the weight average ionic weight of Na_2WO_4 in solution and the weight average molecular weight of raffinose in solution were made to check the sensitivity and resolution of the photometer. These proved quite satisfactory as indicated in Table II.

3/2	2820	2380	$W_{12}O_{40}^{8-} = 2848$
	Na_2WO_4	271	$WO_4^{2-} = 248$

[a] The weight average molecular weight for raffinose was found to be 584. The theoretical value for hydrated raffinose is 594 and for anhydrous raffinose is 504.

Table I contains sample data and sample calculations for solutions with H^+/WO_4^{2-} ratio 3/2. Table II shows the weight average ionic weight for the solute at the various H^+/WO_4^{2-} ratios studied.

Discussion

The data given in Table II verify the fact that aggregation or polymerization of the tungstate species takes place as the solutions are acidified. Note the agreement between the observed values at the 2/3 and 7/6 ratios and the theoretical values for octatungstate and heptamer, respectively.

Figure 1 is a plot of τ, turbidity, *versus* H^+/WO_4^{2-} ratio. The rate of increase of τ increases above the 7/6 ratio in all cases. This increase is more striking the greater the total tungsten concentration. It would seem from these observations that an equilibrium exists between the tungsten-containing species (hexamer) found at a H^+/WO_4^{2-} ratio of 7/6 and a larger species, possibly the dodecamer, such that this larger species becomes increasingly more predominant not only as the 3/2 ratio is approached but also as the total tungsten concentration is increased. In other words, for a given ratio above 7/6 the more concentrated the solution the more predominant the larger species.

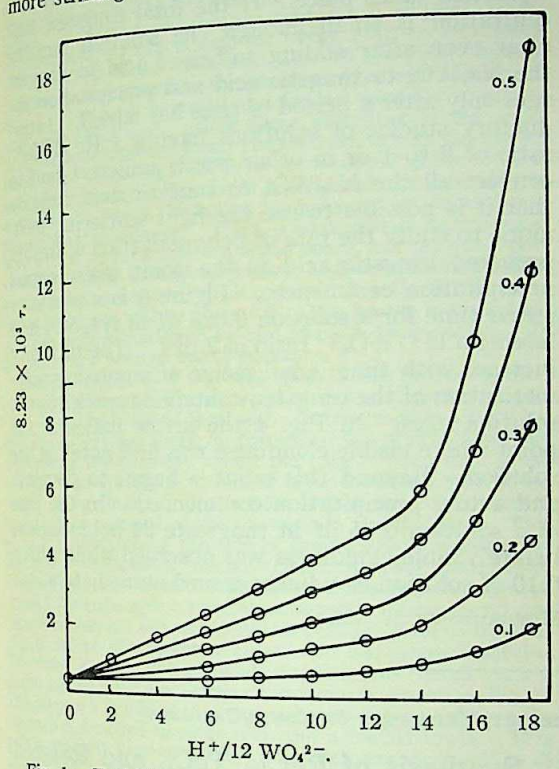

Fig. 1.—Turbidity, τ, as a function of H^+/WO_4^{2-} ratio for solutions 0.1, 0.2, 0.3, 0.4 and 0.5 M in sodium tungstate.

Figure 2 is a plot of Δn, the difference between the index of refraction of the solution and solvent, *versus* H^+/WO_4^{2-} ratio for a solution 0.5 M in tungstate. A theoretical Δn value was obtained for a given solution by adding together the Δn value for a tungstate solution of that concentration plus a Δn value for the perchloric acid used in that case, assuming no reaction between the tungstate and the perchloric acid. (It should be noted that indices of refraction of dissolved salts are additive if no reaction takes place.[1,26]) The observed Δn values for these solutions always fall below the theoretical values indicative of reaction at all H^+/WO_4^{2-} ratios. An inflection in the observed curve at the 7/6 ratio is indicative of a predominant species (hexamer) present at this ratio. The gradual inflection between H^+/WO_4^{2-} ratios 0 and 7/6 indicates the possibility of an intermediate pre-

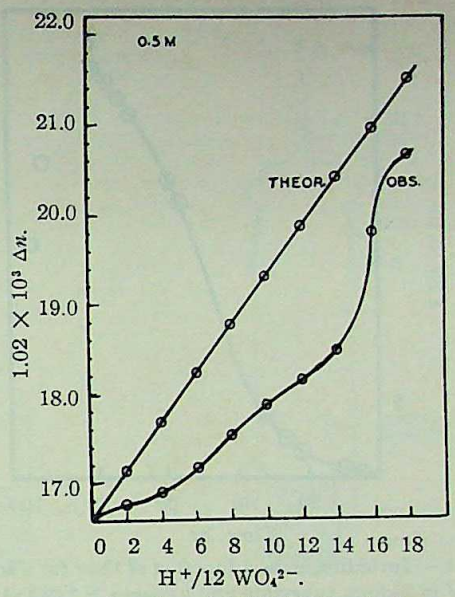

Fig. 2.—Δn as a function of H^+/WO_4^{2-} ratio for a solution 0.5 M in sodium tungstate.

dominant species between the monomer and the hexamer.

Figure 3 is a differential curve of the data plotted in Fig. 2. Here $\Delta(\Delta n)$, the difference between the observed Δn and theoretical Δn is plotted *versus* H^+/WO_4^{2-} ratio for a solution 0.5 M in tungstate. The sharp break at H^+/WO_4^{2-} ratio

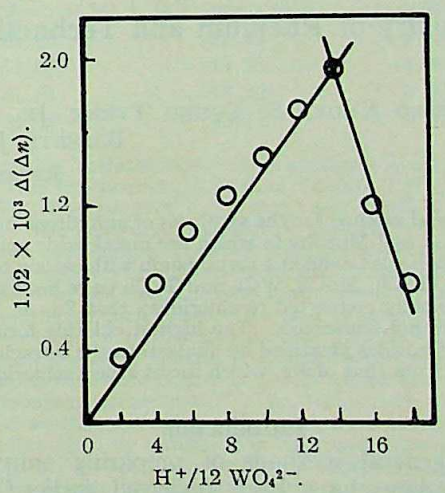

Fig. 3.—A differential curve of the data plotted in Fig. 2.

of 7/6 is indicative of the predominance of the hexamer at this ratio. If no intermediate species existed between the monomer and hexamer one would expect the points on the $\Delta(\Delta n)$ *versus* ratio curve between the 0 and 7/6 ratio to fall on the straight line drawn between these points. As is shown in Fig. 3 the observed points do not fall on the expected line but rather veer away from the expected line and then about half way between the 0 and 7/6 ratio turn back toward the expected line. This could be interpreted to be indicative of an intermediate about half way between the 0 and 7/6 ratio. In support of this idea note again the fact that the observed weight average ionic weight at the

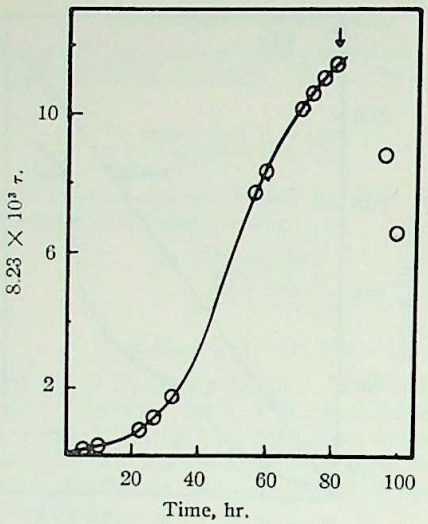

Fig. 4.—Turbidity, τ, as a function of time for a solution 0.025 M in sodium tungstate and having a H^+/WO_4^{2-} ratio of 2 to 1. The arrow indicates the point when cloudiness was first noted in the solution.

2/3 ratio agreed remarkably well with the theoretical value for a trimer. This indication of an intermediate between the monomer and the hexamer is most evident in the solutions of high total tungsten concentration.

On treating a tungstate solution with sufficient acid to convert the Na_2WO_4 to tungstic acid precipitation takes place. If the total tungsten concentration is small enough the solution remains clear even after adding sufficient acid to convert the Na_2WO_4 to tungstic acid and precipitation ensues only after a period of time has lapsed. Introductory studies of solutions having a H^+/WO_4^{2-} ratio of 2 to 1 or in other words sufficient acid to convert all the Na_2WO_4 to tungstic acid indicate that it is possible to use the light scattering technique to study the rate of polymerization of freshly prepared tungstic acid to the point where actual precipitation commences. Figure 4 is a plot of τ *versus* time for a solution 0.025 M in Na_2WO_4 and having a H^+/WO_4^{2-} ratio of 2 to 1. The turbidity increase with time is indicative of increasing polymerization of the tungsten containing species as the solution ages. In Fig. 4 the arrow indicates the point where visible cloudiness was first noted in the solution. Beyond this point τ began to decrease and actual precipitation commenced. In the case of a solution 0.05 M in tungstate 24 hours passed before visible cloudiness was observed while with a 0.10 M solution cloudiness ensued immediately.

Chemistry of Rhenium and Technetium. I. Synthesis of $ReCl_5$, $TcCl_4$ and Related Compounds

BY KERRO KNOX,[1] S. YOUNG TYREE, JR., RAM DULARAY SRIVASTAVA, VELLO NORMAN, JOSEPH Y. BASSETT, JR., AND J. H. HOLLOWAY

RECEIVED FEBRUARY 7, 1957

A general method for the synthesis of anhydrous metal chlorides has been developed. It is a modification of the method of Michael and Murphy in which the metal oxide and carbon tetrachloride are heated to 400° in a sealed glass tube. The glass tube is contained in a metal bomb with carbon tetrachloride or water in it to equalize the pressure. Pure preparations of $ReCl_5$, $TcCl_4$, $MoCl_5$, WCl_6 and $TaCl_5$ have been made. Preliminary results also indicate that Fe, Zr, Be and V oxides are completely converted to chlorides; that Zn, Al, La, Th and Nb oxides are partially converted; and that Co and Ni oxides are not converted. The highest chloride formed by the metal is found in all known cases. Technetium yields a blood-red powder identified by analysis as the tetrachloride. Thus, under ordinary conditions, the highest chloride of Tc is different from that of Re, which forms a pentachloride.

Introduction

The general methods of preparing anhydrous metal halides have been reviewed earlier.[2] The method of Michael and Murphy,[3] in which the metal oxide and carbon tetrachloride react in a sealed tube, has been modified to overcome the difficulty of frequent breaking of the glass tubes at higher temperatures. At the temperature required to bring about the complete conversion of some oxychlorides to the chlorides, high pressures are generated which must be balanced by an external pressure. The balancing pressure is supplied by placing the sealed tube inside a high-pressure steel reaction vessel with heater[4] containing the proper amount of a liquid. Then the whole assembly is heated. If water is used as the external liquid, heavy wall tubes must be used, because although the pressure at the reaction temperature can be made equal inside and outside the glass tube, the pressure difference at intermediate temperatures is great enough to break standard wall tubing. If carbon tetrachloride is used outside, standard wall glass tubing can be used. In the latter case, however, corrosion of the containing steel vessel is more rapid, but not alarmingly so.

Experimental

Method.—The standard conditions used in this Laboratory are 8 cc. of liquid carbon tetrachloride at room temperature for every 26 cc. of volume in the glass reaction vessel. The amount of metal oxide is that calculated to have a five-fold excess of carbon tetrachloride present, according to the equation for the reaction; *e.g.*, $Re_2O_7 + 7CCl_4 \rightarrow 2ReCl_5 + 7COCl_2 + 2Cl_2$. The excess CCl_4 is needed to dissolve and

thereby reduce the final pressure of the product gases, $COCl_2$ and sometimes Cl_2, and to dissolve the solid chlorocarbon by-products which would otherwise contaminate the product. If standard wall glass tubes are used, the same proportion of CCl_4 to free volume is maintained in the steel bomb. If heavy wall tubes are used, 66 cc. of liquid water at room temperature is used for every 1410 cc. of outside volume. The metal oxide and C.P. CCl_4 without further purification are placed in the glass reaction vessel shown in Fig. 1. The neck is sealed and heated carefully to give a uniformly thick seal. After flame annealing of the neck, the glass tube is placed inside the steel bomb with the proper amount of balancing fluid in it (commercial grade CCl_4 is satisfactory here). Closure is made, and the assembly is heated to 400° for a few hours, the pressure developed being about 100 atmospheres. There is no danger of an explosion here with a properly selected metal bomb, but the usual precautions taken in high-pressure, high-temperature work should be observed. If a leak should develop in the seal, obnoxious gases will be given off. The heater is turned off and the assembly allowed to cool to room temperature. It is opened in a hood or out of doors.

The glass tube now contains gases under pressure, estimated to be about 1–2 atm. excess at room temperature, and so it should be handled carefully. It is opened in a hood by playing an oxy-gas flame on the sealed tip, which blows out because of the pressure inside the tube. (Caution: Heat the tip on a side which will make it blow out in a safe direction.) The whole top of the tube is then taken off in order to facilitate removal of the contents in the dry box. This is done by scratching the side of the tube with a sharp file just below the shoulder (the scratch is most easily made before opening the tip with the flame) and leading the scratch around the tube with a red-hot glass rod. These operations should be carried out as rapidly as possible so as to be completed before effervescence ceases and air enters the tube. The tube is then placed inside another tube fitted with a ground-glass joint and stopcock at the top, shown in Fig. 2. The stopcock is joined to a vacuum system by a rubber tube through a Dry Ice–acetone trap and a NaOH tower. It is partly opened very carefully, adjusting the stopcock so as to give a steady but not violent ebullition. The rapid boiling causes cooling which tends to slow down the rate of boiling to the point where bumping can be very bad. The external application of sufficient heat by means of an infrared lamp has been found very effective in overcoming the trouble and in maintaining a steady ebullition. About one-half of the volume of the liquid is slowly pumped away in order to remove dissolved $COCl_2$ and Cl_2. It is not all pumped away, otherwise the solid chlorocarbons deposit. The tube is removed to an efficient dry-box, opened, the product filtered and washed with CCl_4.

Rhenium Pentachloride.—Rhenium metal is burned in oxygen to the heptoxide[5] which is sublimed into the glass reaction vessel previously sealed onto the oxidation apparatus. The oxygen pressure is brought to just above atmospheric pressure, the connecting tube cut, and the CCl_4 quickly poured in through a funnel. The tube is sealed and heated as above. The product is large green-black crystals of $ReCl_5$ beneath a green liquid. The over-all yield is about 90%; in one preparation, 1.2 g. of Re gave 2.0 g. of $ReCl_5$, 87%; in another starting with the heptoxide, 9.0 g. of Re_2O_7 gave 13.4 g. of $ReCl_5$, 99%. Rhenium pentachloride can be kept indefinitely in the sealed tube, but once this is opened, the product must be used promptly because it slowly decomposes, probably losing chlorine.

For analysis, samples of about 200 mg. are weighed out in a dry box, removed and dissolved in a sodium hydroxide–hydrogen peroxide mixture. The solution is evaporated to dryness in a platinum casserole to decompose any hexachlororhenate(IV) formed. If the residue is not colorless, more sodium hydroxide-hydrogen peroxide solution is added and evaporation repeated. This treatment is sometimes required as many as three times to break up this robust complex. The residue is taken up with water, neutralized and made slightly acidic with nitric acid, and titrated potentiometrically with standard silver nitrate, care being taken not to go too far over the end-point. Hydrochloric acid is then added to remove excess silver. The precipitate is digested and filtered off. Since nitrate interferes with tetraphenylarsonium perrhenate precipitation, it is removed by adding concentrated hydrochloric acid and evaporating a few times. Then tetraphenylarsonium perrhenate is precipitated and weighed according to the method previously described for perchlorate analysis.[6] The results on several preparations are

% Re (theory 51.24)	% Cl (theory 48.76)	Cl/Re
51.69	47.90	4.87
50.85	48.25	4.99
51.61	48.12	4.90
51.59	48.17	4.91

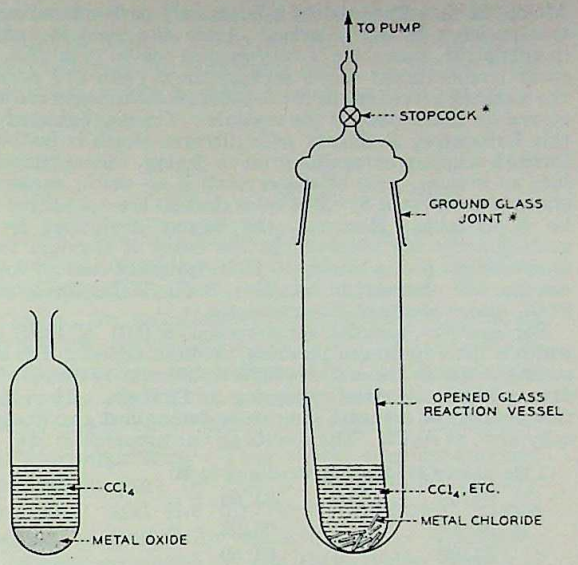

Fig. 1 (Left).—Glass reaction vessel.

Fig. 2 (Right).—Container for removal of opened reaction vessel to dry-box. *The best grease to use here is holocarbon chemically inert stopcock grease, obtainable from Holocarbon Products Corp., 2012–88th St., North Bergen, N. J.

Technetium Tetrachloride.—This synthesis is exactly the same as that for rhenium; 0.14 g. of Tc gave 0.27 g. of $TcCl_4$, 79%. The product is, in this case, small blood-red crystals. The analytical procedure is essentially the same, except that considerable Tc is lost for some unknown reason upon evaporation with concentrated HCl, and so this step is omitted. In addition, the halo-complexes of Tc are more easily hydrolyzed than those of Re, and so ammonia can be used as the base for the dissolution of the chloride. Thereby, only a small amount of nitric acid is needed after evaporation, and so no interference occurs in the precipitation of tetraphenylarsonium pertechnate.[7] The technetium is easily recovered as the metal from the analytical precipitate in quantitative yield by reduction in hydrogen according to a method described for the reduction of ammonium perrhenate.[8] The results of triplicate analyses on two different preparations are

% Tc (theory 41.09)[9]	% Cl (theory 58.91)	Cl/Tc
41.00	58.00	3.95
41.28	58.91	3.98

Molybdenum Pentachloride.—In this case a weighed amount of reagent grade MoO_3 is placed directly into the reaction vessel, CCl_4 is added, and the synthesis is carried out as above; in one synthesis, 5.1 g. of MoO_3 gave 8.1 g. of

Digitized by Arya Samaj Foundation Chennai and eGangotri

$MoCl_5$, 85%. The product is large, very dark-colored crystals under a brown solution. Again the yield is nearly quantitative, indicative of very modest solubility in CCl_4 at room temperature. Upon sucking the crystals dry during the washing procedure in the dry box, color changes are observed on the surface of the crystals. The dry box used in this Laboratory is flushed with nitrogen which is bubbled through alkaline pyrogallol prior to drying. Since the surface to volume ratio of the crystals is so small, chemical changes manifested by these color changes are not judged to be appreciable. However, the largest deviations from stoichiometry are observed in the cases of rhenium and molybdenum pentachlorides. It is significant that no color changes are observed in handling $TcCl_4$, WCl_6, $TaCl_5$ and $FeCl_3$ under identical circumstances.

For analysis, samples are dissolved in 0.01 *M* KOH to which a little hydrogen peroxide has been added. The resulting solutions are analyzed for molybdenum by the molybdate method, ultimately weighing as $PbMoO_4$. The chloride content of separate samples is determined gravimetrically also, as AgCl. The results on one preparation are

% Mo (theory 35.12)	% Cl (theory 64.88)	
35.46	64.63	
35.47	64.63	
35.38	64.59	
Av. 35.44	Av. 64.62	Cl/Mo = 4.93

Tungsten Hexachloride.—Reagent grade tungsten(VI) oxide is used as starting material; in one synthesis, 6.8 g. of WO_3 gave about 10 g. of WCl_6, 86%. Large crystals of WCl_6 are obtained which are so dark as to appear black beneath a dark reddish liquid. Samples prepared by this method are not easily soluble in water, as reported of the direct synthesis product[10]; nor are they very soluble in CCl_4 at room temperature. It is observed that digestion with hot, aqueous ammonia for one hour is necessary to dissolve completely samples of WCl_6 prepared by this procedure.

For analysis, samples of about 275 mg. are weighed in the dry box and dissolved, after removal, by digestion in aqueous ammonia. The solutions are neutralized to a *p*H between 2 and 4 with nitric acid and titrated potentiometrically for chloride content, using a silver electrode with a calomel reference electrode. Samples of about 1 gram are weighed directly into platinum crucibles for the W determinations. After removal from the dry box the samples are metathesized by digestion with concentrated aqueous ammonia, carefully evaporated to dryness, ignited at 800°, and weighed as WO_3. The results on one preparation are

% W (theory 46.37)	% Cl (theory 53.63)	
46.17	53.43	
46.22	53.54	
46.35	53.52	
Av. 46.25	Av. 53.50	Cl/W = 6.000

Tantalum Pentachloride.—Reagent Ta_2O_5 is converted to $TaCl_5$ as above. The product is white crystals, in agreement with the color of the pure preparations of Alexander and Fairbrother[11] and contrary to the yellow color previously reported.[12] The supernatant liquid is yellow, due to dissolved chlorine and phosgene (CCl_4 alone turns yellow under these conditions), but the solid is white when filtered, washed and dried.

For analysis, samples of a few hundred milligrams are weighed out in a dry-box and treated with a large excess of water. The tantalum precipitation is completed by ammonia, the precipitate ignited and weighed as Ta_2O_5. Chloride is determined gravimetrically or potentiometrically as AgCl. Analysis of two samples of one preparation gave

% Ta (theory 50.51)	% Cl (theory 49.49)	Cl/Ta
50.88	49.17	4.93
50.79	49.46	4.97

Other Metal Halides.—The method is of wider applicability than the few syntheses reported here indicate. The extensive studies of Camboulives,[13] of Michael and Murphy,[3] and of many others, indicate that many metal oxides are converted to chlorides by CCl_4 under a variety of conditions. In fact, we have reacted a number of other oxides with CCl_4 under these conditions, but we have not analyzed all the products yet nor, in some cases, obtained good looking products, and so only qualitative observations on other metals will be reported now.

Iron(III) oxide reacts easily and completely to give large flat dark green plates that are very probably pure $FeCl_3$; some of the smaller crystals exhibit dichroism, being reddish brown by transmitted light.

Zirconium oxide gives white needles without any finely powdered oxide residue visible. The crystals are expected to be $ZrCl_4$.

Beryllium oxide appears to be completely converted also, since the finely powdered oxide is replaced entirely by white crystals.

Vanadium(V) oxide yields liquid products only; a red liquid phase under a yellow vapor appeared in the tube. From the color and the phase, it is expected that the product is VCl_4. Its separation from the excess CCl_4 would involve a fractional distillation under anhydrous conditions.

For refractory oxides the extent of reaction is quite sensitive to the history of the oxide. It appears that the activated oxides, that is, those precipitated as hydrous oxides and ignited at low temperature, will react, whereas they become inert when ignited to high temperature. Activated Al_2O_3 reacted completely to give large crystals with no residual oxide powder. Highly ignited Al_2O_3, on the other hand, gave a few small crystals but the bulk of the product was identical in appearance with the original oxide. With Nb_2O_5, two solids were present; one consisted of nice yellow needles which, when picked out, analyzed close to $NbCl_5$, while the other was a button of white powder which was largely, but not completely, converted to hydrous Nb_2O_5 by water. It is peculiar that we have found Ta_2O_5 more reactive to CCl_4 than Nb_2O_5, contrary to previous experience.[14] The Nb case is complicated by dimorphism,[11] and it may be that both the low and high temperature phases of $NbCl_5$ were present.

For the oxides of metals with relatively non-volatile chlorides (we have made preliminary investigations on ZnO, La_2O_3, and ThO_2), a few crystals usually are produced, but the oxide appears not to have reacted completely. The material is always partially water-soluble after reaction but never completely so.

Cobalt and nickel oxides did not appear to react at all.

Preliminary experiments have also been carried out on the preparation of bromides by a similar technique. Carbon tetrabromide and bromoform have been used primarily as the brominating agents. A considerable amount of free bromine is produced in the reaction. After washing with CCl_4, however, products were obtained which analyzed close to $ReBr_3$ and $FeBr_3$.

Work is continuing in this Laboratory on the wider applicability of the method.

Discussion

The Method.—There are several advantages of this method of preparing anhydrous chlorides, when applicable, over other procedures. Oxides of the metals are generally available or easily made in pure form. The reagents need not be excessively dry because small amounts of water are converted to $COCl_2$ and HCl, which are easily removed from the product. Manipulation of the starting materials, except the hygroscopic Tc_2O_7 and Re_2O_7, is easy, and the subsequent operations are not difficult when a dry-box is available. The conversion is complete and the only losses are manipulative ones. In most cases rather large crystals are formed which then tend to be quite pure and are relatively insensitive to hydrolysis by virtue of their small surface to volume ratio.

The method is especially valuable for those metals which have volatile oxychlorides, such as Nb, Ta, Mo, W, Tc and Re, thereby requiring repeated sublimation of the chloride to free it from oxychloride even when the preparation is begun with "pure" metal.

It appears to be the method of choice for Tc since direct synthesis and other methods do not work.[15] In fact, interest in the method was greatly stimulated by the search for a means of synthesizing technetium chloride in pure form.

Technetium Tetrachloride.—Since previous work and these experiments prove that this reaction gives the highest known chloride of the metal in question (*cf.* $MoCl_5$, WCl_6, $ReCl_6$, etc.), it is of interest that technetium forms a tetrachloride rather than a penta- or trichloride as rhenium does. In this respect it resembles manganese more than rhenium. The fact that technetium tetrachloride can be isolated in a pure state bears out its expected greater stability over manganese tetrachloride. Thus, technetium, whose oxides differ from those of rhenium only in degree,[16] has a highest chloride which differs in kind from rhenium chlorides.[17] When compared to the behavior of the elements near Tc and Re in the periodic table, this reduced affinity of technetium for chlorine is not surprising on an empirical basis, as can be seen by considering the highest known anhydrous chlorides in this region

$NbCl_5$	$MoCl_5$	$TcCl_4$	$RuCl_3$
$TaCl_5$	WCl_6	$ReCl_5$	$OsCl_4$

The affinity for chlorine definitely falls off in going up as well as across the periodic table. The fluorides of these metals follow a similar pattern. To our knowledge, no satisfactory explanation has been given for the general phenomenon; stereochemical grounds alone are not sufficient.[18] We have none to offer, and regard the question as one of the interesting unsolved problems in inorganic chemistry.

Acknowledgments.—This work was financially supported in part by the U. S. Atomic Energy Commission and the du Pont Company, whose assistance is gratefully acknowledged. Appreciation is also expressed to the Oak Ridge National Laboratory for the loan of the technetium.

(16) W. T. Smith, Jr., J. W. Cobble and G. E. Boyd, *ibid.*, **75**, 5773, 5777, 5783 (1953).

(17) As pointed out by one referee, a higher chloride of Tc may later be found under conditions other than those of this experiment, maybe "as a constituent of the vapor phase or perhaps even as a solid at lower temperatures and higher chlorine pressures." Except for $MnCl_4$, the discussion refers to the highest chlorides stable at room temperature with no excess chlorine gas present. They are, in all the cases cited, the highest known chlorides under any condition thus far studied.

Complexes Formed between Copper(II) Ion and N,N,N′,N′-Tetrakis-(2-hydroxypropyl)-ethylenediamine[1,2]

BY JAMES L. HALL, F. ROBERT JONES,[3] C. EUGENE DELCHAMPS AND CHARLES W. MCWILLIAMS[3]

RECEIVED JANUARY 7, 1957

The compound N,N,N′,N′-tetrakis-(2-hydroxypropyl)-ethylenediamine, "Quadrol" (abbreviated "Q"), reacts with copper(II) ion in aqueous solution to form the complex ion CuQ^{+2}. This ion reacts further with Quadrol to form $Cu(Q-H^+)^{+1}$, and reacts with strong base to form successively, $Cu(Q-H^+)^{+1}$ and $Cu(Q-2H^+)^0$. The ions CuQ^{+2} and $Cu(Q-H^+)^{+1}$ have distinctly different absorption maxima in the vicinity of 700 mμ in the visible region but the two have nearly identical absorption maxima at about 280 mμ in the ultraviolet region. The ion CuQ^{+2} may be considered as a dibasic acid in solution and as such gives successive dissociation constants of 1.41×10^{-7} and 8.92×10^{-9}. The formation constant for formation of CuQ^{+2} from Cu^{+2} and Q is of the order of 10^9.

Introduction

This paper reports a study of the complexes of copper(II) ion with the compound N,N,N′,N′-tetrakis - (2 - hydroxypropyl) - ethylenediamine, "Quadrol" (abbreviated "Q"), with and without additional strong base added to the solutions. In the Quadrol molecule the nitrogen atoms and the hydroxyl radicals are in favorable position for the formation of stable five-membered chelate rings. The hydroxyl radicals of the Quadrol have nearly negligible acidic properties in solution in water but become appreciably acidic whenever the hydroxyl radical becomes a part of the chelate ring. These complexes have been investigated in aqueous solution by spectrophotometric methods and by potentiometric and conductometric titrations.

Experimental

The Quadrol was a gift of the Wyandotte Chemicals Corporation, and was designated as being at least 99.5% pure, the principal impurity being water. It was used without further purification. The concentration of the solutions as determined by titration with acid corresponded very closely to the concentration calculated from the weight of Quadrol used. The pure Quadrol and its dilute solutions are quite stable toward change on contact with the atmosphere. An 0.5 *M* solution, stored in contact with air, developed a slight yellow color after a few months.

Carbonate-free sodium hydroxide solutions and solutions of hydrochloric, nitric and perchloric acids were prepared from reagent-grade stock and were standardized by the usual methods. Sodium perchlorate was prepared by neutraliza-

tion of perchloric acid. Copper(II) perchlorate solutions were prepared from G. F. Smith Co. reagent or from basic copper carbonate as described previously.[4] The copper(II) perchlorate solutions were standardized by titration with disodium Versenate.[5]

The spectral data were obtained with a Beckman Model DU spectrophotometer, using 1 cm. matched silica cells. The solutions for spectrophotometric studies were made up to a constant ionic strength of 0.5 by addition of $NaClO_4$. Conductometric titrations were performed using a highly precise conductance bridge built around the Leeds and Northrup Co. No. 1553 ratio box.[5] A dip-type cell with a cell constant of approximately 0.1 was used. The potentiometric titrations were performed with a Beckman Model H-2 *p*H meter with appropriate calomel and glass electrodes. For all potentiometric and conductometric titrations the temperature was maintained constant at 25 ± 0.02°. The solutions for potentiometric titrations were made 0.5 *M* in KNO_3.

Results

Complexes Identified.—The complexes identified are believed to have the formulas CuQ^{+2}, $Cu(Q-H^+)^{+1}$ and $Cu(Q-2H^+)^0$. The first of these is believed to have the four coördination positions of the copper(II) ion occupied by the two nitrogen atoms and two oxygen atoms of the Quadrol, forming three five-membered chelate rings. The other two complexes have had removed one and two protons, respectively, from the two coördinated oxygen atoms of the first-formed complex.

Spectrophotometric Work.—Figure 1 shows the spectra in the visible region of solutions 0.005 *M* in copper(II) ion and containing varying amounts of Quadrol. The intermediate position of the 1:05 (Cu^{+2}:Q) curve midway between the 1:0 and 1:1 curves indicates that there is no complex of ratio less than 1:1. The intersection of the 1:1 and 1:2 curves near 850 mμ and the near coincidence of the 1:2, 1:3 and 1:4 curves strongly suggests that 1:1 and 1:2 complexes exist in these solutions. A series of solutions of various ratios of copper(II) ion to Quadrol was prepared at a constant total concentration of 0.005 *M*. Their spectra were determined and analyzed by the method of Vosburgh and Cooper.[6] The Y and Y′ curves at 850 and 675 mμ are shown in Fig. 2. Reaction of copper(II) ion with one and two moles of Quadrol is thus indicated.

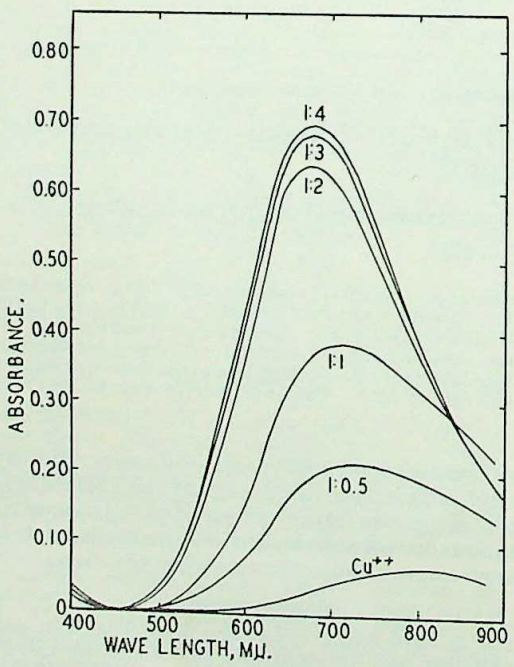

Fig. 1.—Absorption spectra of solutions 0.005 *M* in $Cu(ClO_4)_2$ with varying amounts of quadrol.

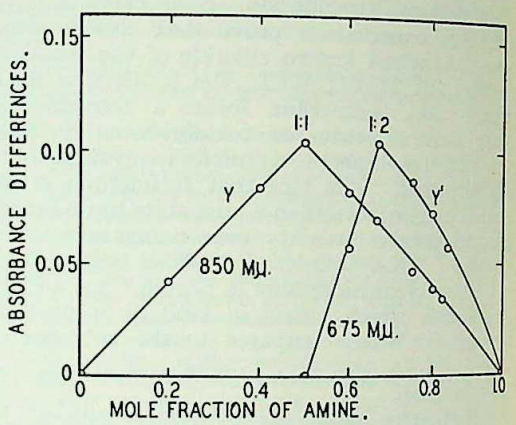

Fig. 2.—Derived absorbance curves for the copper(II) ion-quadrol system at 850 and 675 mμ.

In addition to the absorption maximum near 675 mμ, these copper(II) ion–Quadrol solutions show a second and much more intense absorption at about 280 mμ. Absorption curves for solutions 0.00025 *M* in copper(II) ion with varying amounts of Quadrol are shown in Fig. 3. In contrast to the results in the visible part of the spectrum, these curves show definite indication of only one complex with a Cu^{+2}:Q ratio of 1:1. Spectra were obtained for a series of solutions of constant total composition, copper(II) ion plus Quadrol, of 0.0005 *M*, and these data were analyzed by the method of continuous variations. At any wave

length in the vicinity of the maximum of absorption a Y curve was obtained with a simple sharp maximum showing the 1:1 complex and giving no indication of any other complex.

The small increase in absorbance at the maximum, beyond the 1:2 ratio in the visible region and beyond the 1:1 ratio in the ultraviolet region was attributed to reaction of the complex with base formed by the additional Quadrol in solution. To further study this question, spectra were determined for solutions having a copper(II) ion concentration of 0.005 *M* and to which Quadrol and sodium hydroxide had been added to obtain final solutions with Cu^{+2}:A:OH^- ratios of 1:1:0, 1:2:0, 1:1:1, 1:2:1, 1:1:2 and 1:2:2. These are shown in Fig. 4. The near identity of the spectra of the 1:2:0 and 1:1:1 solutions indicates that these both contain the complex $Cu(Q-H^+)^{+1}$. The near identity of the spectra of the 1:1:2 and 1:2:2 solutions suggests that these both contain the complex $Cu(Q-2H^+)^0$.

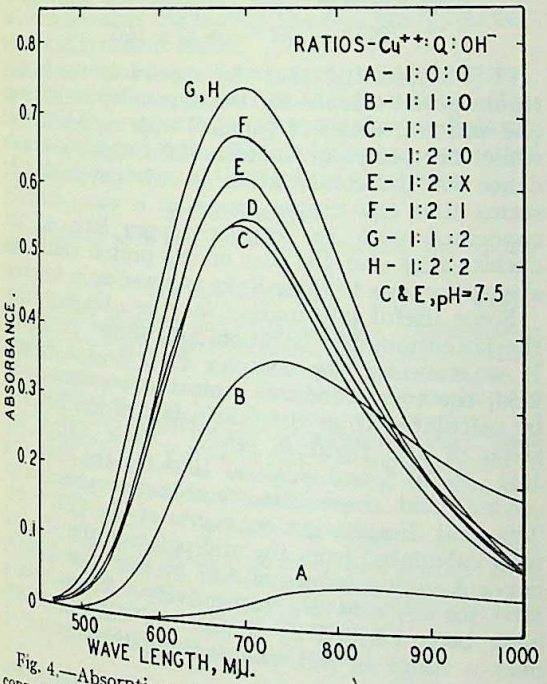

Fig. 4.—Absorption spectra of solutions made by mixing copper(II) perchlorate, Quadrol and sodium hydroxide in various ratios.

Potentiometric Titrations.—Figure 5 shows the results of addition of 1.0097 *M* sodium hydroxide solution to solutions initially 0.5 *M* in KNO_3, 0.01 *M* in Quadrol, 0.03 *M* in HNO_3, and with solution A containing no copper(II) ion, solution B being 0.005 *M* in $Cu(ClO_4)_2$, and solution C being 0.01 *M* in $Cu(ClO_4)_2$. At corresponding values of *p*H, curve B is nearly midway between curves A and C, indicating that the complex formed in these solutions contains only one mole of Quadrol per mole of copper(II) ion. After neutralization of the excess acid in addition to that required to form the amine salt, curve C, for the solution containing Cu^{+2} and Q in the ratio 1:1, shows definite end points corresponding to 2, 3 and 4 moles of hydroxyl ion.

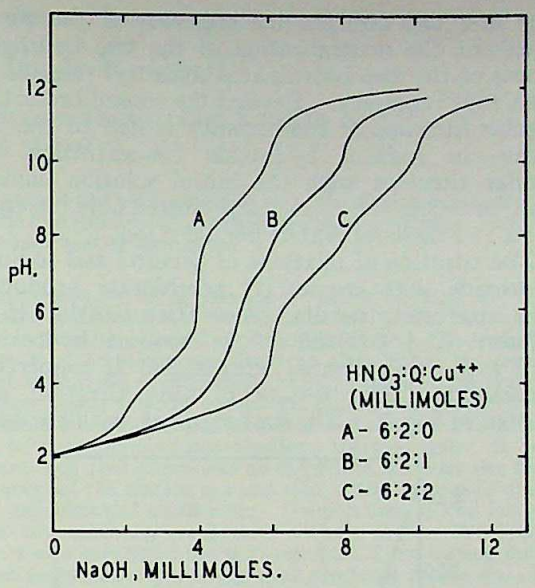

Fig. 5.—Titration of acid-Quadrol and acid-Quadrol-copper-(II) ion mixtures with sodium hydroxide.

Conductometric Titrations.—The addition of Quadrol to copper(II) perchlorate solution was studied conductometrically. Quadrol solution, 0.1005 *M*, was added to a solution 0.00493 *M* in copper(II) perchlorate. The conductance decreased throughout. The plot of conductance as a function of the mole ratio of Quadrol added showed three straight-line segments, with decreasing slope, and with distinct breaks corresponding to 1 and 2 moles of Quadrol per mole of copper(II) ion. The decrease of conductance to the first break is due to the decreased mobility of the copper(II) ion as its size is increased by addition of the ligand. The further decrease to the second break is due to a reduction in the charge of the complex ion from +2 to +1.

A conductometric titration was performed by adding 0.4653 *M* sodium hydroxide to a solution made 0.00493 *M* in both copper(II) perchlorate and Quadrol. The results are shown in Fig. 6.

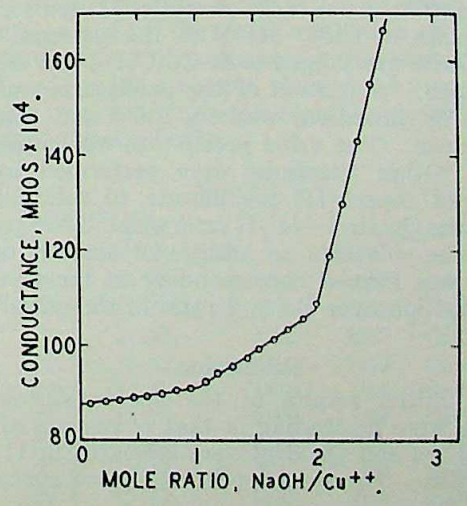

Fig. 6.—Conductometric titration of a solution 0.00493 *M* in CuQ^{+2} with 0.4653 *M* NaOH.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The first two straight-line segments of the curve represent the neutralization of the two hydrogen atoms of the two coördinated hydroxyl radicals of the CuQ^{+2} complex. Beyond the second break the regular increase in conductance is due to the increase in sodium hydroxide concentration. A similar titration with the initial solution having Cu^{+2} and Q in the ratio 1:2 produced only one end-point at 2 moles of NaOH per Cu^{+2} ion.

The titration of mixtures of Quadrol and sodium hydroxide with copper(II) perchlorate produced very interesting results. A solution 0.00493 *M* in Quadrol and 0.00985 *M* in sodium hydroxide (1:2 ratio) was titrated with 0.0985 *M* copper(II) perchlorate. The results of this titration are plotted in Fig. 7. The first segment, with the end-

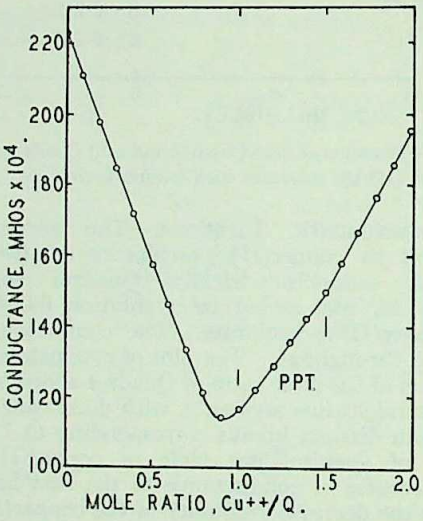

Fig. 7.—Conductometric titration of a solution 0.00493 *M* in Quadrol and 0.00985 *M* in NaOH with 0.0985 *M* $Cu(ClO_4)_2$.

point at the end of the rounded section, corresponds to the formation of the compound $Cu(Q–2H^+)^0$. The second segment, of increasing conductance, is accompanied by the formation of a precipitate and the length of the segment indicates the reaction of one mole of copper(II) ion for each two moles of $Cu(Q–2H^+)^0$ in the solution. The precipitate was judged to be $Cu(OH)_2$, and this was confirmed. A portion of the precipitate was separated by filtration, washed, dried and analyzed for copper. The dried precipitate was copper(II) oxide. Other titrations were performed by addition of copper(II) perchlorate to solutions for which the Quadrol–NaOH ratio was 1:3 and greater. For these solutions an additional amount of $Cu(OH)_2$ was formed corresponding to the excess of hydroxyl ion over the 1:2 ratio in the initial solution.

Discussion

The initial results of the spectrophotometric studies were misleading in that complexes of copper(II) ion and Quadrol were indicated in 1:1 and 1:2 ratios. The spectra of the solutions containing added sodium hydroxide and the titration curves show that the second molecule of Quadrol serves as a base to neutralize a hydrogen atom from one of the two coördinated hydroxyl radicals of the first Quadrol molecule. The successive acid ionization constants of the two acidic hydrogen atoms of the complex and the dissociation constants of the QH_2^{+2} ion are such that the second hydrogen atom of the complex is only partially neutralized in solutions containing a considerable excess of Quadrol. If sodium hydroxide is added to any solution containing copper(II) ion and an equivalent or greater amount of Quadrol, an end-point is always obtained at the ratio of two equivalents of hydroxyl ion per mole of copper(II) ion. The reactions which take place in the various solutions may be written as follows where OH^- represents hydroxyl ion from sodium hydroxide.

$$CuQ^{+2} + Q \longrightarrow Cu(Q–H^+)^{+1} + QH^+$$
$$Cu(Q–H^+)^{+1} + OH^- \longrightarrow Cu(Q–2H^+)^0 + H_2O$$
$$CuQ^{+2} + 2OH^- \longrightarrow Cu(Q–2H^+)^0 + 2H_2O$$
$$QH^+ + OH^- \longrightarrow Q + H_2O$$

It is interesting that the spectra in the visible region give evidence for the successive reaction of one and two moles of Quadrol with copper(II) ion while the spectra in the ultraviolet region give evidence for the combination of only one mole. It seems that the visible spectrum is more directly concerned with the copper–oxygen links in the chelate ring and the loss of the proton shifts the absorption due to these links to lower wave lengths.

Some useful information may be obtained from the potentiometric titration data shown in Fig. 5. If we consider the complex CuQ^{+2} as a dibasic acid, the two successive ionization constants may be calculated from the mid-points of the last two steps of the titration curve. These values are 1.41×10^{-7} and 8.92×10^{-9} for the first and second acid dissociation constants, respectively. The acid dissociation constants of the QH_2^{+2} ion were calculated from the mid-points of the steps of curve A giving values of 4.67×10^{-5} and 1.45×10^{-9} for K_1 and K_2, respectively. These values have been verified by a series of determinations over a range of *p*H values using the method of Bjerrum.[7]

The very distinct rise of *p*H after addition of two equivalents of hydroxyl ion to the Cu^{+2} and QH_2^{+2} mixture indicates that the formation of CuQ^{+2} ion is essentially complete before neutralization of the hydrogen atoms of the bound hydroxyl radicals is begun. One should then be able to calculate a stability constant for the formation of CuQ^{+2} from Cu^{+2} and Q by the method of Bjerrum.[7] Values of [Q] and $\bar{n}$ were calculated for the interval *p*H 2.3 to 5 and the corresponding values of *K* were determined. The value of *K* is approximately 2.9×10^9 if $\bar{n}$ is between 0.2 and 0.5. The values of *K* decrease outside this range.

Equilibrium in the System GeO_2–H_2–Ge–H_2O[1]

BY TOSHIO YOKOKAWA, MASUMICHI KOIZUMI, MITSUO SHIMOJI AND KICHIZO NIWA[2]

RECEIVED JANUARY 3, 1957

A measurement has been carried out as to equilibrium in the system GeO_2–H_2–Ge–H_2O by a circulation method over the temperature range of 500–650°. An equation is obtained for the free energy of formation of germanic oxide: $\Delta F^0 = -131{,}700 + 41.4T$, and −132.3 kcal./mole is derived for the standard heat of formation.

The free energy of formation of germanic oxide has not yet been measured experimentally in spite of its great practical importance. Becker and Roth[3] and Hahn and Juza,[4] respectively, found the heat of oxidation of germanium to be −128.1 and 128.6 kcal./mole at 298°K. Jolly and Latimer[5] measured the heats of solution of germanium and of its oxide in an alkaline solution of hypochlorite. From those values they determined the heat of formation of the oxide to be −129.2 kcal./mole. By using these data and other thermodynamic quantities, Coughlin[6] calculated the free energy of formation of germanic oxide.

In the present paper a measurement of the reduction and oxidation equilibrium in the system GeO_2–H_2–Ge–H_2O is reported and some thermodynamic values computed from those results are compared with the data shown in the table of Coughlin.

Experimental

Experiments were performed for measuring the equilibrium

$$Ge(s) + 2H_2O(g) = GeO_2(s) + 2H_2(g) \qquad (1a)$$

from both the reduction and oxidation sides. A circulation method was selected in preference to a simple static method, because in the latter, (1) a much longer time (50–60 hr. in this case) is necessary to reach equilibrium; (2) the effect of thermal diffusion must be taken into consideration; and (3) side reactions involving gaseous germanous oxide make the measurement erroneous by the following reason. In this germanium–germanic oxide coexisting system, germanous oxide vaporizes by the reaction

$$Ge(s) + GeO_2(s) = 2GeO(g)$$

Thus the vapor pressure of germanous oxide is of the order of 10^{-6} atm. at 800°K.[5] This vapor diffuses from the part surrounding the sample toward the colder part of the reaction tube, being accompanied by the reactions

$$GeO(g) + H_2(g) = Ge(s) + H_2O(g)$$

or

$$GeO(g) + H_2O(g) = GeO_2(s) + H_2(g)$$

Then, the partial pressure ratio of hydrogen to water vapor tend to vary with the temperature along the tube as far as the both ends of the furnace, where the vapor of germanous oxide condenses on the wall.

The effects (2) and (3) overlapping each other, it is quite difficult to estimate the final deviation. These difficulties seem to be diminished considerably when the circulation method is employed, since the gas mixture, after having reacted with the sample, flows away through a narrow tube (B in Fig. 1) at a sufficient speed not to be influenced by the reaction with the germanous oxide produced as above mentioned. For the sake of comparison an ordinary static method also was used at two temperatures.

Apparatus.—The apparatus is shown in Fig. 1. The furnace was made of a porcelain tube, 25 cm. long and 3 cm. in diameter, wound with nichrome wire. The reaction tube A of porcelain was fitted to glass tubes by ground joint with picein at both ends; through one of these tubes a narrow quartz tube B, 4 mm. int. diam., was fixed. Temperature was measured at the outer wall of the reaction tube by a platinum–platinum–rhodium thermocouple; it was ascertained that there was no difference between the temperature of the flowing gas and that of the outer wall under the experimental conditions. Temperature of the furnace was automatically regulated within ±2°. The water vapor was supplied from a Pyrex flask C containing redistilled water, kept in a thermostat regulated within ±0.01°. Total pressures were read to 0.01 mm. by a cathetometer.

Material.—Germanic oxide (Eagle Picher product) was powdery and of hexagonal modification, having a purity of 99.999%.

Procedure.—A high alumina boat filled with about 1 g. of sample was set in the reaction tube, which was then evacuated to the pressure of 10^{-5} mm.; hydrogen, generated by electrolysis of a potassium hydroxide solution, was introduced up to the desired pressure. The rate of gas flow was 100–200 cc./min. The measurements were thus carried out over the temperature range of 500–650°.

Results

The results are shown in Table I. The 2nd column gives the equilibrium total pressures and the next denotes the water vapor pressures at the temperature of thermostat. The values in the 2nd and 3rd lines of Table I are obtained by using the static method; in these cases each P_{H_2O} value is corrected as to the effect of thermal diffusion. The equilibrium constants K shown in the 4th column have been calculated by the equation

$$\Delta F^\circ_{(1)} = -RT \ln K;\ K = \left(\frac{P_{H_2}}{P_{H_2O}}\right)^2 \qquad (1b)$$

The values of K, thus obtained, are plotted against reciprocal temperature in Fig. 2. The deviation of the data gained by the static method is attributed both to the effect of germanous oxide slightly produced and to the frequent changes of room temperature, which disturb the reaction steadily proceeding to the equilibrium.

TABLE I

Temp., °C.	Pressure, mm. Total	Water vapor	log K	ΔF^0, cal.	Reaction side
500	36.4	13.42	0.4670	−1651	Oxidn.
500[a]	32.0	13.60	.2626	− 929	Oxidn.
530[a]	30.5	11.53	.4322	−1587	Oxidn.

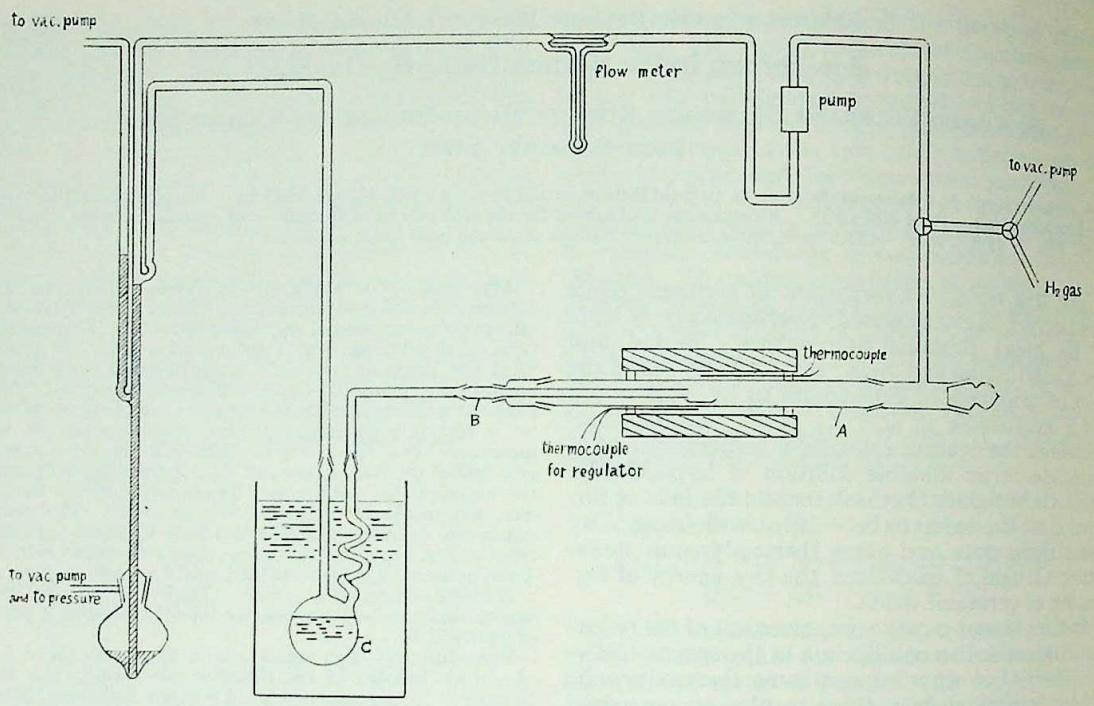

Fig. 1.—Apparatus for circulation method.

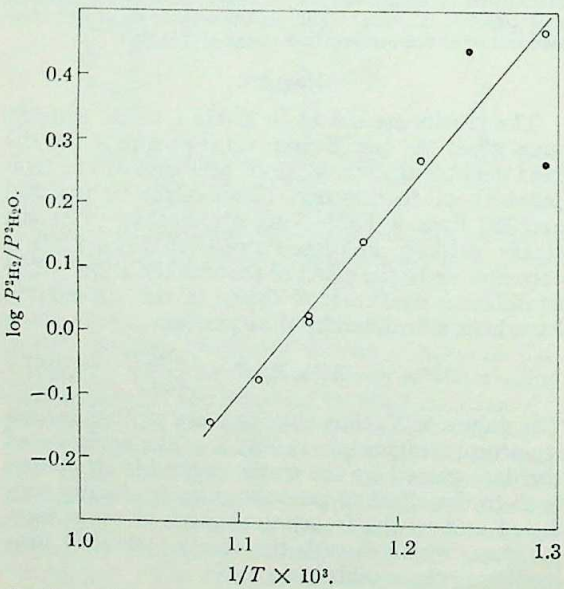

Fig. 2.—Relation between log K and $1/T$: ●, static method; ○, circulation method.

Thermodynamic Calculation and Discussion

By the method of least squares, the temperature dependence of ΔF^0 is obtained

$$\Delta F^0_{(1)} = -13{,}750 + 15.60T \ (\pm 100 \text{ cal./mole})$$

giving the heat of reaction −13,750 cal./mole with an estimated standard deviation of 560 cal./mole. Here the data obtained by the static method are excluded in the calculation.

The heat and free energy of formation of water vapor are $\Delta H^0_{850} = -58{,}070$ cal./mole and ΔF^0_{850} = −47995 cal./mole, according to Rossini, *et al.*[7] Then with regard to the formation of germanic oxide the following results are obtained

$$Ge + O_2 = GeO_2 \quad (2a)$$

$$\Delta F^0_{850} = -96{,}480 \pm 200 \text{ cal./mole}$$

$$\Delta H_{850} = -131{,}700 \pm 1000 \text{ cal./mole}$$

$$\Delta F^0_{(2)} = -131{,}700 + 41.4T \ (\pm 200 \text{ cal./mole}) \quad (2b)$$

A corresponding formula is derived from the values calculated by Coughlin, that is

$$\Delta F^0_{(2)} = -127{,}600 + 40.6T$$
$$(\pm 1500 \text{ cal./mole at } 700\text{–}1000°\text{K.})$$

Using the heat capacities of germanium and its oxide,[8] the standard heat and free energy of formation of germanic oxide can be calculated.

The results are

$$\Delta H_{298} = -132{,}300 \pm 1000 \text{ cal./mole}$$

$$\Delta F^0_{298} = -119{,}700 \pm 1500 \text{ cal./mole}$$

On the other hand, the values in Coughlin's table are

$$\Delta H_{298} = -128{,}300 \pm 1000 \text{ cal./mole}$$

$$\Delta F^0_{298} = -115{,}900 \pm 1500 \text{ cal./mole}$$

ΔH in the present work is more negative than that of Coughlin by 4 kcal/mole at 850°K. ΔS shows a similar deviation, though within uncertainty. These discrepancies seem to be due mainly to the difference of the structure of germanic oxide employed which is hexagonal in the present work but was amorphous in the case of Coughlin. The above result, however, cannot be discussed only from the viewpoint of the modifications of the oxide sample, since ΔH in the present work has uncertainty of 1

kcal. and Coughlin's free energy values show a probable error due to using an estimated entropy of germanic oxide. Table II shows the heat and entropy of formation of germanic oxide, both amorphous and hexagonal, together with the corresponding values of silica.[9] For germanium the comparison was made at 850°K. in order that the error due to the use of the estimated heat capacity may be avoided in the data for the hexagonal modification.

TABLE II

	State	H, kcal.	S, e.u.
GeO_2 (at 850°K.)	Amorphous	−127.6	−40.6 (calcd.)
	Hexagonal	−131.7	−41.4
SiO_2 (at 298°K.)	Amorphous	−202.5	−42.27
	Tridymite	−204.8	−43.11

Solubility of Oxygen.—In the above discussion it was assumed that germanium metal does not dissolve oxygen. However, if there is any solubility in this case, it would decrease the activity of germanium. Contrary to this apprehension, Candidus and Tuomi[10] have reported that the solubility is negligible, and Trumbore and his coworkers[11,12] have shown error in the work of Hoch and Johnston[13] who observed a large solubility of oxygen. It may be concluded, therefore, that germanium does not dissolve oxygen appreciably.

Supplement.—After the present experiment had finished, the authors found that Ono and coworkers[14] had investigated the same equilibrium by a flow method. They obtained −141.8 kcal./mole as the standard heat of formation of germanic oxide. They measured only from the reduction side, while the present measurement were carried out from both the reduction and oxidation sides with sufficient agreement. Besides, the present results seem to show that a circulation method is more suitable than a flow method, since hydrogen pressure is comparable to water vapor pressure in equilibrium. Then, the present results may be more accurate.

Acknowledgment.—The authors wish to express their thanks to Prof. Leo Brewer for his friendly criticism and to Prof. Isao Kayama, Hokkaido Teachers College, who persuaded them to participate in the research group studying germanium. The sample of germanic oxide was supplied by Mr. Hideo Baba, Electrical Communications Laboratory. The preliminary testing of this experiment was carried out by Mr. Satoshi Kado, to whom the authors are also indebted.

Halogen Atom Reactions Initiated by Nuclear Processes in Hydrocarbon Solutions

BY SUKUMAR ADITYA[1] AND JOHN E. WILLARD

RECEIVED FEBRUARY 4, 1957

The organic yields of I^{128} and Br^{80} activated as a result of the $I^{127}(n,\gamma)I^{128}$, $Br^{79}(n,\gamma)Br^{80}$ and $Br^{80m} \xrightarrow{I.T.} Br^{80}$ processes are higher in dilute hydrocarbon solutions than in pure organic halides. They increase with increasing chain length of the hydrocarbon. For the (n,γ) activations in hydrocarbon solutions they decrease by about one-fifth in going from 0 to 100°. These variations in yield are all rather insensitive to the addition of free halogen as scavenger and therefore involve "hot" processes. The results, correlated with those of other investigations, suggest that a number of previously unexplained facts about reactions of hydrogenous material with I^{128}, Br^{80} and Cl^{38} activated by the (n,γ) process may be explained by ionic reactions. The organic yields from the Br^{80m} isomeric transition in liquid hydrocarbons depend on the source molecule containing the Br^{80m} to an extent which is consistent with earlier observations of failure of the transition to rupture C–Br bonds in liquid bromine as the solvent.

Introduction

There are several reasons for studying the chemical consequences of activation of halogen atoms by nuclear processes[2] in each of a series of hydrocarbons: (1) the sizes and weights of the molecules with which the energetic halogen atom is surrounded while losing its energy can be varied without varying the types of bonds to be broken (*i.e.*, only C–C and C–H); (2) conservation of momentum requirements make it impossible for a halogen atom to enter organic combination in such a medium by a "billiard ball collision" mechanism; (3) preliminary observations[3] on such systems have shown changes in organic yields[4] dependent on the size of the hydrocarbon molecules; (4) such studies should contribute to a better understanding of the mechanisms of the various hydrogen replacement reactions cited in the next paragraph; (5) the mechanism of replacement of H^1 by H^3 in tritium recoil reactions[5a] (and possibly also in systems activated by the decay of tritium[5b] may be similar to

that of replacement of hydrogen by halogens activated by nuclear processes.

It has been shown that both iodine[6] and bromine[7] atoms activated by the (n,γ) process can replace hydrogen in pentane, forming the amyl halide, that Cl^{38} atoms from the $Cl^{37}(n,\gamma)Cl^{38}$ process undergo similar reactions in heptane,[8] cyclohexane and benzene,[9] and that the $I^{127}(n,\gamma)I^{128}$ reaction in liquid CH_4 produces both CH_3I^{128} and $C_2H_5I^{128}$.[10a] Further evidence indicates that substitution for hydrogen can occur by a unique "hot" non-radical reaction; *i.e.*, I^{128} atoms or ions freshly formed by the $I^{127}(n,\gamma)I^{128}$ process react[10] with *gaseous* CH_4 in a process of the type $I^{128} + CH_4 \rightarrow CH_3I^{128} + H$, and freshly formed Cl^{38} atoms give a similar reaction with gaseous butane or butyl chloride.[8]

Experimental

Reagents.—Eastman white label C_2H_5Br was purified by mechanical stirring with successive portions of concentrated H_2SO_4 for 12 hours each until further portions showed no coloration. It was then washed with water, dried with $MgSO_4$ and fractionally distilled. Phillips "pure" grade pentane, hexane, heptane and nonane were used. The first three of these were treated with H_2SO_4 in the same way as the C_2H_5Br following which they were stirred with 0.5 *N* $KMnO_4$ solution 6 *N* in H_2SO_4 for 12 hours before drying and distillation. The nonane and decane (Matheson) were fractionally distilled and then subjected to the H_2SO_4 treatment, washing and drying. Following purification all of the hydrocarbons were tested by adding 10^{-3} cc. of elemental bromine labeled with Br^{82} (36 hr.) to 25 cc. of the liquid. The solution was allowed to stand in the dark for about two hours, following which the Br_2 was extracted with aqueous sulfite and the radioactivity in the aqueous and organic layers was determined by counting. The fraction of the bromine which entered organic combination was always less than 0.2%. Hydrocarbons purified only by passing through a column of silica gel showed a high bromine pick-up in similar tests. Michigan Chemical Co. CCl_3Br was freed from stabilizer by distillation, illuminated while containing dissolved Br_2, extracted with aqueous sulfite, washed with water and dried.

Preparation of Organic Compounds Containing Br^{80m}.—$C_2H_5Br^{80m}$ and $CHBr_2Br^{80m}$ were prepared by allowing vapors of the non-radioactive compounds to stand for a few minutes in a flask coated with freshly sublimed $AlBr_3$, which had been prepared by adding radioactive Br_2[11] to dry aluminum, using vacuum system techniques. CCl_3Br^{80m} was prepared by illuminating a mixture of CCl_3Br and radiobromine.

Neutron Irradiations.—All neutron irradiations for studies of the (n,γ) process were made with an Sb–Be photoneutron source[12] which contained about 10 curies of Sb^{127} and emitted about 10^7 neutrons/sec. when received. The liquids to be irradiated were contained either in soft glass test-tubes set in a paraffin block, or in the annular space between the walls of a vessel shaped like a wide mouthed dewar, which was surrounded with water. During irradiations the source was positioned in the center of the paraffin block or of the dewar-like vessel. The γ-ray dosage received by the samples was in the range of about 10^3 to 10^4 r./hr. Irradiations for the production of Br^{80m} (4.4 hr.) were of 8–12 hours duration and those for the production of I^{128} (25 min.) lasted 1–2 hr. The samples irradiated at temperatures above 25° were contained in sealed tubes in a bath of thermostated paraffin oil.

Extraction and Counting.—Following neutron exposure of solutions of the alkyl iodides, a small amount of elemental halogen was added to the irradiation vessel to prevent sticking of tracer amounts of inorganic halogen on the walls. The liquid was then extracted with aqueous sulfite–halide solution. Counting was done by placing the liquid in an annular jacket designed to slide over a type 90NB Amperex Geiger tube. All counts were corrected for the composition of the medium,[13] the relative counting efficiency of the jacket, the volumes of the solutions, and for radioactive decay. In the studies of the $Br^{79}(n,\gamma)Br^{80m}$ reaction, the aqueous and organic layers were allowed to stand 2 to 3 hours following separation, before counting, to allow the Br^{80m} (4.4 hr.) to re-establish equilibrium with the Br^{80} (18 min.) daughter which emits the radiation which is counted. When Br^{80m} was to be determined following irradiation of CCl_3Br, or of alkyl bromides scavenged with I_2, adequate time was allowed for the Cl^{38} (37 min.) or I^{128} (25 min.) activity to decay. Two or more experiments were run for each condition tested and the results given in the tables are the averages of the values obtained. The organic yields[3] of individual determinations regularly agreed within ±0.5% of the average for the (n,γ) studies and ±1% for the isomeric transition studies.

Isomeric Transition Experiments.—For the isomeric transition experiments, the Br_2 or organic compound containing the Br^{80m} was added to 25 ml. of the hydrocarbon to be tested in a glass-stoppered flask and allowed to stand for 2–3 hours. Extraction was carried out as described above. The time of separation was taken as the time when the Br_2 color had just disappeared from the organic layer. When the source of Br^{80m} was Br_2, the activity in the organic layer decayed with an 18 min. half-life. The aqueous layer was allowed to stand until parent–daughter equilibrium was reached, before counting to determine the total 4.4 hr. activity. When the Br^{80m} was in an organic compound the 18 min. activity was counted in the aqueous phase and the 4.4 hr. in the organic. In the latter case the organic yield was given by one minus the ratio of the aqueous 18 min. activity to the organic 4.4 hr. activity, both activities being corrected to the time of extraction.

I_2 as Scavenger for (n,γ) Reactions on Bromides.—Br_2 has been demonstrated[3b,14] to be a powerful tool as a scavenger for thermal atoms and radicals produced by the (n,γ) process in alkyl bromides and I_2 has been shown[15] to serve similarly for alkyl iodides. In the present work I_2 was used as a scavenger for the (n,γ) reaction on solutions of C_2H_5Br in various hydrocarbons in order to minimize the problems of the reactivity of Br_2 with hydrocarbons in the presence of light and γ-radiation. The data of Table I show that its scavenger effect on bromides is equivalent to that reported earlier[3b,14] for Br_2.

Results and Discussion

Effect of Dilution of Alkyl Halide with Hydrocarbon.—The data of Table II show that, consistent with results reported earlier for C_2H_5Br and C_2H_5I in hexane,[3b] the organic yield for the $Br^{79}(n,\gamma)Br^{80m}$ process on bromine in the form of C_2H_5Br is increased by dilution with either pentane or heptane, a limiting value characteristic of the pure hydrocarbon.

drocarbon apparently being reached at concentrations between 0.1 and 0.01 mole fraction. The increase over the value in pure C_2H_5Br toward this limiting value is qualitatively proportional to the mole fraction of hydrocarbon. The increase is predominantly, and possibly wholly, the result of a type of chemical event which occurs to the tagged halogen atoms before they have had an opportunity to diffuse as thermal atoms in the system; that is it is the result of a "hot"[2,3b] process. This is illustrated by the fact that the difference in organic yields between pure C_2H_5I and hydrocarbon solutions containing 0.05 mole fraction C_2H_5I is, within the experimental error, independent of the concentration of I_2 scavenger present (Fig. 1).

TABLE II

ORGANIC YIELDS OF THE $Br^{79}(n,\gamma)Br^{80m}$ PROCESS IN SOLUTIONS OF C_2H_5Br IN *n*-PENTANE AND *n*-HEPTANE AT DIFFERENT CONCENTRATIONS

of C_2H_5I in *n*-pentane, *n*-heptane and *n*-decane, and of Br^{80} from the $Br^{79}(n,\gamma)Br^{80}$ process on C_2H_5Br at 0.1 mole fraction in *n*-heptane and *n*-decane, increase with increasing chain length of the hydrocarbon. Because the difference persists even in the presence of sufficient scavenger to nearly eliminate encounters of the thermalized tagged atom with radicals by diffusion, it must be concluded that the chain length of the hydrocarbon molecules affects the probability that the tagged atom will enter organic combination before diffusion as a thermalized atom. The most probable cause of such an effect seems to be a difference in the effectiveness of the solvent cages for retaining the tagged atom in contact with an organic radical it has just formed long enough for a stable compound to be formed.

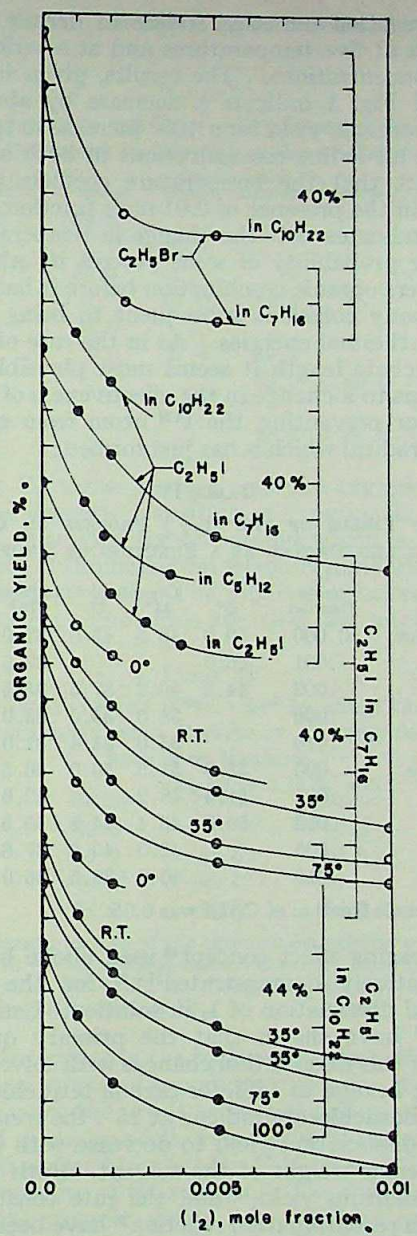

Fig. 1.—Effect of iodine scavenger on the organic yields of the $Br^{79}(n,\gamma)Br^{80}$ and $I^{127}(n,\gamma)I^{128}$ processes in hydrocarbon solutions as a function of solvent and temperature. Concentration of C_2H_5Br for upper two curves 0.10 mole fraction; concentration of C_2H_5I for lower three groups of curves 0.05 mole fraction. Each division on the scales at the right represents 2% in organic yield. The scale for each group of curves is labeled with a single percentage value opposite the center of the curves to which it applies.

Because the effectiveness of the solvent cages might be expected to decrease with increasing temperature, and also because the higher solubility of iodine at higher temperatures makes it possible to use higher concentrations of iodine scavenger, determinations were made of the organic yields of the

(n,γ) reaction on ethyl iodide in decane and in heptane at five temperatures and at a series of iodine concentrations. The results, given in Table IV and Fig. 1 indicate a decrease by about one fifth in organic yield for a 100° increase in temperature at all iodine concentrations in both solvents. The fact that the temperature coefficient is observed in the presence of 0.01 mole fraction I_2 scavenger indicates that the change in temperature alters the probability of some process by which the I^{128} enters organic combination before it has undergone many collisions subsequent to being moderated to thermal energies. As in the case of the effect of chain length it seems most plausible to ascribe this to a change in the effectiveness of solvent cages for preventing the I^{128} atom from escaping from a radical which it has just formed.

[a] The mole fraction of C_2H_5I was 0.05.

The caging effect concept[16] used above has been quantitatively demonstrated[17-19] for the photochemical dissociation of I_2 in solution. Lampe and Noyes[18] have shown that the primary quantum yield for this dissociation changes with solvent from 66% for hexane to 14% for carbon tetrachloride to 4% for hexachlorobutadiene at 25°, the trend being for the dissociation yield to decrease with increase in molecular weight of the solvent. Both the primary quantum yield,[18] and the rate constant for the atom recombination reaction[20] have been shown to increase with increase in temperature.

The only report in the literature on the effect of temperature on the organic yields of the (n,γ) process in pure liquid ethyl halides,[21] of which we are aware gives values of 37.0 and 38.6% for C_2H_5I at −78 and 20° and of 34.5 and 31.8% for C_2H_5Br at −78 and 0° indicating less temperature sensitivity than that shown in the present work for hydrocarbon solutions at higher temperatures. Limited data[3a] indicate a small negative temperature coefficient for the organic yield of Br^{80} from the (n,γ) and isomeric transition processes in CCl_3Br and little or no temperature effect for Cl^{38} in CCl_4.

Consideration of Mechanisms.—The "hot" reactions observed as described above must involve one of the following mechanisms: (a) combination of a neutral recoil atom with an organic radical it had just formed, and with which it combines either before escaping from their common solvent cage or after only a few diffusive encounters with solvent molecules; (b) attack of an energetic neutral recoil atom on a solvent molecule in a displacement reaction in which it replaces a radical or atom; (c) formation of a molecule–ion by reaction of a recoil halogen ion with a solvent molecule, followed by neutralization or reaction of the molecule–ion to yield a stable organic halide molecule. It is impossible, at present, to distinguish between these mechanisms for liquid systems. Gas phase studies have shown, however, that I^{128}, Br^{80} and Cl^{38} when activated as a result of formation by the (n,γ) process can all enter organic combination by displacement reactions between the halogen atom or ion and hydrocarbon molecules, under conditions where the possibility of reaction of the tagged species with free radicals is eliminated.[8,10,22] There is evidence that the atom must have a charge for this type of reaction to occur.[10b] It is probable, therefore, that reactions of ions contribute to the "hot" portions of the reactions discussed in this paper and to many other "hot" reactions initiated by nuclear transformations in both the gas and condensed phases. It is reasonable to assume that these ionic reactions are related in type to the highly efficient ion–molecule reactions[23] currently under intensive study by mass spectrometric techniques. It seems probable that the formation of carbon chains by recoil tritium atoms in methane,[5a] and the other highly efficient reactions of tritium atoms activated by recoil and by tritium decay[5b] are due to ionic reactions of the type revealed by the mass spectrometric studies.

The organic yield of 50% observed for the gas phase reactions of methane with iodine activated by the $I^{127}(n,\gamma)I^{128}$ process is drastically lowered by a few mole per cent. of C_2H_5I and the yield in pure C_2H_5I gas is only about 1%.[10] Because the ionization potential of the C_2H_5I (9.5 e.v.) is lower than that of the I atom (10.4 e.v.) the effect of C_2H_5I in lowering the yield with CH_4 has been ascribed to neutralization of the $I^{128}+$ ions by C_2H_5I before their kinetic energy has been sufficiently reduced to allow them to form a stable combination. It is possible that similar factors may play some role in the reactions of mixtures of liquid alkyl halides and hydrocarbons with halogens activated by the (n,γ) processes. Major differences from the gas phase results might be expected, however, due to caging effects, differences in charge transfer potentials, and differences in the nature and stability of the molecule ions formed. Among the experimentally observed differences are the low organic yields of I^{128} in gaseous C_2H_5I(1%)[10] as compared to liquid C_2-

H_2I(42%),[24] and in gaseous C_2H_6(3%), C_3H_8(4%) and C_4H_{10}(5%)[22] as compared to the liquid hydrocarbons tested in the work of this paper (Table III). Likewise the organic yield of I^{128} reacting with CH_4 in the gas phase is much more sensitive to added C_2H_5I (*i.e.*, 5 mole % C_2H_5I reduces the yield in gaseous CH_4 by more than 50%)[10b] than are the yields from the hydrocarbons of this paper in the liquid phase. In all probability these differences are due in part to the fact that non-ionic reactions in which the recoil atom can combine with a radical it has formed are made possible by the caging effect and greater probability of diffusive recombination in the liquid.

Correlation with Reactions of Cl^{38}.—Unlike the reactions of I^{128} and Br^{80}, the reactions of Cl^{38} activated by the (n,γ) process in liquid hydrogenous media give a constant organic yield (21%) which is independent of whether the solvent is an alkyl chloride or a hydrocarbon or a mixture of the two, and is independent of the chain length.[8] This unexpected independence of the yield on environment has had no satisfactory explanation. Consistent with the discussion in the preceding paragraphs it may now be explained tentatively by the hypothesis that only ionic reactions lead to organically bound Cl^{38} in liquid hydrogenous media, that 21% of the $Cl^{37}(n,\gamma)Cl^{38}$ events occur with internal conversion which produces ions,[25] and that all such ions result in organically bound chlorine. Chlorine atoms, unlike bromine and iodine atoms abstract H from C–H bonds with very low activation energy. In media where such bonds are available, every neutral chlorine atom would be expected to be fixed in inorganic combination as HCl. Br^{80} and I^{128} atoms, which do not abstract hydrogen as readily, have a greater opportunity to react with radicals which they form in losing the energy from the (n,γ) process. Consequently they may be expected to show organic yields which vary with the varying fragmentation and caging characteristics of different media. Similar variations are to be expected for Cl^{38} in non-hydrogenous solvents where the activation energy for reaction of chlorine atoms with the solvent is high. This is illustrated by the relatively high organic yield (44% total, *ca.* 32% "hot") and scavenger effect observed[8] with carbon tetrachloride in contrast to the 21% total organic yield with no scavenger effect for hydrogenous solvents.

Reaction of Hydrocarbons with Bromine Activated by the Br^{80} Isomeric Transition.—The data of Table V show that the organic yields of bromine activated by the isomeric transition process in hydrocarbons increase with increasing chain length of hydrocarbon regardless of scavenger concentration, as in the case of (n,γ) activation. Although the two nuclear processes are very different both can contribute both charge and recoil energy to the atoms involved. These data add further to the growing evidence[14,26,27] that the chemical events induced by the two types of activation are largely identical.

TABLE V

ORGANIC YIELDS OF THE $Br^{80m} \rightarrow Br^{80}$ ISOMERIC TRANSITION IN SOLUTIONS OF BROMINE IN HYDROCARBONS

Table VI shows further that the organic yields from the isomeric transition of bromine in hydrocarbons vary with the compound which is used as the source of bromine even when its mole fraction is as low as 1×10^{-5}. The differences between different source compounds are, to a first approximation, independent of the hydrocarbon solvent and of the concentration of bromine scavenger. It appears that they are the result of partial failure of the C–Br bond to rupture following isomeric transition, as observed earlier[28] for CCl_3Br, C_6H_5Br and CH_3Br in liquid bromine as the solvent. The differences between the organic yields from CCl_3Br and from Br_2 observed for the solvents of Table VI are 12.5, 11.0 and 11.0%, in striking agreement with the bond rupture failure of 10–13%[22,28] observed for CCl_3Br in the previous work; the differences between C_2H_5Br and Br_2 of 5, 9.5 and 6% are similar to the failure value of 6.5% for CH_3Br[28]; and the differences between CH_2Br_2 and Br_2 of 3.4, 8.5, 5.5 and 5.0% correspond to the failure value of 4.3%.[22] If the interpretation here is correct, it is of particular interest that the retention, in the parent molecule, of bromine atoms which have undergone isomeric transition, is so similar in hydrocarbon solvents and in liquid bromine.

TABLE VI

ORGANIC YIELDS OF THE $Br^{80m} \rightarrow Br^{80}$ ISOMERIC TRANSITION IN HYDROCARBONS WITH DIFFERENT COMPOUNDS AS THE SOURCE OF BROMINE

	Organic yield, in %, with $CHBr_3$[a]	CCl_3Br[a]	C_2H_5Br[a]	Br_2[a]

Antiferromagnetic Ordering and Electronic Structure of $CuCl_2 \cdot 2H_2O$ as Determined from Nuclear Magnetic Resonance[1]

BY R. E. RUNDLE

RECEIVED JANUARY 18, 1957

The nuclear magnetic resonance study of $CuCl_2 \cdot 2H_2O$ by Poulis and Hardeman is coupled with neutron diffraction data on proton positions to obtain the type of antiferromagnetic ordering in $CuCl_2 \cdot 2H_2O$, and the distribution of the odd-electron in the $CuCl_2 \cdot 2H_2O$ "molecule." It is found that the odd-electron must be about 25% on each chlorine, 50% on copper. This distribution is consistent with a molecular orbital treatment of the complex, but not with crystal field theory or with Pauling's theory of directed valence in square copper complexes. The use of nuclear magnetic resonance in crystals as a probe for determining the distribution of magnetic electrons appears to be sensitive and deserving of further use.

Introduction

Recently Poulis and Hardeman (P and H) have examined proton magnetic resonance in $CuCl_2 \cdot 2H_2O$ down to very low temperatures, finding that below 4.3°K. $CuCl_2 \cdot 2H_2O$ is antiferromagnetic.[2] By studying the proton resonance in single crystals both above and below the Néel point they have attempted to determine both the magnetic structure and the proton positions in this compound.[2] These problems are related since, in a paramagnetic or antiferromagnetic crystal, the magnetic field at the proton is a function of the crystal field as well as the external field.

The conclusions of P and H on the magnetic structure are shown in Fig. 1. The positions of copper, oxygen and chlorine were determined by Harker, using X-ray diffraction,[3] which, of course, did not yield proton positions. In Fig. 1 the arrows give the spin arrangement inferred by P and H.

The proton positions of P and H are quite unsatisfactory, leading to O–H distances of 1.7 Å. within the water molecules, whereas positions determined by neutron diffraction yield O–H distances and HOH angles which are nearly the same as in free water molecules[4] (0.97 Å. and 104.5°, respectively).[5] Since, as noted above, the proton positions and antiferromagnetic ordering are related, it seems likely that the erroneous proton positions resulted from an erroneous magnetic structure.

In the subsequent sections of this paper using proton positions as obtained by Peterson and Levy,[4] it is shown that the magnetic ordering suggested by P and H is unable to account for the field at the proton. A different magnetic ordering is next shown to be more consistent with the structure of $CuCl_2 \cdot 2H_2O$, and, finally, taking the proton position and the magnetic ordering to be known, it is shown that the odd-electron in $CuCl_2 \cdot 2H_2O$ is not localized on copper but is distributed over copper and chlorine sites. In an independent paper it is shown that this electron distribution arises naturally from a molecular orbital treatment of square, planar copper complexes.[6]

Proton Magnetic Resonance and the Proton Position.—In a proton magnetic resonance experiment the energy difference between parallel and antiparallel arrangements of the proton magnetic moment in the field at the proton is measured. Under these circumstances the energy difference is proportional to the magnitude of the field at the proton, or

$$\Delta E = K|\mathbf{H}| \tag{1}$$

In a magnetic substance, such as $CuCl_2 \cdot 2H_2O$, the local field at the proton is the vector sum of the external field, $\mathbf{H}_0$, and the crystal field, $\mathbf{H}_c$, and since $\mathbf{H}_c$ depends upon the location of the electrons giving rise to the magnetic properties of the compound, proton resonance may yield information concerning electronic structure by serving as a measure of $\mathbf{H}_c$.

In the antiferromagnetic region at low fields, $H_0 < 2000$ oersteds P and H have shown that the moments in $CuCl_2 \cdot 2H_2O$ point parallel and antiparallel to a, and this result seems certain although their exact arrangement of spins may be in error. Let the moment on the jth atom be μ_j. Then

$$\mathbf{H}_c = \sum_j - \text{grad}\, \frac{\mu_j \cdot \mathbf{r}_j}{r_j^3} \tag{2}$$

where $\mathbf{r}_j$ is the vector from the jth atom to the proton in question. It follows that

$$H_{c_x} = \sum_j \pm \mu_j \frac{[2(X - x_j)^2 - (Y - y_j)^2 - (Z - z_j)^2]}{r_j^5} \tag{3}$$

$$H_{c_y} = 3\sum_j \pm \mu_j \frac{(X - x_j)(Y - y_j)}{r_j^5} \tag{4}$$

$$H_{c_z} = 3\sum_j \Sigma \pm \mu_j \frac{(X - x_j)(Z - z_j)}{r_j^5} \tag{5}$$

where H_{c_x}, H_{c_y}, H_{c_z} are the components of $\mathbf{H}_c$, and the sign of μ_j is positive or negative depending upon whether the moment on the jth atom is parallel or antiparallel to a. X, Y, Z are coördinates of the proton under consideration, and x_j, y_j, z_j are the coördinate of the jth atom. In the crystal there are many hydrogen positions, all related by symmetry, so that only one is unique.

For $\mathbf{H}_0$ in the ab plane, $H_{0_x} = H_0 \sin\alpha$ and $H_{0_y} = H_0 \cos\alpha$ where α is the angle between b of the crys-

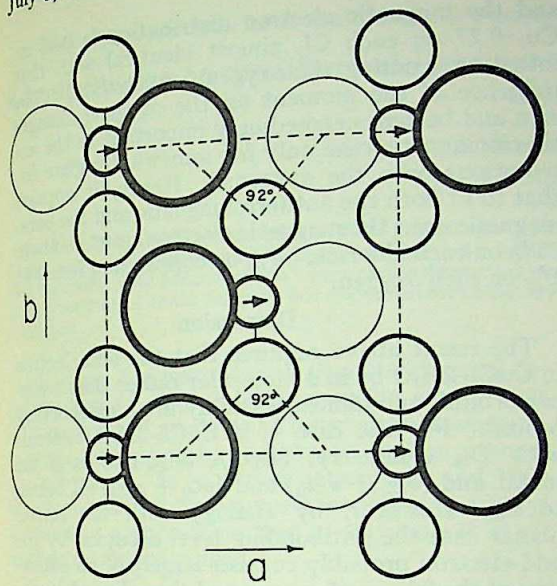

Fig. 1.—Structure of $CuCl_2 \cdot 2H_2O$. Large circles are chlorine atoms, medium are oxygen atoms, small are copper atoms. Arrows show magnetic ordering on (001) as proposed by Poulis and Hardeman. Copper atoms in alternate planes have antiparallel moments.

tal and the external magnetic field vector $\mathbf{H}_0$. Then

$$|H| = [(H_0 \sin \alpha + H_{c_x})^2 + (H_0 \cos \alpha + H_{c_y})^2 + H_{c_z}^2]^{1/2} \quad (6)$$

The maximum energy difference between the parallel and antiparallel proton alignments will then occur at H_{max}, and setting $\partial |H|/\partial\alpha = 0$

$$\tan \alpha_{ab_{max}} = H_{c_x}/H_{c_y} \quad (7)^7$$

where $\alpha_{ab_{max}}$ is the direction of $\mathbf{H}_0$ which maximizes the proton resonance energy for $\mathbf{H}_0$ in the *ab*-plane. P and H have examined resonance in the *ab* plane, and find $\alpha_{ab_{max}} = 56°$.

To find H_{c_y} and H_{c_x} at the proton it is necessary to sum over the copper atoms. P and H summed over the nearest nine coppers which form a trigonal prism with the proton in question off-center within the prism. Convergence is not excellent, and we have summed over the nearest thirty copper atoms. This results in a correction of several per cent. It was found that for the known proton position the calculated $\alpha_{ab_{max}}$ was ~12°, far from that observed by P and H. In this stage of the calculation the magnetic ordering suggested by P and H, Fig. 1, was used, and it was assumed that the magnetic moment was localized on copper.

In another paper we show that localizing the odd-electron, responsible for the moment, upon copper cannot be justified[6]; consequently, the calculations were repeated with part of the moment on chlorine. Taking the moment on chlorine to be $\lambda\mu_{Cu}$, the magnetic ordering suggested by P and H produced negative values for λ. This is physically unacceptable since the moment of an electron shared between copper and chlorine should surely have the same orientation on both. A similar negative value arose when the moment was delocalized onto oxygen *and* chlorine.

(7) These equations are equivalent to those of P and H except for some typographical errors.[1]

The Antiferromagnetic Ordering.—Having been satisfied that the suggested magnetic ordering is incorrect we have considered what to expect for magnetic ordering from the structure. Here it is to be noted that $CuCl_2 \cdot 2H_2O$ is unusual among known antiferromagnetic materials, in that the metal ions are not bridged together into a three-dimensional network. Along the **C**-axis of the crystal run chains, Fig. 2, with short (3.73 Å.) copper–copper distances. Two oxygen and/or chlorine atoms separate each chain from its neighbors, and the Cu–Cu distance between chains is 5.5 Å. Hence, it seems unreasonable to expect super-exchange to cause the ordering except within the chains, where the spin arrangement along the chains should be alternate.

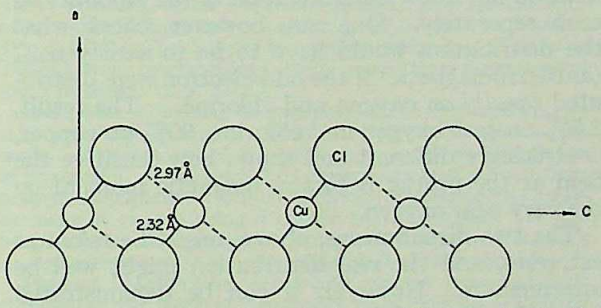

Fig. 2.—$CuCl_2$ chain in the hydrate. Water molecules lie above and below each chain, so that copper atoms in neighboring chains are well shielded from each other.

If it is correct that super-exchange is important only along the chains, it then seems likely that direct magnetic interaction among the chains is responsible for the rest of the ordering. Looking at the (001) face, the copper arrangement within the face is face-centered (Fig. 3). It is, then, easily seen that spin arrangement (A) (Fig. 3) is favored

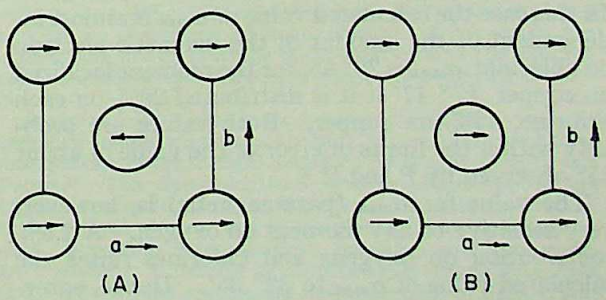

Fig. 3.—(A) is magnetic ordering proposed in this paper; (B) is the magnetic ordering of P and H. In both cases, alternate planes are antiparallel.

by magnetic interactions if an appreciable part of the moment is on chlorine, as seems likely, while B is the arrangement suggested by P and H. It is to be noted that the chains with alternating spins run normal to (001), and in proposing arrangement (A) we are proposing not that direct magnetic interactions of spins cause antiferromagnetic ordering, but that whole chains of already ordered spin-moments interact magnetically to cause the three-dimensional magnetic ordering.

Electron Distribution in $CuCl_2 \cdot 2H_2O$.—The proton position and magnetic arrangement (A), Fig. 3, still will not explain the proton resonance data of P and H if all the magnetic moment is centered on copper. (A calculation of α_{max} for this case yielded $\sim 80°$ *vs.* 56° observed.) It is necessary, therefore, to again consider whether the odd-electron is also distributed over chlorine positions. To do this we have considered that the moment on copper is μ, while that on chlorine is $\lambda\mu$, and have carried out the sums in equations 3 and 4 over the nearest thirty coppers and the nearest forty-four chlorine atoms, assuming the magnetic ordering (A) above. For this model, equation 7, above, yields $\lambda = 0.55$, whence the odd-electron distribution is approximately 26% on each chlorine, 48% on copper.

The magnetic electron might well be distributed over oxygens *and* chlorines, but unfortunately the data do not allow determination of the amounts on each separately. One can, however, check what the distribution would have to be to satisfy α_{max} (antiferromagnetic) if the odd-electron were distributed *equally* on oxygen and chlorine. The result, 2.5% on *each* oxygen and chlorine, 90% on copper, is strikingly different and shows how sensitive the field at the proton is to any magnetic moment on the very near oxygen.

The two distributions, above, might be taken as extremes, and the real distribution might well be intermediate. However, it can be demonstrated from the data of P and H in the paramagnetic range[2] that the former is more nearly correct than the latter.

Neutron Resonance in the Paramagnetic Region.—In the paramagnetic case, proceeding as before, but assuming that on the average field and proton moment are parallel, it is found that

$$\tan 2\alpha_{max} = \frac{-2\sum_j (X - x_j)(Y - y_j)/r^5}{\sum_j (X - x_j)^2 - (Y - y_j)^2/r^5} \qquad (8)$$

In this case the calculated value of α_{max} is almost independent of the amount of the magnetic electron on chlorine; α_{max} is 26° 45′ for the moment localized on copper, 27° 17′ if it is distributed 26% on each chlorine, 48% on copper. Both values are probably within the limits of error of the value of about 25° observed by P and H.[2]

The value for α_{max} (paramagnetic) is, however, very sensitive to any moment on oxygen. A 2.5% contribution on oxygens and chlorines raises the calculated value of α_{max} to 32° 35′. Hence, agreement with the observed value of α_{max} (paramagnetic) is lowered by putting any amount of the odd-electron onto oxygen.

It seems reasonable to assume that the observed value of α_{max} may be in error by several degrees. (P and H gave no estimate of their error in mounting the crystals, etc.). Setting an upper limit upon α_{max} (paramagnetic) of 29°, the maximum allowable part of the magnetic electron on each oxygen is 0.008. Using this value, and solving for λ_{Cl} in the antiferromagnetic case, it is found that $\lambda = 0.63$ and the magnetic electron distribution is 0.44 on Cu, 0.27 on each Cl, almost identical with that found by ignoring the oxygen contribution. (The influence of the moment on the oxygens changes sign and becomes exceedingly important in the antiferromagnetic case only for somewhat higher distributions onto the oxygens.) Hence, it appears that to fit both the antiferromagnetic and the paramagnetic data the magnetic electron must be about 25% on each chlorine, 50% on copper, and less than 1% on each oxygen.

Discussion

The result above requires that the odd-electron in $CuCl_2 \cdot 2H_2O$ be in a molecular rather than a copper orbital, and almost certainly in an antibonding orbital. For the case of a $CuCl_2 \cdot 2H_2O$ molecule with D_{2h} symmetry, $3d_{x^2-y^2}$, $3d_{z^2}$, and 4s of the metal, and $(\sigma_{Cl_I} + \sigma_{Cl_{II}})$ and $(\sigma_{O_I} + \sigma_{O_{II}})$ all belong to a_{1g}. However, by analogy with the square planar case the antibonding level occupied by the odd-electron probably consists largely of an admixture of the $3d_{x^2-y^2}$ of copper and the σ-ligand levels. The strong mixing in the antibonding level suggests a similar strong mixing in the corresponding bonding level.

These results are clearly incompatible with crystal field theory, where the odd-electron is assumed to be localized in a 3d-orbital of copper, or with Pauling's theory of directed valence, where the odd-electron is localized in a 4p-orbital of copper. They are, however, in keeping with other recent work where quite generally magnetic electrons of transition metal complexes are found to occupy antibonding molecular orbitals rather than localized metal orbitals.[8]

It is to be noted that the conclusions reached here relative to magnetic ordering and odd-electron distribution are, in principle, and probably in fact, subject to check by neutron diffraction. It is hoped that studies along these lines will be possible in spite of the very low temperature required for the neutron diffraction work.

Finally, the method employed, of using a nucleus with spin as a probe for the magnetic field within a magnetic crystal, appears to give a sensitive method for discovering the magnetic electron distribution within the crystal. The interpretation of the experimental results appears to be straightforward when the crystal structure is known, and the method appears to deserve wide use.

Acknowledgment.—Thanks are due to Drs. S. W. Peterson and H. A. Levy of the Oak Ridge National Laboratory for making their proton positions available to me prior to publication, and for their interest in the problem. Both have made some refinements of this paper possible.

Kinetic Studies on the Thermal Decomposition of *t*-Butyl Hydroperoxide in Dodecane Solution

BY B. KATHLEEN MORSE[1]

RECEIVED NOVEMBER 5, 1956

The kinetics of the decomposition of *t*-butyl hydroperoxide in dodecane solution, 0.05–0.6 molal, were studied in a closed system and in a helium-swept apparatus at 98.5°. An initial first-order rate constant prevails for the helium-swept reaction over the twelve-fold concentration range and is dependent upon the removal of evolved oxygen. This initial decomposition is apparently not a chain reaction nor does it involve *t*-butoxy radicals. A mechanism is suggested, and an approximate E_a is calculated.

Milas and Surgenor[2] found that the thermal decomposition of *t*-butyl hydroperoxide above 150° led to an array of products: *t*-butyl alcohol, acetone, methane, methanol, formaldehyde, carbon monoxide and water. In contrast between 95 and 100° they found that it decomposed smoothly to *t*-butyl alcohol and oxygen according to equation 1[3] in almost quantitative yields.

$$\mathrm{ROOH} \longrightarrow \mathrm{ROH} + {}^1/_2\mathrm{O}_2 \qquad (1)$$

This decomposition has been one of the curiosities of the literature in view of the mechanistic studies conducted at higher temperatures. The qualitative work in the vapor phase[4,5] and kinetic studies in octane solution[4] between 150 and 195° led to the conclusion that the decomposition occurred by a combination of unimolecular and chain processes dependent upon the fission of the O–O bond (equation 2), the ability of *t*-butoxy radical to liberate a methyl group[6] (equation 3), the hydrogen-abstraction reactions of these radicals with either the solvent or the hydroperoxide (equation 4), and the conversion of the alkyl peroxy radicals to alkoxy radicals either bimolecularly or *via* peroxide formation by reaction with an alkyl radical.

$$\mathrm{ROOH} \longrightarrow \mathrm{RO}\cdot + \cdot\mathrm{OH} \qquad (2)$$

$$\mathrm{RO}\cdot \longrightarrow \mathrm{MeCOMe} + \mathrm{Me}\cdot \qquad (3)$$

$$\mathrm{X}\cdot + \mathrm{ROOH} \longrightarrow \mathrm{XH} + \mathrm{ROO}\cdot \qquad (4)$$

The decomposition below 100° (equation 1) is difficult to understand in terms of the mechanism found at higher temperatures. The relative stability of the *t*-butoxy radical seems an insufficient basis for the difference in the course of the two reactions. In this paper kinetic evidence for a non-chain reaction independent of equation 2 and dependent upon the evolution of oxygen is presented. It is believed that the evidence reported is important not only in itself but with respect to the mechanism of oxidation where the hydroperoxide has a nebulous role as a source of chain-branching.

Experimental

Reagents.—*t*-Butyl hydroperoxide (Lucidol) carefully fractionated at reduced pressure in a 1 m. vacuum-jacketed column packed with 1/4" helices could be stored in the refrigerator six months without change in the infrared spectrum, peroxidic titer, or refractive index. A typical sample had the following properties: b.p. 36.5° at 15 mm.; n^{17}D 1.4012; 98.56% ROOH by iodometric titration. Dodecane (Eastman practical grade) was distilled from sodium at reduced pressure, stored over sodium wire, and flushed with oxygen-free helium before use; b.p. 97.5–99.5° at 5 mm.; n^{19}D 1.4215. The 2,6-di-*t*-butyl-4-methylphenol (Eastman Tenox) was recrystallized from methylcyclohexane and dried *in vacuo;* m.p. 71.5°.

Inert Gas.—Flushing or sweeping of the system to maintain anaerobic conditions was necessary throughout the work. The removal of oxygen from nitrogen by absorption in pyrogallol, metal ketyl,[7] or chromous chloride[8] solutions proved inadequate for some concurrent studies on the measurement of oxygen using a carrier gas so purified. It was necessary therefore to use helium which was passed through an Ascarite tower to remove water and carbon dioxide.

Product Identification.—Infrared spectra were obtained throughout the work in matched 1 mm. cells on a Perkin–Elmer Double Beam Spectrophotometer with sodium chloride optics. Spectral changes throughout a run indicated *t*-butyl alcohol and acetone were the major products; comparisons were made with the spectra of the pure substances at comparable concentration in dodecane solution. The characteristic absorption bands used for identification in dodecane solution were 5.78–5.80 μ for acetone, 10.98–11.00 μ for *t*-butyl alcohol and 11.98–12.00 μ for *t*-butyl hydroperoxide.[9] There was no spectral evidence for the formation of di-*t*-butyl peroxide which has a characteristic absorption band at 11.4 μ.[9] The absorption at 2.7–3.0 μ was sufficiently ambiguous to preclude any interpretation for the absorption band for water. Chromous chloride solutions[8a] were investigated for quantitative work on the measurement of oxygen, but difficulties in maintaining a standard solution and in the absorption of small amounts of oxygen in the effluent gas stream preclude the presentation of the data except as qualitative evidence for the early evolution of oxygen.[10]

Analyses.—The change in hydroperoxide titer was determined iodometrically in absolute isopropyl alcohol by a modification of the method described by Wagner, Smith and Peters.[11] The determinations were reproducible within 1%. At room temperature (or 0°) no difficulty was experienced with an oxygen error so samples could be handled with ease. Peroxidic determinations by iodometric procedures are equivocal; a number of iodometric methods have been used to determine specifically hydroperoxide or dialkyl peroxide which depend only upon differences in reaction time, solvent and temperature.[12] In the present work a depend-

able method for *t*-butyl hydroperoxide in conjunction with spectral checks for its presence and the absence of other peroxide bands was considered more reliable than an empirical method. In experiments where additional hydroperoxide could be formed the titer was treated as total peroxidic titer and is so noted. Acetone was the only product of the decomposition which lent itself to spectrophotometric determination in dodecane solution. Above 0.01 molal, the concentration could be determined within 7%. The detectable limit was about 0.005 molal.

Kinetics.—The apparatus for the swept experiments, shown in Fig. 1, consisted of a conical flask with a condenser

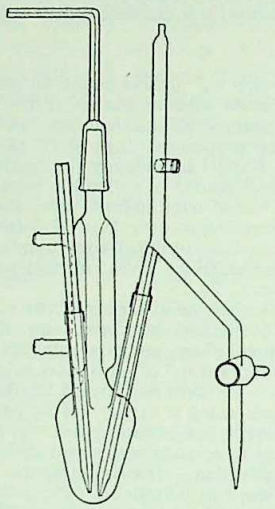

Fig. 1.—Apparatus for the helium-swept experiments.

and two side arms. One side arm held a capillary as an inert gas inlet, the other a λ-pipet[13] designed to allow the removal of liquid samples under a stream of inert gas. A hypodermic syringe was used to pull the sample into the arm of the pipet while the inert gas flow at the "T" was closed off. The condenser was packed with Pyrex wool to act as a vapor barrier; the temperature of the column was maintained at about 20°. Solutions were prepared by weight, transferred to the apparatus which had been flushed with oxygen-free helium for at least an hour. Sweeping of the system at 14–22 ml./hr. was continued another five minutes before the solution was thermostated in an oil-bath at 98.5 ± 0.1°. The apparatus was cleaned between experiments by various methods, ranging from a few rinses with isopropyl alcohol to treatment with hot nitric acid followed by a final rinse with ammonia before drying at 110°; the method of cleaning did not have any effect upon the experimental reproducibility.

The initial titer was determined 15 or 20 minutes after thermostating. Since there was danger of entrainment of the hydroperoxide at this temperature, each run was checked finally by pouring the remaining solution through the condenser to determine the increase, if any, in the hydroperoxide titer. All experiments in which the number of milliequivalents of entrained hydroperoxide exceeded the initial drop in titer upon thermostating were rejected. In illustration at 86° over a period of 11 days the total entrainment represented only 3% of the hydroperoxide initially in the solution.

The experiments in a closed system were conducted by the usual sealed ampoule technique. The ampoules were flushed with inert gas, filled, flushed again, and sealed with about a 1 cc. "air-space."

Calculations.—The order of the initial reaction in the swept system was found to be one by the ordinary procedures or the more precise method of Bateman.[14] Linear relationships between the logarithm of the concentration and time were obtained from the data throughout the period of observation. Representative data are so plotted in Fig. 2. The specific first-order rate constants for the respective slopes in each experiment (11–15 points per run) were determined however by an unweighted least-squares method which was independent of the initial titer. These data are presented in Table I. The probable error in the initial rate constants so calculated lay between 1 and 5%. Since the calculation reflects the fit of the line to the data, and there seemed to be no real trend in the variation of the rate constants with concentration, the rate constants for the helium-swept reactions were averaged. The average deviation of 10% is a realistic error for this experimental razor's edge between maximum rate of decomposition and excessive entrainment.

[a] The first-order rate constants, k_1 and k_2 (pseudo first-order), are those of the initial and final decompositions, respectively. [b] An air leak developed overnight. [c] 0.04037 molal in 2,6-di-*t*-butyl-4-methylphenol. The solution showed a transition rate between k_1 and k_2 of 10.0×10^{-6}. [d] Pseudo first-order rate constants. [e] At 98.1° flushed or swept with "ketyl" treated nitrogen. [f] 0.05008 molal in 2,6-di-*t*-butyl-4-methylphenol. [g] Swept with "ketyl" treated nitrogen after heating 404 hours in a sealed tube. [h] System opened through a second condenser to remove samples. [i] Surface of the solution swept with helium.

Also shown in Fig. 2 are two representative growth curves of acetone.

Results and Discussion

Oxygen Evolution.—From a survey of Table I and Fig. 2 the slowness of the decomposition reaction at 98.5° is evident as well as the inhibitory effect of oxygen which was first noted by Stannett and Mesrobian.[15] The rate of the reactions is dependent not only upon the exclusion of air but also upon the removal of evolved oxygen. Maximum rates of decomposition were observed only if the solution were swept with a fine stream of bubbles of oxygen-free helium to remove the evolved oxygen. Under these conditions a constant first-order rate of decomposition was obtained over a twelve-fold concentration change (Table IA). The initial rate of decomposition, k_1, then increased somewhat erratically about threefold after a period of 20 to 22 hours when the hydroperoxide concentration had decreased by one third. In ampoules, though (Table IB), the hydroperoxide persisted

over a 404-hour period, decomposing only 28% at a rate 1/40.8 (to 1/130) as rapidly as in the helium-swept reaction.

Between these two extremes intermediate rates were observed depending upon the nicety of the system. If the helium stream were passed over the surface of the solution, the observed maximum rate of reaction (anaerobic conditions) decreased almost twofold initially and as much as sevenfold during the last two-thirds of the reaction. If an air-leak developed, as in run I-21, the initial rate decreased over fourfold instead of increasing three-fold. If nitrogen containing a trace of oxygen were used to sweep the system (I-10) again the initial rate decreased.

The Reaction Intermediates.—The contrast in the rates of the swept and partially swept reactions observed throughout the experiments suggests that oxygen is retained by compound formation since the titer of the solution could not be altered by refluxing the samples in isopropyl alcohol solution before analysis. In peroxide decompositions or hydrocarbon oxidations three types of free radicals have been shown to be participants: alkyl, alkoxy and alkyl peroxy.[4,16-18] Of the three the alkyl radical is the one which may react rapidly, if not instantaneously with dissolved oxygen. This could be derived either from the solvent by the hydrogen-abstraction reaction of an oxygenated precursor or from the *t*-butoxy radical if it is formed, which liberates methyl radicals in reaction 3. Thus along with the evolution of oxygen concurrent alkyl radical formation to some extent must take place. Again comparison of the difference in the rates in the two systems, swept and partially swept, after 20 to 30 hours indicates the importance of the alkyl radical for the subsequent swept reaction, and one concludes that the retention of oxygen (Table IC) removes alkyl radicals which are necessary to realize the enhanced reaction identified by the specific rate constant k_2 in Table IA. The threefold increase in the rates of the swept reactions can best be attributed to the occurrence of reaction 4 between the hydroperoxide and an alkyl radical derived from the solvent. The occurrence of the abstraction reaction has been demonstrated in the vapor phase at 195° by the identification of methane-*d* in the reaction of methyl radicals with *t*-butyl deuteroperoxide.[5]

The reaction of the alkyl radicals with oxygen has been well established in oxidation reactions[16-18]

$$S\cdot + O_2 \longrightarrow SOO\cdot \qquad (5)$$

$$SOO\cdot + HS \longrightarrow SOOH + S\cdot \qquad (6)$$

where S· is an alkyl radical derived from the hydrocarbon, HS. In view of the important role of alkyl radicals in supporting the rapid reaction one concludes that in the unswept reactions the decreased rate may be attributed not only to the formation of a hydroperoxide (SOOH) but also to the exclusion of reaction 4. Experimental confirmation for the existence of *t*-butyl hydroperoxide was obtained by a prolonged period of observation of its characteristic absorption band when oxygen was left in the system to participate in reactions 5 and 6.

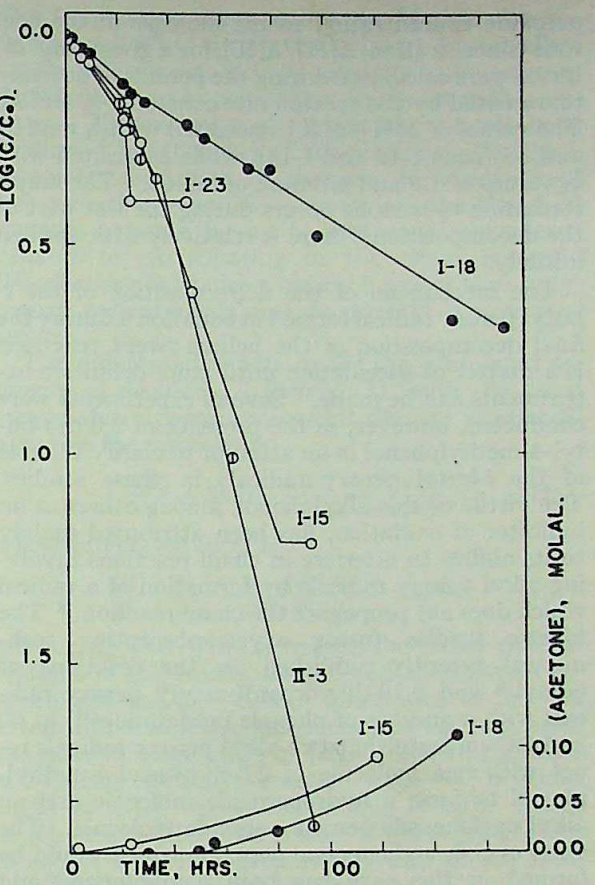

Fig. 2.—Representative data illustrating the effect of oxygen (●) and 2,6-di-*t*-butyl-4-methylphenol (Φ) on the first-order decomposition of ROOH (O) and on the formation of acetone.

Associated with the decrease in the rate when oxygen was allowed to remain or was added to the solution was an inhibition period in the formation of acetone. Representative curves of acetone formation for the anaerobic and aerobic reactions are shown in Fig. 2. When oxygen was allowed to remain in the solution acetone formation was delayed 30 or as many as 72 hours. The rate of formation of acetone after the period of inhibition was approximately the same for both the swept and the partially swept reactions, and could not be identified specifically with either the slow or rapid reaction. The absence of acetone during a period of net hydroperoxide decrease denotes the absence of *t*-butoxy radical (or the acetone precursor) and implies that *t-butoxy radical is not formed by an independent unimolecular cleavage* such as reaction 2. The absence of acetone during this period of oxygen absorption when reaction 4 is believed to be prohibited implies a dependence of acetone formation upon alkyl peroxy radical formation. Thus one is led to the interpretation that *t*-butyl peroxy radical is the precursor of *t*-butoxy radical or that acetone is formed directly from the alkyl peroxy radicals.

In the swept reactions where the observed hydroperoxide concentration is real, *i.e.*, no hydroperoxide is formed by the solvent radicals, there was little acetone formation during the initial decomposition. The ratios of the decrease in the hydro-

Digitized by Arya Samaj Foundation Chennai and eGangotri

peroxide concentration to the increase in the acetone concentration, $\Delta[H]/\Delta[K]$, for a given time interval were calculated during the periods of decrease represented by the specific rate constants k_1 and k_2. The values of $\Delta[H]/\Delta[K]$ associated with k_1 were 51 and 88 (runs I-12 and I-15), while associated with k_2 values of 1.9 and 4.8 were obtained. The major formation of acetone occurs during the last part of the decomposition; there is relatively little formed initially.

The mechanism of the decomposition of the *t*-butyl peroxy radical formed in equation 4 during the final decomposition of the helium-swept reactions is a matter of speculation until more definitive experiments can be made. Several experiments were conducted, however, in the presence of 2,6-di-*t*-butyl-4-methylphenol in an attempt to clarify the role of the *t*-butyl peroxy radicals in these studies. The virtue of this alkylphenol, among others as an inhibitor of oxidation, has been attributed mainly to its ability to interfere in chain reactions involving alkyl peroxy radicals by formation of a radical which does not propagate the chain reaction.[16] The kinetic studies (using oxygen-absorption techniques) recently published on the reactions of cumyl[19] and 9,10-dihydroanthracyl[20] peroxy radicals with a number of phenols (and amines[19]) at 60 and 62° indicate that two alkyl peroxy radicals react with one molecule of 2,6-di-*t*-butyl-4-methylphenol to form a hydroperoxide molecule and an alkyl cyclohexadienenone peroxide molecule. The alkyl cyclohexadienenone peroxide which would be formed in this case has been characterized and studied under a number of conditions.[21]

In contrast between 80–100° the 4,4′-dihydroxybiphenyl derivative as well as the stilbene quinone has been isolated from this alkylphenol under a variety of oxidative conditions: with benzoyl peroxide in chloroform,[22] with air in cumene containing ferric stearate,[23] and air in aqueous alkali.[24]

In the helium-swept experiments neither the rate nor the duration of the initial decomposition was affected by the alkylphenol (runs I-23 and II-3) as would be expected where one has evidence for a non-radical oxygen evolution with some concurrent alkyl radical formation. (The amount of alkyl peroxy radical formation was negligible.) The final stage of the decomposition is considered to be dependent upon the reaction of the remaining hydroperoxide with alkyl radicals and is probably responsible for the major destruction of the hydroperoxide at the enhanced rate k_2. But here also the rate, k_2, is unaffected. The only marked difference made by the alkylphenol is that it aids in effecting the completeness of the decomposition.

The experiment with the alkylphenol in the swept system (as well as the ampoule experiment) verifies the interpretation that the observed rates are measures of the (slowest) initiation and not the (fastest) termination reaction. Since the initial decomposition was totally unaffected by the alkylphenol one may assume that it is not a chain reaction and is indeed not dependent upon alkyl peroxy radical as the amounts of acetone obtained indicate. The concurrent alkyl radical formation is evidently unimpaired since the rate increases as before. The fact that there is an effect only on the final decomposition leads one to believe that the interpretation of the final decomposition based on equation 4 is correct. The present kinetic results though are incompatible with the formation of peroxides in the termination step as found in the oxygen-rich systems at 60°. Peroxide formation in the termination step by the postulated mechanisms[19,20] would mean in these experiments that every two alkyl peroxy radicals formed in equation 4 form a hydroperoxide and an alkyl cyclohexadienenone peroxide molecule, so that the net rate of decrease in the titer would be at most equal to that of the initial reaction, and no increase from k_1 to k_2 would be observed with the change in mechanism.[25] That only the completeness of the final decomposition is affected and not the rate suggests that the alkylphenol is more efficient than the solvent in irreversibly terminating the reaction (in a non-rate-determining step). It seems more reasonable to assume that alkyl peroxy radical–solvent interaction leading to equivalent amounts of hydroperoxide accounts for the final *impasse* observed in all the experiments without the alkylphenol (two are shown in Fig. 2) where the hydroperoxide concentration finally ceases to decrease at the rate k_2 than to attribute the effect to the alkylphenol–peroxy radical interaction. A termination step for the fast reaction (k_2) comprising the formation of two peroxidic molecules (one of which is determinable analytically) from every two alkyl peroxy radicals is hardly compatible with the observations in this oxygen-depleted system. The formation of non-peroxidic products such as the dihydroxybiphenyls and stilbene quinones in these experiments with the alkylphenol would appear to give a more consistent over-all kinetic picture at these temperatures.

Conclusions

From the data obtained under the various experimental conditions several facts emerge: (1) oxygen is evolved quite rapidly at the beginning of the decomposition in a reaction which is first order with respect to the hydroperoxide concentration; (2) the termination step during this part of the reaction does not depend upon alkyl peroxy radical; (3) alkyl radicals appear to be a critical intermediate for the subsequent reaction; (4) acetone and hence *t*-butoxy radicals, if formed, are apparently derived solely from *t*-butyl peroxy radical; and (5) the peroxy radicals are involved in the chain terminating reaction which is not rate determining.

(25) The *t*-butyl 3,5-di-*t*-butyl-1-methylcyclohexa-2,5-diene-4-one peroxide which could be formed in these experiments from the alkylphenol would yield only 5% of its peroxidic oxygen by the analytical method used, therefore only the hydroperoxide was considered in the approximation. If every alkyl peroxy radical reformed a hydroperoxide (no alkylphenol present), then the rate would decrease to one-half of the initial rate.

The decomposition in an anaerobic system evidently may occur by at least two related mechanisms, one, which rapidly evolves oxygen, occurs at relatively high hydroperoxide concentration, is first order with respect to the hydroperoxide concentration, and to which alkyl peroxy radical termination with acetone formation is incidental, the other reaction which follows after about 31% of the hydroperoxide has decomposed proceeds by a chain reaction dependent upon the existence of alkyl radicals. During the first reaction there is little ketone formation, the major product is *t*-butyl alcohol. During the more rapid decomposition which follows, ketone formation is fairly consistent with about one mole of acetone being formed for every 2 to 5 moles of hydroperoxide decomposing. The facts and their interpretation at this stage of experimentation are not sufficient to permit the derivation of a wholly satisfying mechanism or a precise mathematical expression for the decomposition.

Tentatively the following mechanism is proposed for the initial reaction.

$$\mathrm{ROOH} \xrightarrow{a} \underset{\mathrm{I}}{\mathrm{ROOH^*}} \qquad (7)$$

$$\mathrm{ROOH^* + ROOH} \xrightarrow{b} \mathrm{2ROH + O_2} \qquad (8)$$

The conditions imposed by the observed first-order kinetics and the specificity of the initial reaction are met by reaction steps 7 and 8. The nature of intermediate I and the transition state for step 8 can only be surmised. The experimental observations indicate that the hydroperoxide yields an intermediate which initially is able to liberate oxygen from the hydroperoxide or alkyl radicals by reaction with the solvent and which is not a precursor to acetone formation, *i.e.*, it is neither *t*-butoxy nor *t*-butyl peroxy radical. It is suggested that the driving force of step 8 is the formation of molecular oxygen and hence that I may be an excited form of the hydroperoxide akin to the oxo-oxide structure suggested by Milas[26] to account for the observed exaltations in the molecular refraction of a number of peroxidic compounds. The atomic refractivity of the peroxidic oxygen was found to be equal to that of a carbonyl oxygen. The transition state for step 8 probably depends upon hydrogen bonding. Both the decomposition of cyclohexenyl hydroperoxide[14] and the oxidation of a sulfide to a sulfoxide with a hydroperoxide[27] were reported to proceed *via* a hydrogen-bonded dimer. Reaction of intermediate I with the solvent liberates alkyl radicals

$$\mathrm{ROOH^* + 2HS} \xrightarrow{c} \mathrm{ROH + H_2O + 2S\cdot} \qquad (9)$$

which in turn destroy the hydroperoxide.

$$\mathrm{S\cdot + ROOH} \xrightarrow{d} \mathrm{HS + ROO\cdot} \qquad (4)$$

The chain termination which may be composed of several steps for convenience is envisioned as

$$\mathrm{ROO\cdot + HS'} \xrightarrow{e} \mathrm{(ROO{\cdot}HS')} \qquad (10)$$

$$\mathrm{(ROO{\cdot}HS') + ROO\cdot + HS} \xrightarrow{f} \mathrm{ROH + MeCOMe + CH_4 + S\cdot + S'\cdot + O_2} \qquad (11)$$

The termination steps utilize the bimolecular destruction of alkyl peroxy radical, but do not allow for the reformation of hydroperoxide in an oxygen-depleted system as pointed out in the preceding sections. The evolution of oxygen has not yet been confirmed for this part of the reaction. The stoichiometry (equation 11) requires the liberation of two radicals, S· and S′·; to explain the threefold increase between k_1 and k_2 only one is considered capable of participating in the chain reaction. Whether or not *t*-butoxy radical forms or the *t*-butyl peroxy radical yields acetone directly is pure conjecture.

The differential equations for the postulated sequence of reactions, 7 through 11, with the usual steady-state approximations for the four intermediates give the relationship

$$-\frac{\mathrm{d[H]}}{dt} = 2k_a[\mathrm{H}]\left\{\frac{[\mathrm{H}] + 2.5\alpha[\mathrm{HS}]^2}{[\mathrm{H}] + \alpha[\mathrm{HS}]^2}\right\} \qquad (12)$$

whose integrated form is

$$\frac{[\mathrm{H}]}{[\mathrm{H_0}]}\left\{\frac{[\mathrm{H}] + 2.5\alpha[\mathrm{HS}]^2}{[\mathrm{H_0}] + 2.5\alpha[\mathrm{HS}]^2}\right\}^{2/5} = e^{-5k_a t} \qquad (13)$$

where [H] and [HS] represent the molal concentrations of the hydroperoxide and the solvent, respectively, and $\alpha = k_c/k_b$. Expression 13 to some extent illustrates the dependency of the rate upon the relative magnitudes of [H], [HS] and the ratio α. During the initial reaction when [H] is about equal to [H_0], regardless of the relative values of [H_0] and α[HS]^2, the value of the second factor in equation 13 is approximately that of the ratio [H]/[H_0] and equation 13 becomes

$$[\mathrm{H}]/[\mathrm{H_0}] = e^{-2k_a t} \qquad (14)$$

The observed initial rate, k_1, may be identified with the value $2k_a$.

The value of α may be approximated by two methods: from the rate of ketone formation and by extrapolation of the enhanced rate of decomposition $(k)_2$ to its intercept at zero time. The rate of formation of acetone, d[K]/dt, based upon equations 7 to 11 with the same steady-state approximations used above is expressed by the equation

$$\frac{d[\mathrm{K}]}{\mathrm{d}t} = \frac{2k_a\alpha[\mathrm{HS}]^2[\mathrm{H}]}{[\mathrm{H}] + \alpha[\mathrm{HS}]^2} \qquad (15)$$

The solution of the simultaneous differential equations 12 and 15 is

$$\ln\left\{\frac{[\mathrm{H}] + 2.5\alpha[\mathrm{HS}]^2}{[\mathrm{H_0}] + 2.5\alpha[\mathrm{HS}]^2}\right\} = -\frac{[\mathrm{K}]}{\alpha[\mathrm{HS}]^2} \qquad (16)$$

Substitution of the logarithmic form of equation 13 into equation 16 gives the expression

$$\frac{[\mathrm{K}]}{\ln\{[\mathrm{H}]/[\mathrm{H_0}]\} + 5k_a t} = \frac{2\alpha[\mathrm{HS}]^2}{3} \qquad (17)$$

from which a value of $(2 \pm 1.5) \times 10^{-3}$ for α is obtained upon substitution of the appropriate values of [K], [H], [H_0], [HS] (5.6 molal), t and either k_2 or $5k_a$ from the data of run I-15. In dilute solution the value of the hydroperoxide concentration rapidly drops below that of $2.5\alpha[\mathrm{HS}]^2$ so that equation 13 may be expressed as

$$\ln[\mathrm{H}] = -5k_a t + \ln[\mathrm{H_0}] + \frac{3}{2}\ln\left\{\frac{[\mathrm{H_0}]}{2.5\alpha[\mathrm{HS}]^2} + 1\right\} \qquad (18)$$

(26) N. A. Milas, D. M. Surgenor and L. H. Perry, THIS JOURNAL, 68, 1617 (1946).

The experimental intercept obtained by extrapolation of the k_2 slope may be equated to the last two terms at the right in equation 18. Evaluation of the intercepts for runs I-23 and I-12 gives values of 0.9 and 1.3×10^{-3} for α.

In the partially swept reactions, where initially reaction 8 prevails but the oxygen is not removed and may react with any alkyl radicals formed in reaction 9 by reactions 5 and 6 to form a hydroperoxide, SOOH, $-\mathrm{d}\ \ln\{[\mathrm{H}] + [\mathrm{SOOH}]\}/\mathrm{d}t = k_a$. (It was assumed that SOOH may be treated as ROOH and that $\mathrm{d}[\mathrm{O}_2]/\mathrm{d}t = 0$.) Thus the proposed mechanism and the assumptions above can account for the fact that the observed rates in the partially swept system were about half of those in the swept system.

The extremely slow decomposition in sealed ampoules can be explained in terms of the postulated mechanism with the additional assumptions that the evolution of oxygen is prohibited in a closed system and instead reaction 8 leads to a dimer, D, which effectively lowers the hydroperoxide concentration available for reaction with any alkyl radicals. The dimer would still have peroxidic properties toward iodide ion and would be so determined throughout the observation period. The rate under these circumstances would be a function of the total peroxide concentration, [P], where $[\mathrm{P}] = [\mathrm{H}] + 2[\mathrm{D}]$, and $-\mathrm{d}\ \ln[\mathrm{H}]/\mathrm{d}t = 2k_a$ and $\mathrm{d}[\mathrm{D}]/\mathrm{d}t = k_a k_b[\mathrm{H}]^2/\{[\mathrm{H}] + \alpha[\mathrm{HS}]^2\}$. These equations may be solved to give the relationship

$$[\mathrm{P}] = \alpha[\mathrm{HS}]^2 \ln \left\{ \frac{[\mathrm{H}_0]e^{-2k_a t} + \alpha[\mathrm{HS}]^2}{[\mathrm{H}_0] + \alpha[\mathrm{HS}]^2} \right\} + [\mathrm{H}_0] \quad (19)$$

which cannot be conveniently used. The pseudo first-order rates in Tables IB are of value only for orientation. That the formation of a dimer is not unreasonable was demonstrated by one of the experiments, run I-9, which was initially heated in a sealed tube for 404 hours before being transferred to a swept system in which there was a trace of oxygen being added systematically. The remaining hydroperoxide still had an absorption band appearing at 12 μ, and decomposed at a rate equal to that of the anaerobic system. This observation (similar results were noted qualitatively on dilute solutions) would only be possible if conversion to the dimer occurred in the sealed tube and it could decompose unaffected by the trace of added oxygen. (Run I-10 affords a comparison for the aerobic system.)

An approximate E_a may be calculated for the reaction from data obtained at 86.1° in the helium-swept apparatus: $k_1 = 1.32 \times 10^{-6}$, $k_2 = 3.88 \times 10^{-6}$ sec.$^{-1}$. From the respective values of k_1 at the two temperatures one obtains a value of 30.7 kcal./mole for the E_a of reaction 7. Using the absolute rate equation

$$k = (kT/h)e^{-\Delta H^*/RT}e^{\Delta S^*/R}$$

and assuming that Δv^* is equal to zero for reaction 7 in the expression, $\Delta H^* = E_a - RT + p\Delta v^*$, one obtains the following values: $\Delta H^* = 30.0$, $\Delta F^* = 30.9$ kcal./mole, and $\Delta S^{\ddagger} = -2.3$ cal./deg./mole.

The author wishes to thank the referees for their comments, which were of great benefit in the preparation of the final manuscript.

The Interaction of Purified Anti-β-lactoside Antibody with Haptens[1]

BY FRED KARUSH

RECEIVED FEBRUARY 16, 1957

A study has been made of the combination of purified anti-β-lactoside antibody with the uncharged azo dye p-(p-dimethylaminobenzeneazo)-phenyl β-lactoside by the method of equilibrium dialysis. The extrapolation of the binding curves yields a value of 2.0 for the valence of the antibody. The values of ΔF^0 fall within the same range previously observed for another system involving an anionic haptenic group. The temperature dependence of the binding curves reveals, however, a substantial difference in the values of ΔS^0 and ΔH^0 for the two systems. These differences are related to the absence of a charge in the β-lactoside haptenic group. The heterogeneity of the antibody as shown by the non-linearity of the binding curves can, except in one case, be described by a Gauss error function with a value of 1.5 for the heterogeneity index. The large value of ΔH^0, about -10 kcal./mole of hapten, is interpreted to mean that the R groups of the antibody can form strong hydrogen bonds with the disaccharide portion of the hapten, sufficient to withstand the disruptive effects of competing water molecules. The association constants of a number of sugar derivatives have been evaluated by their inhibition of the dye binding. These results demonstrate in quantitative energetic terms the selective character of the combining region of the antibody with respect to the configuration of the terminal hexoside and the geometry of the glycosidic linkage (α or β), as well as the participation of the non-terminal hexoside in the specific interaction.

In a previous communication[2] we have presented the results of a study of the structural and energetic aspects of the combination of haptens with a purified antibody specific for the haptenic group phenyl-(p-azobenzoylamino)-acetate (I_p). In order to extend our understanding of these aspects of antibody–hapten interaction, it appeared desirable to obtain similar results with an antibody homologous to a different type of haptenic group. The particular differences that were of greatest interest were the absence of a charged group in the new haptenic group and a strong affinity for water in contrast to the uncharged form of the earlier haptenic group.

The choice of p-azophenyl β-lactoside as the haptenic group to be studied was based largely on the investigations of Goebel, Avery and

Babers.[3] Following the demonstration by Avery and Goebel[4] that antibodies were formed against the azophenyl β-glycosides of glucose and galactose which could distinguish between these sugars, these authors investigated the properties of antisera specific for the azophenyl β-glycosides of several disaccharides, maltose, cellobiose, gentiobiose and lactose. This work showed that the homologous antibody was complementary to both hexose units of the disaccharide and sufficiently closely fitted to the contour of the latter to be able to distinguish between a galactose unit and a glucose unit as the terminal hexoside and between the 1,4-α- and 1,4-β-linkages. The use of a disaccharide as the main portion of the haptenic group was also of interest because of its close relationship to the large number of naturally occurring polysaccharide antigens.

To secure the information desired we have studied the combination of purified antibody specific for the *p*-azophenyl β-lactoside group (Lac group) with the uncharged azo dye *p*-(*p*-dimethylaminobenzeneazo)-phenyl β-lactoside (Lac dye) and quantitatively evaluated the competitive effect on this combination of structurally related haptens.

Experimental

Materials.—The compound which was required for the preparation of the immunizing and precipitating antigens and for the synthesis of Lac dye was *p*-aminophenyl β-lactoside. The first step in its synthesis was the preparation of acetobromolactose by the adaptation of a method described for acetobromoglucose.[5] The main difference in the procedures is that the reaction product in our case was suspended in isopropyl ether rather than recrystallized from the solvent because of its relative insolubility. This crude preparation of acetobromolactose was then employed for the synthesis of *p*-aminophenyl β-lactoside in accordance with the procedure of Babers and Goebel.[6] The acetobromolactose was converted to heptaacetyl *p*-nitrophenyl β-lactoside according to the method of Glaser and Wulwek[7] as described by Babers and Goebel. It was found that an improvement in yield was obtained if the reaction was carried out at *p*H 9 for three hours and the *p*H maintained constant by addition of 50% NaOH solution. After one recrystallization from methanol the product melted at 131–133°. It was then deacetylated with barium methylate to yield *p*-nitrophenyl β-lactoside which melted at 259° with decomposition as reported by Babers and Goebel. The reduction of this material was effected by hydrogenation in aqueous solution at a pressure of 45 p.s.i. with 5% Pd on alumina as the catalyst. The product was crystallized from 70% ethyl alcohol and melted at 240°. Recrystallization of the material left the melting point unchanged. The value of $[\alpha]_D$ at room temperature was −35° (*c* 2.5) as compared with $[\alpha]^{27}_D$ −36° reported by Babers and Goebel.[6]

The antigens used in this study were prepared by diazotizing *p*-aminophenyl β-lactoside and coupling to bovine γ-globulin and human fibrinogen to yield Lac-BγG and Lac-HF. The former was employed as the immunizing antigen and was obtained by the method previously described.[2] The human fibrinogen used to prepare the precipitating antigen, Lac-HF, was contributed by the American Red Cross and was further purified by the method of Laki.[8] Some modification of the previously reported procedure[9] for the preparation of azofibrinogen was necessary. The coupling was done at *p*H 10 to keep the product in solution and the reaction mixture was dialyzed *vs.* twenty volumes of 0.01 *M* borate buffer, *p*H 10 for several days in the cold room with daily changes of the outside solution. Prior to its use as a precipitating agent the Lac-HF was diluted in 0.15 *M* NaCl to a concentration of 400 μg. N/ml. and the solution adjusted to *p*H 7.4. This was done at least 24 hours preceding its addition to antiserum. The original solution at *p*H 10 was stored in the frozen state.

The binding experiments were carried out with the Lac dye prepared by coupling diazotized *p*-aminophenyl β-lactoside with dimethylaniline at *p*H 4.1 to give *p*-(*p*-dimethylaminobenzeneazo)-phenyl β-lactoside. The product was separated from the reaction solution by virtue of its low solubility at *p*H 7 and recrystallized twice from 95% ethanol; m.p. 238°. On drying to constant weight *in vacuo* over P_2O_5 at 80° the melting point remained unchanged. However, when the product was subjected to prolonged heating (44 hr.) at 170° there was a weight loss of 2.8%, before evidence of decomposition was observed, compared to a calculated value of 3.1% for a monohydrate. On the basis of this information and its elementary composition, the compound obtained after drying at 80° was considered to be a monohydrate.

Anal. Calcd. for $C_{26}H_{35}O_{11}N_3.H_2O$: C, 53.51; H, 6.40. Found: C, 53.44; H, 6.32.

The absorption spectrum of Lac dye in 0.15 *M* NaCl, 0.02 *M* phosphate, *p*H 7.4 is shown in Fig. 3. The molar extinction coefficient, ε, at the wave length of maximum absorption λ 455 mμ is 2.48×10^4. A minimum occurs at λ 340 mμ with a value of ε of 0.52×10^4.

Of the nine compounds used in the inhibition experiments lactose, galactose, cellobiose and maltose were commercial products of which all but cellobiose were reagent grade. Methyl α-D-galactoside, methyl β-D-galactoside and methyl β-lactoside were generously provided by Dr. N. K. Richtmyer and methyl β-D-glucoside by Dr. H. B. Wood, Jr. The remaining compound, *p*-nitrophenyl β-lactoside, was the intermediate used in the preparation of the corresponding amino compound.

Preparation of Antisera.—The same procedures for injection, bleeding and pooling of sera were employed in the preparation of anti-Lac antisera as were described for the anti-I_p system.[2]

Purification of Anti-Lac Antibody.—The purification of anti-Lac antibody follows the same general procedure which has been presented for anti-I_p antibody.[9] After removal of complement by the BγG–anti-BγG precipitate the anti-Lac antibody was precipitated by the addition of Lac-HF in the amount of 10 μg. N/ml. of serum. The washed specific precipitate was extracted with 25 ml. of a solution containing 0.1 *M* lactose in 0.05 *M* phosphate, *p*H 7.4. The extraction was carried out for one hour at 37° and provided a solution which contained almost all of the originally precipitated antibody. The amount of antigen which was solubilized could be judged from the color of the solution and was quite variable. When the quantity was more than negligible it was removed from the extract by precipitation with 0.8 *M* phosphate, *p*H 7.4, with some loss of antibody. The antibody was then precipitated in an ice-bath by the addition of the quantity of 4 *M* phosphate solution required to give a final concentration of 1.6 *M*. The 4 *M* phosphate solution was a mixture of K_2HPO_4 and KH_2PO_4 whose *p*H was adjusted so that on dilution to 1.6 *M* a *p*H of 7.4 was obtained. The precipitated antibody was dissolved with 24 ml. of 0.05 *M* phosphate and reprecipitated in an ice-bath by the addition of 16 ml. of the 4 *M* phosphate solution. This step was repeated two times and the antibody was then dissolved in 25 ml. of 0.15 *M* NaCl. The solution was dialyzed against 2 liters of 0.15 *M* NaCl in the cold for several days with daily changes of the outside solution. The small amount of precipitate which was formed during the dialysis was removed by centrifugation. The N content of the supernatant was determined by micro-Kjeldahl analysis. Finally, 1% of its volume of 2 *M* phosphate was added to give 0.02 *M* phosphate, *p*H 7.4. The yield of antibody appears to be about 50% of that initially precipitated. A quantitative precipitin analysis with one preparation of purified antibody showed that 144 μg. N/ml. of antibody could be precipitated with Lac-HF from a solution containing 150 μg. N/ml.

Binding Experiments.—The binding of Lac dye by the purified antibody was measured in the specially designed cells and under the same conditions as described for our previous investigation.[2] One ml. of 2.5×10^{-5} *M* antibody,

based on a molecular weight of 156,000, in 0.15 M NaCl, 0.02 M phosphate, pH 7.4, was used in one compartment of the cell and one ml. of dye in the same solvent in the other. In the experiments involving inhibitors these were included in the dye solutions. The dye concentrations measured after equilibration ranged from 0.2×10^{-5} M to 5×10^{-5} M. In calculating the amount of dye bound to antibody correction was made for the dye adsorbed to the cellulose casing. The amount of adsorbed dye relative to the amount bound to antibody ranged from 11 to 22% at 25° and from 6 to 19% at 7°.

Absorption Spectrum.—The absorption spectrum of the Lac dye bound to antibody was determined as previously described.[2] The total concentration of the dye in the solution measured was 1.72×10^{-5} M of which 93% was bound to the antibody present at a concentration of 2.64×10^{-5} M.

Results and Discussion

The Binding of Lac Dye by Antibody.—The binding curves for the combination of Lac dye with its homologous antibody are shown in Figs. 1 and 2 for two different pools of purified antibody. Data

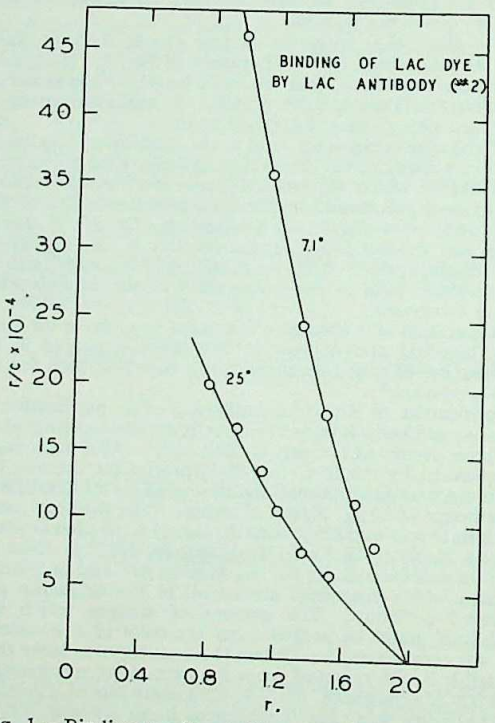

Fig. 1.—Binding results at 25 and 7.1° for the reaction between Lac dye and purified anti-Lac antibody (#2). The points are experimental and the curves are theoretical.

were obtained at two temperatures and the results were plotted in the form of r/c *vs.* r, for reasons previously given,[2] where r is the average number of dye molecules bound per antibody molecule at the equilibrium concentration of free dye c. In agreement with the results of the earlier study the present data allow the unambiguous extrapolation of the binding curves to yield a value of 2.0 for the binding capacity (n) or valence of the antibody. The same result was found with binding curves obtained at 25° with two other pools of purified antibody.

The deviation of the binding curves from linearity reflects the heterogeneity of the purified antibody with respect to its affinity for the Lac dye. It was found previously that such heterogeneity could

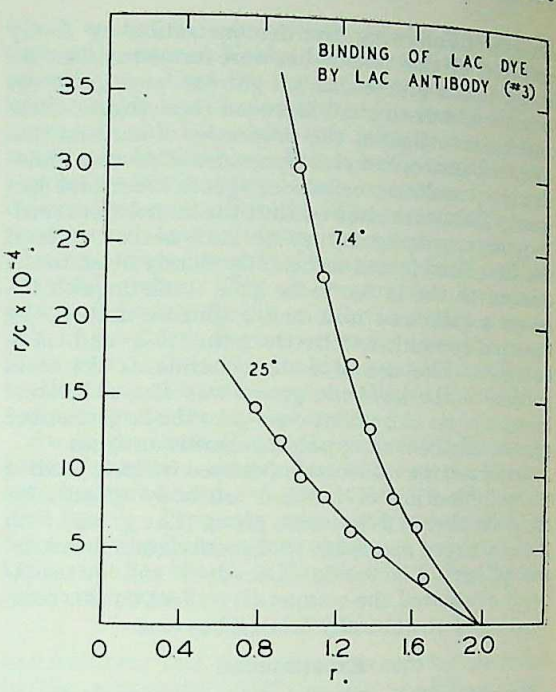

Fig. 2.—Binding results at 25 and 7.4° for the reaction between Lac dye and purified anti-Lac antibody (#3). The points are experimental and the curve for 25° is theoretical.

be adequately described by a Gauss error function in terms of the free energy of binding. Except for the measurements at 7.4° the present data can be satisfactorily fitted by such a function with a value of 1.5 for the heterogeneity index σ. The curves shown for the three sets of points involved are theoretical curves calculated assuming values of σ and n of 1.5 and 2.0, respectively. The average value of the association constant, K_0, which must also be known for the calculation, was taken as equal to the experimental value of r/c for r equal to 1. The reason for the failure to describe adequately the data at 7.4° with σ equal to 1.5 is not clear. It is of interest to note that the heterogeneity of the purified antibody specific for the Lac group is considerably less than that observed previously with the anionic hapten. In the latter case a value of 2.3 for σ was required to fit the experimental results.

The values of the thermodynamic quantities shown in Table I were calculated in the usual way using the indicated association constants. Comparison with our earlier results shows that the present values of ΔF^0 fall within the range observed before in spite of the considerable difference in the chemical nature of the hapten groups under comparison. This difference does, however, manifest itself in the comparative values of ΔS^0 and ΔH^0. Whereas the anionic hapten gave a value of ΔS^0 of about zero for the association reaction, the combination of the Lac dye with its homologous antibody yields a substantially lower value, −9 e.u. per mole of dye. Such a negative value is not unexpected in view of the fact that it refers to an association reaction, although the loss of translational and rotational degrees of freedom is probably not the only contribution to entropy change for the process of combina-

tion. Since complex formation between the anionic dye and its antibody most probably involves charge neutralization, the difference in the entropy results may be reasonably attributed to the positive entropy contribution which arises from the release of ion-bound water on ion-pair formation.

TABLE I

THERMODYNAMIC RESULTS FOR THE BINDING OF LAC DYE BY PURIFIED ANTI-LAC ANTIBODY[a]

Plac no.	n	σ	25° $K_0 \times 10^{-4}$, l./mole	25° $-\Delta F^0$, kcal./mole	7° $K_0 \times 10^{-4}$, l./mole	7° $-\Delta F^0$, kcal./mole	$-\Delta H^0$, kcal./mole	ΔS^0, e.u./mole
2	2.0	1.5	15.7	7.09	44.8	7.25	9.7	−8.8
3	2.0	1.5	10.4	6.85	29.0	7.01	9.7	−9.5

[a] The lower temperatures for Plac #2 and Plac #3 were 7.1 and 7.4°, respectively. The value of 1.5 for σ applies, in the case of Plac #3, only to the results obtained at 25°. The values of the thermodynamic functions are expressed as per mole of Lac Dye.

The large negative value of ΔH^0, about −10 kcal./mole of hapten, is of considerable interest, particularly since by far the greatest portion of it, as will be seen from the inhibition results, is due to the interaction between the disaccharide portion of the hapten and the antibody. This result emphasizes the capacity of the antibody to provide attractive interactions, for this type of molecule, which in their total energetic effect greatly exceed the competitive interactions between solvent molecules and the disaccharide. The latter interactions, which are primarily hydrogen bonding, are of considerable magnitude as is evident from the high solubility of sugars, including lactose, in aqueous solution. We surmise from these considerations that the R groups of antibody, and of proteins in general, can form hydrogen bonds with hapten, and with each other, of such stability as to withstand the disruptive competitive influence of water molecules.

The similarity in the ΔF^0 values for the two kinds of haptens in spite of the large difference in ΔH^0 is noteworthy. The reason for this may be, as was originally suggested by Pauling,[10] that the process of antibody formation and release into the circulation provides an effective selection of only those antibody molecules whose affinity does not exceed some maximum value. A lower limit for the affinity could, of course, result from the procedure employed to isolate the antibody, namely, specific precipitation.

Absorption Spectrum of Bound Dye.—It is evident from the spectra of bound Lac dye and free dye shown in Fig. 3 that complex formation in this system leads to a spectral shift similar to that observed in our earlier study. This consists of an increase in the molar extinction coefficient, ϵ, at the wave length of maximum absorption, accompanied by a broadening of the absorption band. Although the effect is less pronounced in the case of the Lac dye than in the case of the anionic dye, we interpret the spectral shift of the bound Lac dye to be due, as before, to the formation of a hydrogen bond between the azo group of the dye and a proton-donating group of the antibody.

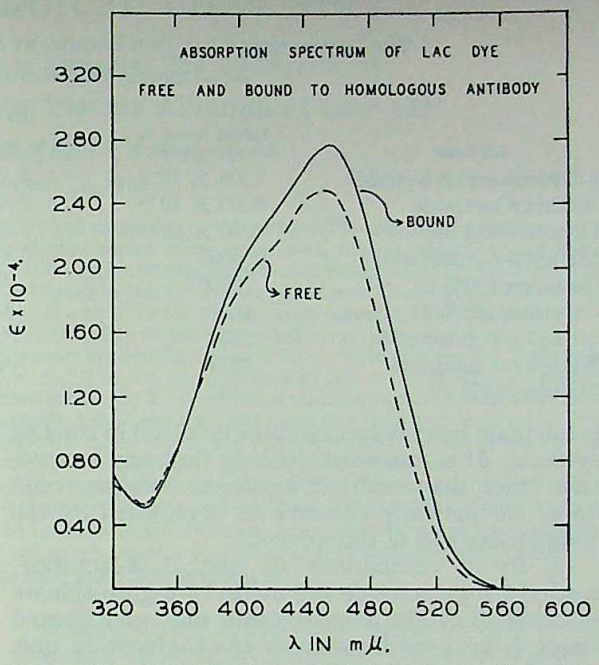

Fig. 3.—The absorption spectra of Lac dye free and bound to anti-Lac antibody.

Inhibition by Structurally Related Haptens.—Further information about the scope and selectivity of the combining region of the antibody has emerged from inhibition experiments. These experiments were designed to give the association constants for combination with antibody of the compounds listed in Table II. The values were obtained in an indirect manner, namely, by measuring the capacity of these colorless compounds to inhibit the binding of Lac dye by the antibody. The calculation of the constants utilized equations 4 and 5 of our previous paper. Several preliminary experiments were done to establish the concentrations of the inhibitors which would yield the most accurate results. The concentrations which were finally selected are shown in Table II. Except for methyl β-D-glucoside and maltose, they gave a degree of inhibition which minimized the uncertainty in the calculation of the average association constants due to experimental error and the heterogeneity of the antibody.

A close examination of Table II allows a number of interesting conclusions to be drawn regarding the combining region of the antibody:

(1) The fact that the ΔF^0 value for *p*-nitrophenyl β-lactoside is only slightly greater (0.4 kcal.) than that for the Lac dye indicates that the size, or volume, of the energetically effective region is probably not much larger than that required to accommodate this hapten. This inference agrees well with our earlier estimate of the size of the combining region specific for the anionic hapten group.

(2) The large negative values of ΔF^0 for methyl β-lactoside and lactose demonstrate that the interaction between the disaccharide portion of the haptenic group and the antibody provides the dominant contribution to the stability of the complex. From this conclusion we further deduce, as has already been mentioned, that hydrogen bonding

THE INHIBITION OF LAC DYE BINDING BY STRUCTURALLY RELATED MOLECULES AT 25°

p-(*p*-Dimethylaminobenzeneazo)-phenyl β-Lactoside

Inhibitor	Initial concn. in dye soln., moles/l.	Plac #12 (K_0 = 13.4 × 10^4, $-\Delta F^0$ = 7.00 kcal./mole) $K_I \times 10^{-4}$, l./mole	Plac #12 $-\Delta F^0$, kcal./mole	Plac #13 (K_0 = 11.9 × 10^4, $-\Delta F^0$ = 6.92 kcal./mole) $K_I \times 10^{-4}$, l./mole	Plac #13 $-\Delta F^0$, kcal./mole
p-Nitrophenyl β-lactoside	1.00 × 10^{-4}	6.75	6.60	7.26	6.63
Methyl β-lactoside	2.00 × 10^{-4}	2.02	5.88	2.38	5.98
Lactose (64% β)	4.00 × 10^{-4}	1.10	5.52	....	..
Methyl β-D-galactoside	0.0600	0.00747	2.56	0.0114	2.81
Galactose (69% β)	.0600	.00457	2.27	....	..
Cellobiose (66% β)	.100	.00275	1.96	....	..
Methyl α-D-galactoside	.200	.00134	1.54	0.00130	1.52
Methyl β-D-glucoside	.200	.00051	0.97	.00059	1.05
Maltose (64% β)	.200	.00033	0.70	....	..

is the main intermolecular force involved in the Lac system. It seems most unlikely that any interaction other than multiple hydrogen bonding could be as energetically effective as is required by the competitive role of the solvent.

(3) By a comparison of methyl β-lactoside, methyl β-D-galactoside and methyl β-D-glucoside we estimate that the β-galactoside unit contributed about 5 kcal./mole whereas the β-glucoside unit contributes only 3 kcal./mole. Thus the terminal hexoside is the dominant one of the two hexosides of the haptenic group although both play a major energetic role. These conclusions are entirely consistent with those drawn by Goebel, Avery and Babers[3] from their observations on cross-reactivity and the inhibition of specific precipitation in their disaccharide systems.

(4) The sharp specificity of the antibody with respect to the configuration of the terminal hexoside is clearly demonstrated by the difference of 3.6 kcal. between lactose and cellobiose. These sugars differ only in the reversal of the positions of the hydrogen atom and the hydroxyl group on carbon atom 4 in the terminal hexoside, and yet their association constants differ by a factor of 400. The difference in free energy is probably compounded of two factors. One would be the loss of a hydrogen bond and the other steric repulsion arising from the presence of an hydroxyl group in a position for which, in the original antigenic group, the antibody needed to provide accommodation only for the much smaller hydrogen atom.

(5) Finally, the specificity of the antibody with respect to the configuration of the linkage between the hexosides, α or β, may be noted. This is shown by the lower affinity of methyl α-D-galactoside compared to methyl β-D-galactoside and by the comparison between maltose and cellobiose. In both instances the homologous β-configuration is more stable than the α-configuration by about one kcal.

Acknowledgment.—I am indebted to Mr. Robert Marks for carrying out the organic syntheses and antibody purification and to Mrs. F. Karush for the binding and spectrophotometric measurements.

Electrophoretic Behavior of Bovine Plasma Albumin at Low pH[1]

BY KOICHIRO AOKI AND JOSEPH F. FOSTER

RECEIVED DECEMBER 15, 1956

Electrophoresis of bovine plasma albumin was carried out in the pH range 2.0 to 4.7 using 0.2% solutions mainly at 0.02 ionic strength chloride and at 0°. Some experiments were conducted under other conditions, that is, changing the ionic strength (0.10) or temperature (25°), or changing the medium (0.02 ionic strength acetate and thiocyanate). In 0.02 ionic strength chloride and at 0°, there were two boundaries (F and N forms) in the pH region between 3.5 and 4.5, and the percentage composition changed continuously with pH. At pH 4.0 N and F forms existed approximately in equal amounts. The results are explained by an equilibrium, $N + 3H^+ \rightleftarrows F$. Reversibility of the isomerization process was demonstrated. Thermodynamic parameters of the reaction were calculated by comparing results at 0 and 25°. Values when the N form is changed to the F form are: $\Delta F^0 = -15.0$ kcal./mole, $\Delta H^0 = +3.0 \pm 1.5$ kcal./mole and $\Delta S^0 = +66 \pm 4$ e.u./mole. The magnitude and the sign of ΔH^0 is similar to that found calorimetrically by Gutfreund and Sturtevant. The half-time of the N–F equilibrium could not be determined in the present study, but it was deduced to be less than two hours. Under other experimental conditions similar results were obtained except for minor shifts in the equilibrium constant and possibly in the number of hydrogen ions involved. Charge–mobility curves were drawn at the two ionic strengths. It was found that the slopes of these curves changed at pH 3.5, indicating that the electrophoretic behavior was different above and below this pH. Radius of bovine plasma albumin was calculated from electrophoretic mobility and Z value using Henry's equation. It was 33 ± 2 Å. above pH 3.5 at the two ionic strengths for both N and F forms, agreeing with previous estimates. With decrease of the pH from 3.5 the molecule expanded. At pH 2.0 the radius was 50 Å. at 0.02 ionic strength and 43 Å. at 0.10 ionic strength. The isoelectric point varied with the medium and its ionic strength.

Introduction

It has been known that serum albumin is not electrophoretically homogeneous in the pH region near 4; that is, two or more boundaries exist in the electrophoretic pattern. Luetscher[2] observed that crystallized human and horse serum albumins showed two electrophoretic boundaries in acetate buffer of pH 4.0 and ionic strength 0.02. Neurath and co-workers[3] stated that, while horse serum albumin migrated with a single boundary in pH regions remote from the isoelectric point, such as 7.6 and 3.6, the boundary became complex as the pH of the solution approached that of the isoelectric point. More recently, Longsworth, *et al.*,[4] made an electrophoretic study of bovine plasma albumin (BPA) associated with anion binding to that protein. They obtained heterogeneous boundaries in pH regions near the isoelectric point. Alberty[5] observed that BPA was resolved into three components in 0.15 *M* sodium chloride between pH's 4.0 and 4.5. Alberty and co-workers[6,7] made extensive studies of the heterogeneity of proteins by the "reversible boundary spreading" method at their isoelectric points. Furthermore, the heterogeneity of human serum albumin in the acidic region was observed by Miller, *et al.*,[8] and by Saifer, *et al.*[9]

Independently it has been suggested that serum albumin expands at low pH. Both Scatchard[10] and Tanford[11] suggested such expansion to account for the character of the titration curve of this protein. Measuring viscosity and optical rotation of BPA, Yang and Foster[12] interpreted the behavior at low pH in terms of molecular expansion. More recently Tanford and co-workers[13] suggested the existence of an additional intermediate form, the "expandable" form.

The object of the present investigation was to gain more insight into the heterogeneity of BPA as related to the molecular expansion of this protein. The electrophoretic behavior of BPA was investigated over a wider pH region, 2.0 to 4.7. Experiments were carried out mainly in chloride media of 0.02 ionic strength and 0°. Other experiments were carried out in chloride media changing the temperature (25°) or the ionic strength (0.10). Electrophoresis was also conducted in other media, such as acetate and thiocyanate of 0.02 ionic strength.

Experimental

Materials.—Pentex bovine plasma albumin, Lot No. A 1201, was used without further purification. All the reagents used, except thiocyanic acid, were of C.P. grade. Thiocyanic acid was obtained by passing potassium thiocyanate solution through cationic ion exchanger (IR-120) in the hydrogen form.[14]

Procedure.—Electrophoresis was carried out at 0° in a Tiselius type electrophoresis apparatus, Model 35 of the Perkin–Elmer Corporation, equipped with the schlieren scanning system. The pH of the sample was measured with a Beckman Model G pH meter. Concentration of BPA was determined spectrophotometrically using a Beckman Model DU spectrophotometer. Extinction of BPA in distilled water was assumed to be $E^{1\%}_{1\,cm.}$ 6.67 at 279 mμ.[15] Electri-

cal conductivity was measured by a conductivity bridge, Model RC 16 of the Industrial Instruments, Inc. The *p*H values described in this paper were obtained by measuring at room temperature the *p*H of the protein solution after dialysis. The conductivity of the protein solution was measured at 0°.

Three different supporting media were used in the present investigation. They were (1) mixtures of hydrochloric acid and sodium chloride, (2) acetic acid and sodium acetate, and (3) thiocyanic acid and potassium thiocyanate. The total ionic strength of the media was kept constant, 0.02 or 0.10. Dialysis was carried out in a cold room at 1–2° for at least 15 hours with continuous mechanical agitation. A protein concentration of 0.2% was employed when the ionic strength was 0.02 for the reason described in the next section. For analysis, patterns were enlarged approximately eight diameters and traced carefully on graph paper. Resolution of components was carried out in the customary manner by sketching Gaussian peaks in such a manner that they summed to yield the observed gradient curve. Areas were measured using a planimeter and the percentage composition obtained from relative areas on the assumption that each component had the same refractive increment.

Results

Effect of Protein Concentration and Determination of Limiting Mobilities.—Since most of the studies were conducted at relatively low ionic strength (0.02) and in poorly buffered media (chloride) one must be concerned with the possibility of salt and *p*H gradients which would vitiate interpretation of the patterns. The only practical criterion of such effects appears to be the degree of enantiography of the patterns obtained on the rising and descending sides. At 0.5% protein and above, in the low ionic strength media, patterns were far from enantiographic, the rising boundary being very sharp, the descending boundary broad and diffuse. At 0.2% boundaries were reasonably enantiographic, in general showing the same number of boundaries and very nearly the same relative areas under such boundaries. At 0.05% results were qualitatively very similar to those at 0.2% but areas could not be estimated with sufficient precision. Mobilities could, however, be determined with no difficulty.

The relationship between electrophoretic mobilities and protein concentration was studied in a mixture of hydrochloric acid and sodium chloride at ionic strength 0.02, *p*H 2.1 and temperature 0°. As is seen in Fig. 1, the difference in mobility calculated from the ascending side and that from the descending one became greater with increasing protein concentration. When the protein concentration was 0.5% or greater, a diffuse and asymmetric boundary was obtained on the descending side. In this case the centroidal ordinate[16] was used to calculate the mobility. It was found that the mobility value U_0, mobility corresponding to zero protein concentration, could be given by the following empirical equation at any protein concentration in 0.02 chloride ionic strength at 0°

$$U_0 = U_D + \frac{2}{3}(U_A - U_D) \qquad (1)$$

where U_D and U_A represent the electrophoretic mobility found on the descending side and that found on the ascending side, respectively. This relation was found to hold at *p*H 2.6 and 3.0 as well as at *p*H 2.1. At *p*H 3.5 and above the concentration dependence was less pronounced and U_0 could be calculated equally well by eq. 1 or by simple averaging of U_A and U_D.

***p*H–Mobility Curves.**—Figure 2 shows typical electrophoretic patterns obtained in chloride at 0.02 ionic strength. Below *p*H 3.5 and above 4.6 there was a single boundary; between 3.5 and 4.6 there were, in general, two. Strictly speaking, in the narrow *p*H range between 3.80 and 3.95 there were three boundaries. At *p*H lower than 3, where the mobility calculated from the migration velocity in the ascending limb was appreciably different from that calculated from the descending limb, the empirical eq. 1 was used to give the mobility value U_0 at zero protein concentration. Mobility values are shown in Table I. The *p*H–mobility curve is shown in Fig. 3. In the *p*H region above 3.5 there are two curves. When three components existed, mobilities of the two faster components are shown in parentheses in Table I, and mobility of the slowest component and the mean of the two faster components were plotted.

Electrophoretic data obtained in chloride media of 0.10 ionic strength are shown in Table II. In this case the pattern was single below *p*H 3.5 and was not single between *p*H 3.5 and 4.6. In the latter *p*H region the pattern usually consisted of three components, similar to those obtained by Alberty.[5]

Electrophoretic data at 25° and at 0.02 chloride ionic strength are shown in Table III. Below *p*H

in the acetate media.[18] In thiocyanate the resolution was poor, but two boundaries were separated after prolonged migration. In thiocyanate the migration was slow, therefore the difference in the electrophoretic mobilities of two components was smaller. This is doubtless the reason that a longer time was necessary to attain resolution. Below *p*H 3.2 and above *p*H 4.3 there was a single boundary. In the region between these two *p*H's there were two boundaries.

Percentage of the Two Components.—As was described above, the relative area of each component changed continuously with *p*H within a particular *p*H range. Percentages of the areas of each component were calculated on the ascending pattern. When three boundaries were observed, the ratio of the sum of areas of the faster two boundaries to that of the slowest one was taken. The results are shown in Tables I to IV. The results in chloride at 0.02 ionic strength and at 0°, and those at the same ionic strength at 25°, are plotted in Fig. 4.

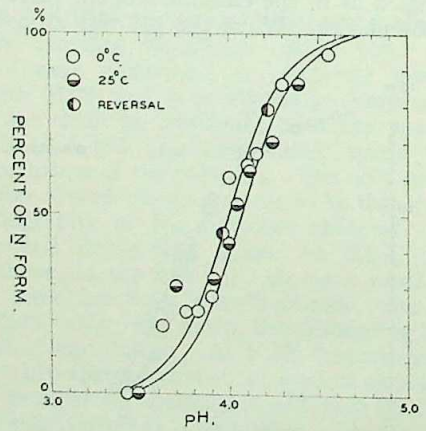

Fig. 4.—Relation between *p*H and the % of the area, 0.02 ionic strength chloride at 0° and 25°.

Discussion

Equilibrium between Two Forms of BPA.—In all of the experiments conducted the percentage composition was found to change continuously with *p*H over the *p*H range in which two or more components existed. This range depended primarily on the medium employed, slightly on temperature and ionic strength. If we term the slow or normal electrophoretic form N and the faster form F, the percentage composition is found to conform closely in all cases to an equilibrium of the form

$$N + nH^+ \rightleftharpoons F$$

Further, the value of n is in all cases between 2 and 3, usually closer to 3. It is inferred that there is an equilibrium of this nature between two discrete forms of the protein which differ in hydrogen-ion binding by approximately three ions. The results in various media are summarized according to this interpretation in Table V which gives the value of n as well as the *p*H of the mid-point of the transition curve (*p*H at which two forms exist in equal amounts). The equilibrium constant corresponding to

$$K = \frac{[F]}{[N][H^+]^n}$$

is also given in each case.

TABLE V

CONSTANTS FOR N–F EQUILIBRIUM

Conditions	n	Mid-point	K
0.02 Cl⁻, 0°	3	4.0	$10^{12.0}$
.02 Cl⁻, 25°	3	4.07 ± 0.03	$10^{12.2 \pm 0.1}$
.10 Cl⁻, 0°	3	4.05	$10^{12.15}$
.02 Ac⁻, 0°	2	4.1	$10^{8.2}$
.02 SCN⁻, 0°	3	3.75	$10^{11.1}$

Recently, Phelps and Cann[20] observed two electrophoretic components in BPA at *p*H near the isoelectric point and noted further that the relative proportion of faster form increased, at constant *p*H, when part of the chloride ion was replaced by acetate. This phenomenon is explained readily by our results. In chloride media the two components existed in equal amounts at *p*H 4.0 and they followed the three hydrogen ion equilibrium. In the acetate media the two components existed in equal amounts at *p*H 4.1 and followed the two hydrogen equilibrium. Therefore when part of chloride ion is replaced by acetate at any *p*H above 3.8 the area of the faster moving boundary increases.

Reversibility of the Process.—To observe whether or not the transition process is reversible the following experiment was carried out. BPA solution of *p*H 2.11, consisting of hydrochloric acid and sodium chloride, was prepared and stored in a cold room about 24 hours. Then by adding the proper volume of sodium hydroxide, the *p*H of the protein solution was changed to around 4.0. The final solution had 0.02 ionic strength and 0.2% protein concentration. After dialysis

(18) The slower moving boundary in chloride media around *p*H 4.5 separated into two after a longer migration as was described before.[19] This phenomenon was not observed in acetate media at the same *p*H.

(19) K. Aoki and J. F. Foster, THIS JOURNAL, 78, 3006 (1956).

(20) R. A. Phelps and J. R. Cann, *ibid.*, **78**, 3539 (1956). While there is qualitative agreement between their results and ours, there does appear to be a serious quantitative discrepancy. Thus their patterns at *p*H 4.7 in 0.025 ionic strength chloride are complex whereas we find only one boundary under such conditions. In a private communication Dr. Cann has informed us that the protein concentration employed in their published experiments was 1%. He further states that they have obtained less complex patterns in subsequent experiments at lower concentration.

in a cold room overnight, the protein solution was analyzed electrophoretically. Electrophoretic mobility and relative area of the two components, with the experimental condition, are shown in Table VI. These data are plotted in Figs. 3 and 4. It is observed that the data obtained in this experiment are the same as those obtained on the fresh BPA solution. This means that the transition process is reversible, at least insofar as electrophoretic behavior is concerned.

TABLE VI

DATA OF THE REVERSAL EXPERIMENT

pH		Mobility, cm.²/v. sec. × 10⁵		Area, %		Exptl. condition
Initial	Final	Slow	Fast	Slow	Fast	
2.11	→ 3.96	+3.5	+4.8	45	55	Kept at pH 2.11 in a cold room for 23 hr. and dialyzed 20 hr.
2.11	→ 4.22	+2.3	+3.6	79	21	Kept at pH 2.11 in a cold room for 23 hr. and dialyzed 24 hr.

Thermodynamic Parameters of the N–F Transition.—It is observed in Fig. 4 that the equilibrium was shifted slightly to a higher pH with rise of the temperature. The shift of the mid-point resulting from a rise of 25 degrees was 0.07 ± 0.03 pH unit. Assuming the three hydrogen equilibrium, the equilibrium constant K was calculated to be $10^{12.0}$ at 0° and $10^{12.2 \pm 0.1}$ at 25° as is shown in Table V. The free energy change is

$$\Delta F^\circ = -RT \ln K = -15 \text{ kcal./mole. (at } 0^\circ)$$

Enthalpy change is

$$\log \frac{K_0}{K_{25}} = -\frac{\Delta H^\circ}{2.303R}\left(\frac{1}{T_0} - \frac{1}{T_{25}}\right)$$

$$\Delta H^\circ = +3.0 \pm 1.5 \text{ kcal./mole}$$

Entropy change is

$$\Delta H^\circ = \Delta F^\circ + T\Delta S^\circ$$

$$\Delta S^\circ = +66 \pm 4 \text{ e.u./mole}$$

The enthalpy of formation of side-chain hydrogen bonds in protein has been estimated as −5 to −10 kcal., the entropy as −20 to −30 e.u.[21] On the basis of the observed third-order dependence on hydrogen ion and the calculated entropy change it is tempting to suggest the transition as involving rupture of three intramolecular hydrogen bonds by protons. The enthalpy of the reaction, while small, is strikingly similar to that found calorimetrically by Gutfreund and Sturtevant.[22] They observed that 3.1 kcal./mole of heat was absorbed when the pH of BPA was changed from 4.5 to 3.4. These two pH values correspond to the practical extremes of the transition in our experiments. They also stated that the process is reversible, had a half-time of 2.5 to 3 minutes, and is first order with respect to protein concentration.

Half-time of the Transition Reaction.—It was observed that the electrophoretic pattern was not affected by the time of dialysis; that is, when the time of dialysis was changed between 19 and 75 hours in 0.02 ionic strength and at 0°, the pattern was not changed. When the medium of HCl–NaCl was used, prolonged dialysis was necessary because of the poor buffering.

In an attempt to estimate the rate of attainment of the N–F equilibrium electrophoresis of BPA was carried out without dialysis in the acetate buffer. The electrophoresis was conducted directly after the protein was dissolved in the buffer solution at pH 4.11 and 0.02 ionic strength. A picture taken two hours after dissolving the protein, however, showed the same resolution as obtained on a sample at the same pH and ionic strength and dialyzed 18 hours. It seems that the N–F equilibrium is completed in a shorter time than two hours, hence is too rapid to study by the electrophoretic technique.

It has been realized that no resolution of boundaries will occur in moving boundary transport experiments, electrophoresis or sedimentation, where two or more components are in an equilibrium which is established rapidly compared with the differential rate of migration. A single boundary will be observed which moves with the weight-mean velocity of its components, and which spreads more rapidly than is accounted for by diffusion. Some discussions have been given[23–25] on this problem. Accordingly, the fact that the two forms were resolved electrophoretically tends to indicate the transition reaction to be slower than that of Gutfreund and Sturtevant.[22] As there is no sufficient theory applicable to the present system, the following experiment was conducted[26] to see whether or not the pattern was affected by the re-equilibration of the system. Protein solution of the same pH and ionic strength was electrophoretically analyzed changing the current density. BPA solution at pH 4.08 and 0.02 ionic strength was analyzed with different currents of 2.2, 1.1 and 0.4 ma. Pictures were taken when the same number of coulombs had passed, that is, at 6,000 sec. in the 2.2-ma. run, at 12,000 sec. in the 1.1-ma. run, and at 33,000 sec. in the 0.4-ma. run. These runs yielded the same mobilities and the same area distribution. Results are shown in Table VII. The picture taken in the 0.4 ma.-run was slightly broader than that in 2.2-ma. run.

TABLE VII

EFFECT OF CURRENT DENSITY ON ELECTROPHORESIS

pH	Mobility, cm.²/v. sec. × 10⁵		Area, %		Voltage gradient, v./cm.
	Slow	Fast	Slow	Fast	
4.08	+4.6	+3.1	75	25	5.80
4.08	+4.6	+3.1	73	27	2.90
4.08	+4.5	+3.0	72	28	1.05

Although it is not known whether this broadening is more than expected only by diffusion, the value of the per cent. of area agrees with the other results

within experimental error. This indicates the area distribution was not disturbed seriously by the re-equilibration in the present system.[28]

The Third Component.—As was described above, there were three boundaries in the *p*H region between 3.80 and 3.95 at 0.02 chloride or acetate ionic strength and at 0°. There were three boundaries over a wider *p*H region at higher ionic strength or at room temperature. Even when the BPA was dissolved and dialyzed in a cold room, there were three components in this particular *p*H region. This boundary probably was not caused by thermal convection.[30]

It has been observed by the ultracentrifuge[32] and by light scattering[33] that BPA aggregates under some conditions. BPA has more tendency to aggregate at higher ionic strength and at lower *p*H. Aggregation of BPA was demonstrated by the above techniques in media, the ionic strength of which was more than 0.1. Kronman, *et al.*,[33] observed the effect of ionic strength on the aggregation of BPA at *p*H around 3. There is hence some possibility that the third component may be aggregated form. Ultracentrifuge runs were made at 0.02 ionic strength and at *p*H 3.85 both at room temperature and around 6°. There was a single boundary with a minor faster boundary amounting to only a few per cent. This minor boundary in the ultracentrifuge pattern is interpreted as the "dimer impurity" which exists in a wider *p*H region. Therefore the third component is not the aggregated form.

Another possibility is that the third component may be the denatured form. Levy and Warner[34] studied the effect of *p*H on the denaturation of BPA, and found that the denaturation velocity was maximum in the *p*H region between 3.5 and 4.0 at 46.2°. It seems probable that this is not the explanation since the component was present even when care was taken not to expose the protein solution to temperatures above 2°.

It seems probable that the third component is real and may in fact represent an intermediate in the transition.[28]

Calculation of the Net Charge of BPA.—The charge Z at a particular *p*H is governed by the total ion binding, *i.e.*, both cations and anions. The number of hydrogen ions bound may be determined from the titration curves of Tanford, *et al.*,[35] or of Foster and Sterman.[15] Chloride binding data are available from the work of Coleman,[36] Carr[37] and Alberty and Marvin.[38] Since it is known that sodium ion does not combine,[39,40] or at most combines only very slightly,[41] to BPA the net charge below the isoelectric point is given by the difference between hydrogen ion binding and chloride binding. The two sets of data on hydrogen ion binding agree reasonably well; the chloride ion binding data are not so complete and not in such good agreement and hence constitute the main uncertainty in calculation of net charge.

Coleman's studies were conducted with bovine mercaptalbumin and chiefly at the isoionic point. According to his results the chloride binding may be calculated under a given set of experimental conditions through the equation

$$\nu_{x^-} = \sum \frac{k_i n_i C_{x^-} \exp(2Zw)}{1 + k_i C_{x^-} \exp(2Zw)} \qquad (2)$$

where ν_{x^-} represents the number of anion x^- bound to one BPA. C_{x^-} is the molar concentration of the anion. Z is the net charge and n_i is the number of groups with intrinsic constant of k_i. w is a function expressed as

$$w = \frac{e^2}{2DkT}\left(\frac{1}{b} - \frac{\kappa}{1 + a\kappa}\right) \qquad (3)$$

where e, D, k and T, represent the electronic charge, dielectric constant, Boltzmann's constant and the absolute temperature, respectively. b and a are the radius of the protein and the exclusion radius of the protein. κ is the Debye–Hückel function expressed as

$$\kappa = \sqrt{\frac{8\pi e^2 N}{1000DkT}}\sqrt{\mu} \qquad (4)$$

where N and μ represent Avogadro's number and the ionic strength, respectively. At 25° κ is

(28) While this result would seem to justify the quantitative deductions we make with respect to the equilibrium between, and properties of, the N and F forms, the important question of why re-equilibration is not serious remains unanswered. This is especially true in light of the earlier mentioned experiment which indicates the half-time for the transition to be much shorter than two hours (possibly approximately 30 minutes). The theory of Gilbert and Jenkins[25] would offer a possible explanation if the equilibrium were of the nature A + B ⇄ C, but this seems most improbable. Another explanation which we have considered is that the boundaries are stabilized by a *p*H gradient arising in electrophoretic separation. This seems doubtful on two grounds: (1) in such case the observed enantiography would not be expected; (2) resolution is very similar in the very poorly buffered chloride systems and in the somewhat better buffered acetate systems. Dr. Charles Tanford has suggested to us that resolution might conceivably be explained along the lines of the Gilbert–Jenkins theory if the transition were actually stepwise, involving one or more intermediates. This suggestion is of great interest to us because we had already reached the conclusion that the transition must indeed be stepwise, probably involving three intermediate forms.[29] If this is true, it must be considered that the thermodynamic parameters given herein refer to some composite of the separate steps rather than to any one step.

(30) The heat H developed in the cell by the current is expressed by

$$H = i^2/q^2k \text{ watt/cm.}^3$$

where i is the current, q is the cross-sectional area of the cell, and k is the specific conductivity. According to Alberty[31] experience has shown that when the thermostat temperature is about 1°, the maximum power which might be dissipated in the electrophoresis cell without causing convection at the usual protein concentration is about 0.15 watt/cm.³. In the present study the H value was 0.08 at these *p*H's. Therefore it seems probable that there was no convective disturbance.

0.47×10^7 at 0.02 ionic strength, and 1.03×10^7 at 0.10 ionic strength. Using these values of κ and taking a as 30 Å.[42] and b as 32.5 Å., w is calculated at 25° to be 0.053 at 0.02 ionic strength and 0.035 at 0.10 ionic strength. Again in Coleman's equation, constants are

$n_1 = 1, n_2 = 8, n_3 = 18, k_1 = 2400, k_2 = 100$ and $k_3 = 3.3$

Using eq. 2, a relation between Z and ν_{Cl^-} is obtained. Since $Z = \nu_{H^+} - \nu_{Cl^-}$, and since ν_{H^+} at a particular pH is given by the titration curve, a curve relating ν_{Cl^-} and pH is obtained. If this chloride binding curve is perfectly correct, the pH at which Z is zero should agree with the isoelectric point found in the present study. Actually there was some discrepancy between the experimental isoelectric points and those calculated, amounting to approximately three charge units and nine units at 0.02 and 0.10 ionic strength, respectively. Accordingly, the entire chloride binding curves were increased by 3 and 9 chloride ions in the two cases. The resulting Z values are given in Tables I and II and are employed in further calculations below.[44]

Charge–Mobility Curve.—Using the pH–mobility curve and the pH–charge curve, the charge–mobility curves were drawn for cases of 0.02 and 0.10 ionic strengths. The charge–mobility curves in the pH region above 3.5, where two components exist, were determined in the following way. In this pH region at 0.02 ionic strength and room temperature, only a single boundary was obtained in the ultracentrifuge pattern.[45] This means that the F and N forms have similar size and different charge. The Z values shown in Tables I and II are the average ones. From these values the net charge of each form, F and N, was found, assuming that the difference in net charge of the two forms is three and that the chloride ion binds in the same way to the two forms, and considering that average Z is calculated using the charge of each form and its percentage in the electrophoretic pattern. The Z values of each form thus calculated are shown in parentheses in Tables I and II. The mobility values of each form were plotted against the Z values of each form. As is seen in Fig. 5 these plots lie on a common straight line, showing that the assumption that the charge difference in the two forms is three is probably right. This is additional evidence that the equilibrium is $N + 3H^+ \rightleftarrows F$. Charge–mobility curves over the whole pH region are shown in Fig. 6. It is seen that the relation between charge and mobility is linear above pH 3.5 but not below that pH. This indicates that the radius of BPA is constant above pH 3.5 but increases at lower pH, in accord with previous conclusions.

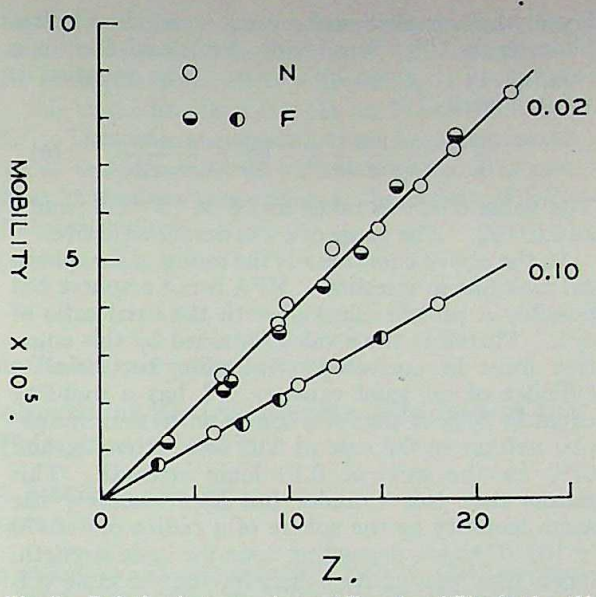

Fig. 5.—Relation between charge (Z) and mobility in the pH region above 3.5.

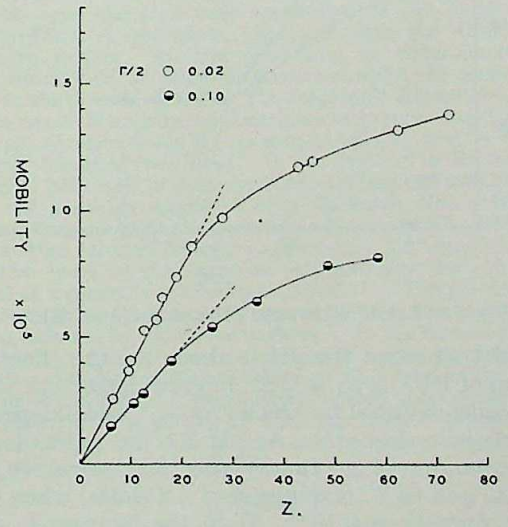

Fig. 6.—Relation between charge (Z) and mobility in the whole pH region.

Calculation of the Radius of BPA.—By use of Henry's equation[46] the radius of BPA was calculated from electrophoretic mobility data and Z values. Henry's equation is

$$Q = \frac{6\pi\eta r(1 + \kappa r + \kappa r_i)}{f(\kappa r)(1 + \kappa r_i)} u \qquad (5)$$

where, Q is the charge (coulomb per molecule), r, the radius of molecule (cm.), r_i, the average radius of electrolyte ion, η, the viscosity coefficient of the solvent, κ, the reciprocal thickness of double

(42) Serum albumin approximates a prolate ellipsoid of 150 Å. major axis and 38 Å. minor axis.[43] Molecular volume of this prolate ellipsoid corresponds to a sphere of 30 Å. radius.

(43) J. L. Oncley, G. Scatchard and A. Brown, *J. Phys. Colloid Chem.*, **51**, 184 (1947).

(44) This mode of correction of the Z values is of course rather arbitrary. It leads to better agreement with the binding data of Carr at low pH but poorer agreement in the pH range 4 to 5. Carr's data would predict an isoelectric point of approximately 5.0 at ionic strength 0.02, a result which is far outside the experimental error. It appears that either both the binding data of Carr and of Coleman are too low near the isoelectric point, or the titration data are in error. The later possibility appears much less likely. Another conceivable explanation lies in the fact that we have restricted our consideration to the titration of carboxyl groups exclusively. This amounts to the assumption that all of the (16) imidazole groups are in the acid (cationic) form at the isoelectric point. It is conceivable that the discrepancy of 3 charge units observed in 0.02 ionic strength could result from this assumption, but not the discrepancy at 0.1 ionic strength.

layer which is expressed by eq. 4, μ, the electrophoretic mobility (cm.^{2}/volt. sec.), and $f(\kappa r)$ is a function of κr given by Henry. The equation is written using Z as

$$\frac{Z}{u} = \frac{300}{4.80 \times 10^{-10}} \frac{6\pi\eta r(1 + \kappa r + \kappa r_i)}{f(\kappa r)(1 + \kappa r_i)} \qquad (6)$$

The value of r_i was taken as 2.5×10^{-8} cm., and η as 0.01792. The value of κ was described above.

In the above equation r is the radius of the spherical molecule in question. BPA is not a sphere but possibly a prolate ellipsoid with the axial ratio of 4/1. Therefore the r value obtained by this equation must be corrected. According to Gorin[47] a cylinder of an axial ratio of 4/1 has a mobility equal to 70% of that of a sphere of the same molecular volume in the case of 0.02 ionic strength, and 67% in the case of 0.10 ionic strength. This means that this cylinder has approximately the same mobility as the sphere of a radius of 100/70 or 100/67 times, depending upon the ionic strength, larger than that of the sphere having the same volume as the cylinder. The effective radius of the BPA molecule is thus taken to be 70/100 or 67/100 that of r obtained from Henry's equation. Results obtained after correction in this manner are shown in Tables I and II, and also shown in Fig. 7. It is

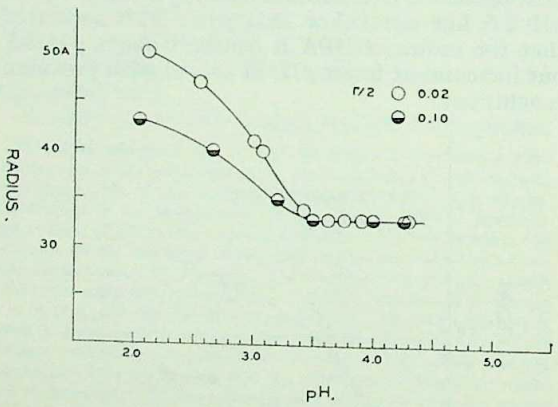

Fig. 7.—Relation between pH and radius of BPA.

found that when the pH is above 3.5 the effective radius of BPA is 33 ± 2 Å., in good agreement with the value deduced by Oncley, *et al.*,[43] and independent of ionic strength. At pH 2.1 the radius is 50 Å. (expansion of 3.4 times) when the ionic strength is 0.02, and 43 Å. (expansion of 2.2 times) when the ionic strength is 0.10.[48] With the increase in the ionic strength, the expansion is suppressed, which is the same conclusion obtained from the measurement of viscosity and optical rotation.[12]

Isoelectric Point.—As is shown in Table VIII, the isoelectric point differs with the media in which the protein is dissolved. Both the isoelectric point and the mid-point were changed with the composition of the media, in the order of higher pH, $SCN^- < Cl^- < Ac^-$. This series is in accord with the result by Longsworth, *et al.*[4] They showed that the isoelectric point of BPA was changed in the order shown above, when a part of the acetate buffer was replaced by other media. So far as the present study, at 0.02 ionic strength, is concerned, the pH at which the F form appears is close to the isoelectric point.

TABLE VIII

MEAN ISOELECTRIC POINT OF BPA IN VARIOUS MEDIA AT 0°

0.02 Cl^-	4.52
.10 Cl^-	4.22
.02 SCN^-	4.25
.02 Ac^-	4.72

A relation between the isoelectric point and ion binding is derived readily. At the isoelectric point $Z = 0$ and $r = \nu_{H^+} = \nu_{x^-}$ so that the titration equation becomes (assuming binding only to carboxyl groups of pK_0)

$$(pH)_I = pK_0 + \log \frac{n - (\nu_{x^-})_I}{(\nu_{x^-})_I} \qquad (7)$$

where x^- is the anion in the medium, $(pH)_I$ represents the isoelectric point, and $(\nu_{x^-})_I$ means the number of anions x^- which bind to the protein at the isoelectric point. It is recognized that the pH at which $r = 1$ is approximately equal to the isoionic point. At this pH, $Z = \nu_{x^-}$ and $\log(n - r)/r$ becomes very nearly $\log n$. Thus eq. 2 is written as

$$(pH)_0 = pK_0 - 0.868(\nu_{x^-})_0 w + \log n \qquad (8)$$

where, $(pH)_0$ represents the isoionic point and $(\nu_{x^-})_0$ the number of the anions bound to the protein at the isoionic point. Combining eq. 7 and 8 equation (9) is obtained

$$(pH)_I = (pH)_0 + \log\left(\frac{1}{(\nu_{x^-})_I} - \frac{1}{n}\right) - 0.868\,(\nu_{x^-})_0 w \qquad (9)$$

It is seen that the difference between the isoionic point and the isoelectric point is a function of the medium and its ionic strength, because w is a function of the ionic strength and ν_{x^-} changes with the media and its ionic strength. In the case of BPA at 0.02 chloride ionic strength the calculated $(pH)_I$ is 4.5 ± 0.1, the experimental value 4.52.

Effect of Temperature.—Comparing the mobility values at 25° and those at 0° at 0.02 ionic strength, it is found that the former are almost exactly double the latter within experimental error. The ratio of viscosity coefficient at 0° to that at 25° is 2.005. Therefore the product of ηu is seen to be constant[49] in this pH region. In Henry's eq. r_i is thought to be constant regardless of temperature. It is found also that κ is nearly independent of temperature.[51] Thus when the ratio of Henry's

(47) H. A. Abramson, L. S. Moyer and M. H. Gorin, "Electrophoresis of Proteins," Reinhold Publ. Corp., New York, N. Y., 1942, p. 131.

(48) Values of the radius found in the present study are smaller than those found at room temperature by Tanford, *et al.*,[12] and by Kronman and Foster.[46] The main reason is that the authors assumed BPA as a prolate ellipsoid, not only as a sphere.

(49) Watanabe, *et al.*,[50] studied the change of the mobility of horse serum albumin with temperature. It was found that the product ηu increased with temperature at pH 7.7. This may be attributed to the increase of the dissociation of the basic groups with temperature. This is reasonable when we consider that the heat of dissociation of the amino groups is much larger than that of the carboxyl group.

(50) I. Watanabe, N. Ui and M. Nakamura, *J. Phys. Colloid Chem.*, **54**, 1366 (1950).

(51) In eq. 4 variables are T and D. The ratio of κ at 25° (κ_{25}) to that at 0° (κ_0) is almost unity as

$$\frac{\kappa_{25}}{\kappa_0} = \sqrt{\frac{273D_0}{298D_{25}}} = 1.013$$

since D_0 (dielectric constant at 0°) is 87.8 and D_{25} (that at 25°) is 78.3.[52]

Digitized by Arya Samaj Foundation Chennai and eGangotri

eq. at 25° to that at 0° is taken (suffix means the temperature), it becomes

$$\frac{Z_{25}}{Z_0} = \frac{r_{25}g(r_{25})}{r_0 g(r_0)}$$

where $g(r)$ is a new function of r. The hydrogen ion binding of proteins in the carboxyl titration region is known to be nearly temperature independent.[53,54] Evidence also exists that chloride ion binding to human serum albumin has a low temperature coefficient (enthalpy).[39] The change of the isoelectric point with temperature is not great, in this study less than 0.1 pH unit between 0 and 25°. These results suggest Z to be nearly independent of temperature. If we assume that Z is constant at the two temperatures, the radius of BPA is also constant.

Electrophoretic and Hydrogen Ion Binding Behavior of Bovine Plasma Albumin in the Presence of 0.02 *M* Thiocyanate Ion[1,2]

BY KOICHIRO AOKI[2] AND JOSEPH F. FOSTER

RECEIVED FEBRUARY 2, 1957

Electrophoretic studies have been conducted on bovine plasma albumin over the pH range 2.0–4.5 in 0.02 *M* thiocyanate. Below pH 3.0 and above 4.3 single boundaries were obtained. Between 3.2 and 4.3 two boundaries were found, the composition varying continuously with pH in accord with the same N–F equilibrium previously reported in presence of chloride. The mid-point of the equilibrium occurs at pH 3.75 in comparison to 4.0 in chloride. Hydrogen ion titration studies were conducted in the region acid to the isoionic point in presence of 0.02 *M* thiocyanate. Molecular radii estimated from electrophoretic mobilities through Henry's equation are in agreement with values in chloride and indicate no appreciable molecular expansion to take place over the pH range of the molecular transition. Assuming a constant value for the electrostatic interaction parameter w, and constant number of binding sites, the apparent intrinsic pK of the carboxyl groups is shown to parallel very closely the electrophoretic composition in both chloride and thiocyanate. These results strongly suggest that the anomaly in the titration behavior of this protein is due essentially to the N–F transition, the carboxyls in the N form having a pK of approximately 3.7 due to stabilization by the native protein structure, while in the F form these stabilizing interactions are largely removed (pK = 4.4).

Introduction

It has been shown in chloride media that bovine plasma albumin (BPA) undergoes an isomerization reaction (N–F equilibrium)[3] in the pH range 4.5 to 3.5, and that the molecule expands below pH 3.5.[3,4] It has been suggested that the anomalous character of the titration curve of this protein above pH 3.5 can be explained on the basis of this equilibrium if it is assumed that the carboxylate groups are stabilized in the N form.[5] To test this idea further, electrophoretic studies have been conducted in the presence of 0.02 *M* thiocyanate ion, which is known to be much more strongly bound to this protein than is chloride. In addition hydrogen ion titration curves were determined in the same medium.

Experimental

Materials.—Pentex bovine plasma albumin, Lot No. A1201, was used. In the electrophoretic study this was used without further purification. In the titration study the protein solution was deionized by passing through the mixed ion-exchange column of Dintzis.[6] Potassium thiocyanate was of C.P. grade. Thiocyanic acid was obtained by passing potassium thiocyanate solution through cationic ion exchanger in the hydrogen form. In the titration study only ion-exchanged water was used.

Procedure.—Electrophoresis was carried out at 0° in a Tiselius type electrophoresis apparatus, Model 35 of the Perkin–Elmer Corporation, equipped with the schlieren scanning system. All the procedures in electrophoresis and the method of calculation were exactly the same as used in the previous work.[3] The total ionic strength of the media was 0.02 and the concentration of protein was 0.2%.

In the titration study the same apparatus as used by Foster and Sterman[7] was used. It consisted of a Beckman Model G pH meter and an external electrode cell assembly. The cell assembly consisted of a Beckman No. 1190-80 General Purpose glass electrode and a Beckman No. 1070-71 sleeve type calomel reference electrode. All temperature sensitive parts of the electrode cell assembly were maintained at a constant temperature, 25 or 0°. The procedure for determining the titration curve at 25° was also the same as was followed by the above workers.[7] In the studies at 0° the electrode system was standardized at each measurement against a standard phthalate buffer of pH 4.00, and the pH reading of the solution, which was prepared in a cold room, was taken after attaining thermal equilibrium (about 15 minutes).[8] In the calculations the molecular weight of BPA was assumed to be 70,000.

Results

Electrophoresis of BPA in the thiocyanate media of 0.02 ionic strength and at 0° was carried out in the pH range of 2.0 to 4.5. Below pH 3.0 there was a single boundary, and between this pH and 4.3 there were two boundaries. The percentage of the area of each form changed continuously with pH in the same way as in chloride media.[9] Here

(8) In measurements at 0°, the temperature dial of the pH meter was adjusted to 25° and the pH reading multiplied by 1.09 (=298/273).
(9) The areas were measured on the ascending pattern. Patterns were reasonably enantiographic in all cases. Resolution of the two components was not quite as good as in either chloride or acetate probably because of the decreased mobility in presence of thiocyanate. Mobilities at zero concentration were estimated using equation 1 in the earlier paper.[3]

again we call the faster moving component F form and the slower one N form. The *p*H–mobility curve[9] is shown in Fig. 1. The percentages of the areas are plotted against *p*H in Fig. 2.

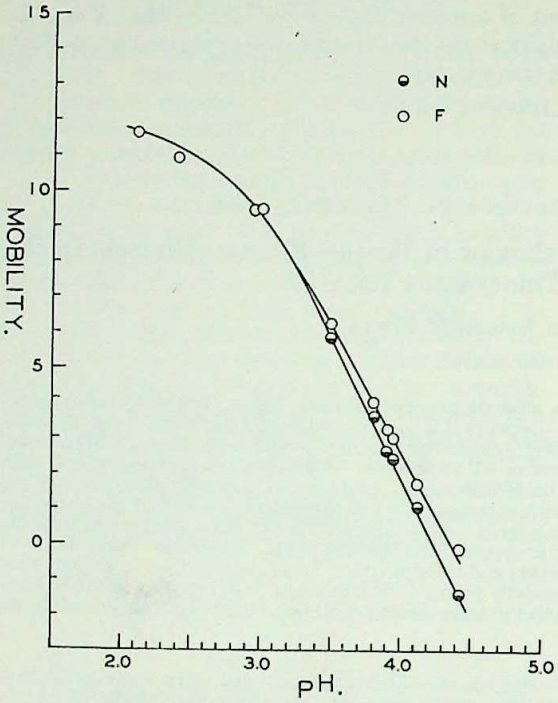

Fig. 1.—*p*H–mobility curve of BPA in 0.02 ionic strength SCN^- and at 0°. The mobility is given in the units cm.²/volt sec. × 10^5.

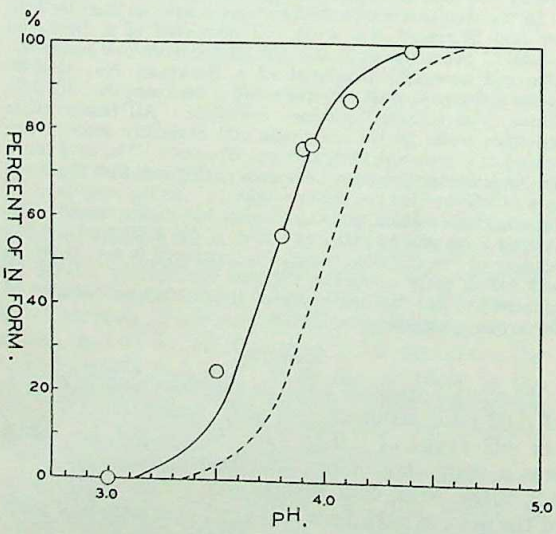

Fig. 2.—Dependence of electrophoretic composition on *p*H at 0°: ——, 0.02 SCN^-; - - - -, 0.02 Cl^- (ref. 2).

Titration curves of BPA in 0.02 thiocyanate media were determined at two temperatures, 25 and 0°. These are shown in Fig. 3, to which the titration curve in 0.02 chloride media at 25° by Foster and Sterman[7] is added.

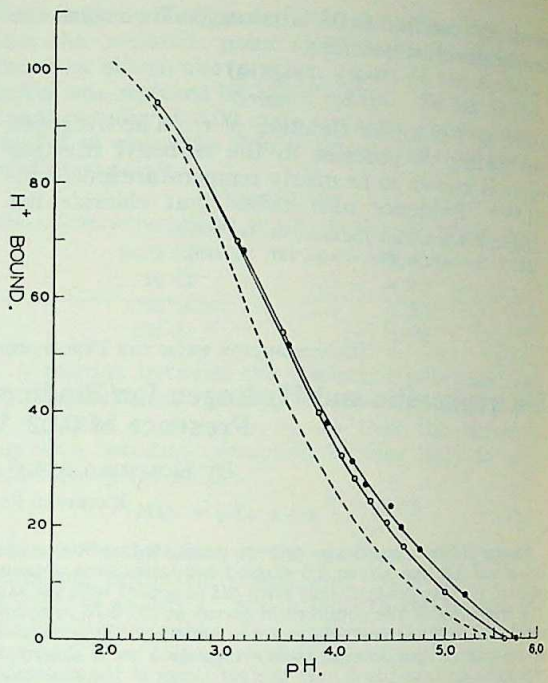

Fig. 3.—Titration curves of BPA in 0.02 ionic strength SCN^- at 25° (o) and at 0° (●). Equivalents H^+ bound per mole of BPA are shown against *p*H; - - - -, 0.02 Cl^- (ref. 6).

Discussion

In all experiments between *p*H 3.2 and 4.3, two boundaries were observed in the electrophoretic patterns. Further, the percentage composition changed continuously with *p*H in close accord with the equilibrium

$$N + 3H^+ \rightleftharpoons F$$

The result is in qualitative agreement with the finding of Longsworth and Jacobsen[10] that BPA gives a single boundary, in presence of thiocyanate, at *p*H 4.31 and 4.61 but two boundaries at *p*H 4.06. The results supplement and extend our earlier finding[2] that such an equilibrium exists in both chloride and acetate. (In the case of acetate the equilibrium corresponded more closely to a two-hydrogen-ion equilibrium.) The "mid-point" *p*H values in the three systems are, respectively, 3.75, 4.0 and 4.1 in 0.02 *M* thiocyanate, chloride and acetate. It should be emphasized that a third component such as was observed over a narrow *p*H range in chloride (3.80–3.95) was not observed in the present studies.

The net charge *Z* was calculated at various *p*H values using the hydrogen-ion titration curve at 25° and the thiocyanate binding equation of Coleman.[11] The latter may be expressed as

$$\nu_{x^-} = \sum \frac{k_i n_i C_{x^-} \exp(2Zw)}{1 + k_i C_{x^-} \exp(2Zw)}$$

where ν_{x^-} represents the number of anions (x^-) bound to one BPA molecule. C_{x^-} is the molar concentration of the anion and n_i the number of

binding sites with intrinsic constant k_1. In the case of thiocyanate, $n_1 = 1$, $n_2 = 8$, $n_3 = 18$, $k_1 = 45{,}000$, $k_2 = 1925$, and $k_3 = 63$. The parameter w is a function which mainly depends upon the molecular size and the ionic strength. The method of calculation of Z is exactly the same as previously used on the data in chloride media. The Z–pH curve thus calculated predicted the isoelectric point to be pH 4.50. The value found experimentally was 4.25. Therefore the thiocyanate binding curve was corrected so that the Z–pH curve yielded the isoelectric point experimentally found. This was carried out by raising the thiocyanate binding curve by four units over the entire range. Using the Z–pH curve thus corrected a plot of mobility (μ) *versus* net charge (Z) was drawn (Fig. 4).[12] Employing Henry's equation, the effective

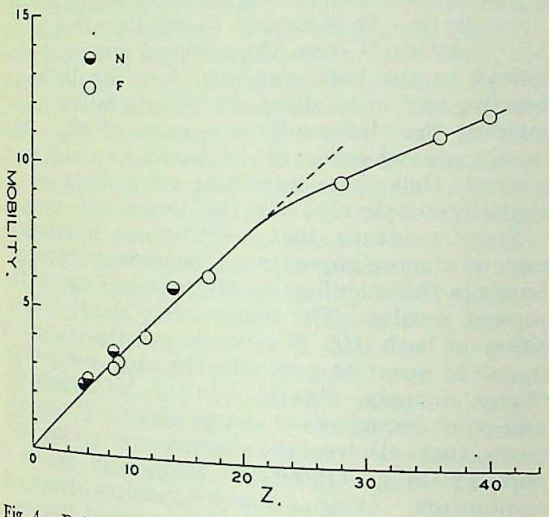

Fig. 4.—Relation between electrophoretic mobility (u) and net charge (Z).

radius of the BPA molecule was calculated from Z/u, in the same manner as previously, at the various pH values. Results are shown in Fig. 5. The radius is constant, 32 ± 2 Å., for both F and N forms above pH 3.2, and is the same as found in chloride media.[3] Slight expansion of BPA takes place below pH 3.2, considerably less than was observed in chloride media. This is in agreement with the finding of Kronman and Foster[14] that the sedimentation constant of BPA at pH 2 and 0.02 ionic strength is larger in thiocyanate media than in chloride. They have estimated effective radii at pH 2.0 of 57.0 and 40.5 Å. in chloride and thiocyanate media, respectively.

It is seen in Fig. 3 that hydrogen ion binding is enhanced in thiocyanate over that in chloride media at similar pH. This is in agreement with

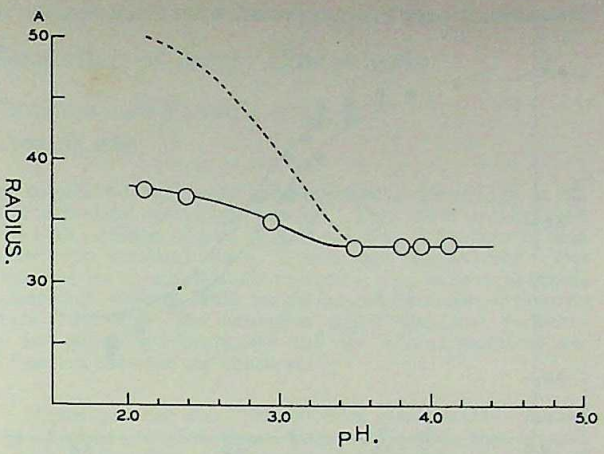

Fig. 5.—Radius of BPA *versus* pH as calculated by Henry's equation: ——, 0.02 SCN^-; - - - -, 0.02 Cl^- (ref. 2).

results described by Scatchard and Black[15] and is also to be expected on the basis of the enhanced binding of thiocyanate ion. This is seen easily from the following form of the titration equation

$$pH = pK_0 + \log \frac{n - r}{r} - 0.868Zw \qquad (I)$$

where n is the total number of basic sites of a particular species in the protein molecule, r the number of hydrogen ions bound to such sites, pK_0 the negative logarithm of the intrinsic dissociation constant for the particular species considered, Z the net charge on the protein and w the Debye–Hückel parameter.[16] Clearly, enhanced anion binding will diminish Z, which is in every case positive on the acid side of the isoelectric point, hence increasing the number of bound hydrogen ions (r).

Tanford has pointed out the inadequacy of eq. I in accounting for the titration behavior of plasma albumin acid to the isoelectric point.[17] In particular, he has shown the titration curve to be too steep in the carboxyl titration region and has suggested that this results from expansion of the protein molecule with a resultant decrease in the interaction parameter w. While the now well-known low pH expansion of this protein appears at first glance to be in good accord with this idea, it has been pointed out that gross molecular expansion takes place only at pH values below that range in which most of the apparent decrease in w occurs.[5,7,18] It has been suggested alternatively that the titration anomaly in the pH region above 3.5 is to be associated with the N–F transition.[5] The present data provide a further test for this idea.

(12) The calculation of the net charge on N and F involved the assumption that $Z_F = Z_N + 3$. The procedure and assumptions were identical with those used earlier.[3] The Z–pH curve was also drawn by use of the thiocyanate binding data of Carr.[13] This Z–pH curve predicts the isoelectric point to be around 4.8. However, there is agreement at pH 3.0 between the Z value calculated by this method and that calculated by our curve.

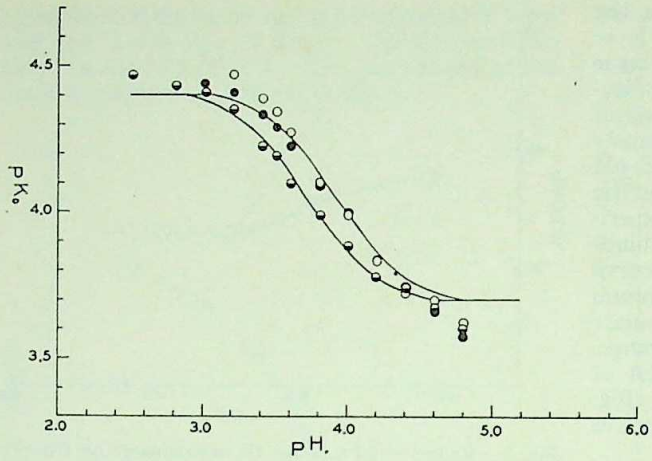

Fig. 6.—Relation between pK_0 and pH: ◒, 0.02 SCN^-; ○, 0.02 Cl^-; and ●, 0.10 Cl^-.

Tanford's calculations of w clearly pre-suppose the constancy of pK_0 and of n, the number of binding sites. We adopt instead the approximation that w is constant over the pH range in which no significant increase in molecular radius occurs. In case of chloride, the radius is substantially constant down to pH 3.5; in thiocyanate down to pH 3.2. We further adopt tentatively the position that n is constant and that all of the deviation from ideal behavior is to be attributed to changes in the intrinsic constant, pK_0.[18] Figure 6 shows results of calculations utilizing data in chloride at two ionic strengths, 0.02 and 0.10, and in thiocyanate at 0.02 ionic strength. The radius of the protein was assumed to be 33 Å. in all cases, corresponding to a w value of 0.046 at 0.02 ionic strength, and 0.029 at 0.10 ionic strength. It is seen that in all cases sigmoid curves are obtained which coincide remarkably well with the electrophoretic composition curves. In particular, the curves in chloride are seen to be independent of ionic strength, as was essentially true also of the electrophoretic composition. The mid-point of the pK_0–pH curve is shifted toward the acid side, when chloride is replaced by thiocyanate, by 0.2 pH unit in comparison with a shift of 0.25 unit in the electrophoretic composition curve. A minor discrepancy is the fact that the pK_0–pH curves in both thiocyanate and chloride appear to fit a two hydrogen ion equilibrium somewhat better than three.[20] The fact that calculated pK_0 values deviate from the drawn curves near pH 5 as well as at the lower end of the curves is not at all surprising. Near pH 5, imidazolium groups must almost certainly begin to titrate, a fact which is not taken into account in the present calculations. At the lower end of the transition, all evidence indicates that molecular expansion is beginning to take place, which will result in a decrease in w and an increase in the apparent pK_0.

To a reasonably close approximation it appears that the anomalous character of the titration curve can be accounted for through the N–F transition. It further appears that the mean pK_0 value for the carboxyl groups is about 3.7 for N form and 4.4 for F form, and that in each case these intrinsic pK_0's are substantially independent of such environmental factors as ionic strength and salt type. It is natural to conclude that in the native N form the carboxyl groups are stabilized in the basic (anionic) form by hydrogen bonding and/or localized electrostatic interactions[21] yielding the abnormally low value of pK_0. The nearly normal value of 4.4 found for the F form suggests that these stabilizing interactions are essentially completely lost in the "isomerized" protein.

Some evidence that electrostatic interactions may be of more importance than carboxyl hydrogen bonds in this stabilization may also be found in the present results. The mid-point of the N–F transition in both 0.02 M chloride and thiocyanate is found to occur at precisely the same net protein charge, namely, plus 11. In 0.1 M chloride the mid-point occurs at net charge plus 8. It thus appears that electrostatic factors are of key importance in governing the position of the N–F equilibrium. *Were carboxyl hydrogen bonds of primary importance it would be expected that thiocyanate binding would actually shift the equilibrium to higher pH rather than lower.* This inference is based on the patent fact that competition of hydrogen ions for hydrogen-bonded carboxylate anions would be greater, at given pH, in the presence of thiocyanate, due to the enhanced hydrogen ion binding. Tanford, *et al.*,[23] have similarly concluded that the forces stabilizing this protein against molecular expansion may be predominantly electrostatic.

LAFAYETTE, INDIANA

(20) A possible explanation for this fact can be given on the basis of a mechanism to be presented in a future paper.[19]

(21) The importance of such localized electrostatic effects has been emphasized recently by Hill.[22]

Kinetics and Mechanism of the Formation of Azoxy Compounds

BY YOSHIRO OGATA, MASARU TSUCHIDA AND YASUO TAKAGI

RECEIVED NOVEMBER 20, 1956

The condensation of phenylhydroxylamine and nitrosobenzene to yield azoxybenzene has been studied kinetically at 50, 40, 30 and 20° in pure and aqueous methanolic solutions using the ultraviolet spectrophotometer. The rate is proportional to the concentration of both reactants. The rate constant varies with addition of acid (0.0001–0.1 *N*). The plots of acid concentration *versus* rate constant show downward and upward curves in pure and 30 vol. % methanol, respectively. The rate data and the acidity–rate relationship show that two mechanisms are simultaneously operating, *i.e.*, in neutral media the reaction of the free amine and the free nitrosobenzene is predominant, while in acidic media the condensation of phenylhydroxylamine and protonated nitrosobenzene becomes important. Moreover, the formation of *p,p'*-dichloro-, *p*-chloro- and unsubstituted azoxybenzenes from *p*-chloronitrosobenzene and phenylhydroxylamine and the related reactions are confirmed; the fact implies a preliminary rapid and reversible reaction between the reactants.

It has been supposed that the formation of azoxy compound by the reduction of nitrobenzene results from condensation between phenylhydroxylamine and nitrosobenzene. However, strange to say, the condensation of *p*-substituted phenylhydroxylamine with nitrosobenzene has been reported to give a mixture containing unsubstituted and *p,p'*-disubstituted azoxybenzene.[1] Since then, little theoretical attention has been paid to this phenomenon, and therefore it appeared valuable to examine the reaction mechanism in detail.

Our experiments indicate the truth of these observations not only with *p*-methyl or *p*-chlorophenylhydroxylamine and nitrosobenzene but also with *p*-chloronitrosobenzene and phenylhydroxylamine. These facts seem to indicate that azoxybenzene formation is truly a reaction between phenylhydroxylamine and nitrosobenzene, but that the reaction between substituted phenylhydroxylamines and nitrosobenzene or substituted nitrosobenzenes and phenylhydroxylamine is complicated by a preliminary rapid equilibrium between phenylhydroxylamine and nitrosobenzene.

$$p\text{-X—C}_6\text{H}_4\text{NO} + \text{C}_6\text{H}_5\text{NHOH} \rightleftharpoons p\text{-X—C}_6\text{H}_4\text{NHOH} + \text{C}_6\text{H}_5\text{NO}$$

Thence we investigated spectrophotometrically the kinetics of the condensation of phenylhydroxylamine with nitrosobenzene in methanol. The reaction was found to be first-order with each reactant, and its second-order rate constant was influenced by the addition of acid or water. The present report summarizes these data which suggest a plausible mechanism.

Experimental

Materials.—Phenylhydroxylamine was prepared from nitrobenzene by reduction with zinc dust in aqueous ammonium chloride solution.[2] The crude material was purified by dissolving it in benzene and then precipitating it by the addition of petroleum ether. Repeated purification gave fine needles of m.p. 82° (lit.[3] m.p. 82°). For each kinetic run freshly purified material was used. *p*-Methyl- and *p*-chlorophenylhydroxylamine were prepared and purified in the same way, m.p. 94° (lit.[4] m.p. 94°) and 88° (lit.[5] m.p. 87.5°), respectively.

Nitrosobenzene was obtained from phenylhydroxylamine by chromic acid oxidation. Recrystallization from a small amount of methanol gave colorless crystals, m.p. 67.5° (lit.[6] m.p. 68°). The product was stored in a dark place. *p*-Chloronitrosobenzene was prepared and purified similarly, m.p. 93° (lit.[7] m.p. 92–93°). The methanol used was of best grade and purified by rectification, b.p. 65°.

Products from *p*-Substituted Phenylhydroxylamine or Nitrosobenzene.—As an example, the condensation of phenylhydroxylamine and *p*-chloronitrosobenzene is described below. A methanolic solution (15 ml.) of phenylhydroxylamine (2 g.) was mixed with a methanolic solution (15 ml.) of *p*-chloronitrosobenzene (2 g.) at room temperature. The greenish color of *p*-chloronitrosobenzene gradually darkened on standing, and after five minutes the color became yellow by warming to 50°. A small amount of water was added, and the solution was warmed until the precipitate dissolved and then chilled. The crystalline material deposited was collected. The mother liquor was worked up similarly until no more precipitation was observed, and the last filtrate was evaporated to dryness in vacuum. Each crop was then carefully submitted to fractional recrystallization. There were obtained pure crystals of *p,p'*-dichloroazoxybenzene, 1.4 g., m.p. 158° (lit.[8] m.p. 158°); azoxybenzene, 0.9 g., m.p. 35° (lit.[9] m.p. 35.5°); and *p*-chloroazoxybenzene, 0.5 g., m.p. 62° (lit.[10b] m.p. 62°).

p-Chloroazoxybenzene was converted to *p*-chloroazobenzene by heating in concentrated sulfuric acid. Recrystallization from aqueous methanol gave orange-red crystals, 0.26 g., m.p. 92°, which showed no depression of m.p. on admixture with authentic specimen, m.p. 92°.[10]

In an analogous manner, the condensation of *p*-chlorophenylhydroxylamine (2 g.) and nitrosobenzene (2 g.) gave *p,p'*-dichloroazoxybenzene, 0.9 g.; azoxybenzene, 0.6 g.; and *p*-chloroazoxybenzene, 0.2 g. From *p*-methylphenylhydroxylamine (2 g.) and nitrosobenzene (2 g.) there was obtained *p,p'*-dimethylazoxybenzene, 1.7 g., m.p. 71° (lit.[11] m.p. 71°); and azoxybenzene, 1.0 g., m.p. 35°.

Determination of Basicity Constants.—The basicity constant[12] of phenylhydroxylamine, $K_1 = [\text{PhNH}_2\text{OH}^+]/[\text{PhNHOH}][\text{H}^+]$, and that of nitrosobenzene, $K_4 = [\text{PhNOH}^+]/[\text{PhNO}][\text{H}^+]$, were determined by measuring at appropriate wave lengths the optical densities of these materials at 0.0002 *M* concentration in acidic methanolic solutions as a function of acid concentrations.[13] From the estimated values of optical densities in neutral, weakly acidic and strongly acidic solutions of these materials con-

(11) E. Bamberger, *Ber.*, **59**, 429 (1926).

(12) In general, the basicity constant is expressed as $[\text{BH}^+][\text{OH}^-]/[\text{B}]$, where B is a base; hence these K_1 and K_4 values should be multiplied by the solubility product of water according to this definition for coincidence with the idiomatic expression.

(13) For convenience, the acid (hydrogen chloride) concentration, measured by the acidimetry, was assumed equal to $[\text{H}]^+$, since no appreciable *p*H change was observed on addition of these substrates.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

taining no, partly and wholly protonated substrates, respectively, the basicity constants were calculated by means of the above equations. With phenylhydroxylamine, the difference between optical density at 236 mμ and that at 280 mμ was used, while with nitrosobenzene the optical density at 260 mμ was utilized. With phenylhydroxylamine, an increase of the protonated amine concentration with increasing acid concentration became negligible at *ca.* 0.04, 0.2 and *N* acid concentrations in pure, 96 and 70% methanol, respectively; *e.g.*, a plot of $E_{236} - E_{280}$, the difference between optical density of 0.0002 *M* methanolic solution of this material at 236 mμ and that at 280 mμ, against acid concentration *c* approaches the extreme value (zero) corresponding to complete ionization when *c* is 0.04 *N*. Using this value, zero and that for neutral solution ($E_{236} - E_{280})_0 = 0.720$, the basicity constant of phenylhydroxylamine, K_1, can be calculated by means of the relation

$$K_1 = [PnNH_2OH^+]/[PhNHOH]c = \frac{0.720 - (E_{236} - E_{280})_c}{\{(E_{236} - E_{280})_c - 0\}\, c}$$

Similarly, K_1 values in 96 and 70% methanolic solutions were obtained, the complete protonation here being reached when *c* is about 0.2 and *N*, respectively; the fact seems to indicate that water is a weaker acid than methanol.

The basicity of nitrosobenzene is so small that it is decomposed by acid before complete protonation of the substrate is attained, even in pure methanol. Therefore, the basicity constant K_4 was calculated by means of two simultaneous equations by inserting two different $(E_{260})_c$ values.

$$K_4 = \frac{(E_{260})_0 - (E_{260})_c}{\{(E_{260})_c - (E_{260})_\infty\}\, c} = \frac{0.320 - (E_{260})_c}{\{(E_{260})_c - (E_{260})_\infty\}\, c}$$

Here (E_{260})'s are optical densities at 260 mμ and the indicated acid concentrations, and *c* means any acid concentration. These data are summarized in Table I.

TABLE I

BASICITY CONSTANTS OF PHENYLHYDROXYLAMINE AND NITROSOBENZENE

Temp., °C.	Phenylhydroxylamine K_1, l. mole^{-1} 100% MeOH	96% MeOH	70% MeOH	Nitrosobenzene K_4, l. mole^{-1} 100% MeOH
5	4.75×10^3	4.77×10^2	15.0×10	1.8
25	2.90×10^3	3.02×10^2	7.95×10	1.3
40[a]	2.14×10^3	2.24×10^2	5.37×10	1.0

[a] The data were obtained by the extrapolation from the values at 5 and 25° by means of the Arrhenius equation.

Analysis of the Components of the Reaction Mixture.—Phenylhydroxylamine, nitrosobenzene and azoxybenzene absorb strongly in the range between 240–300 mμ (Fig. 1).

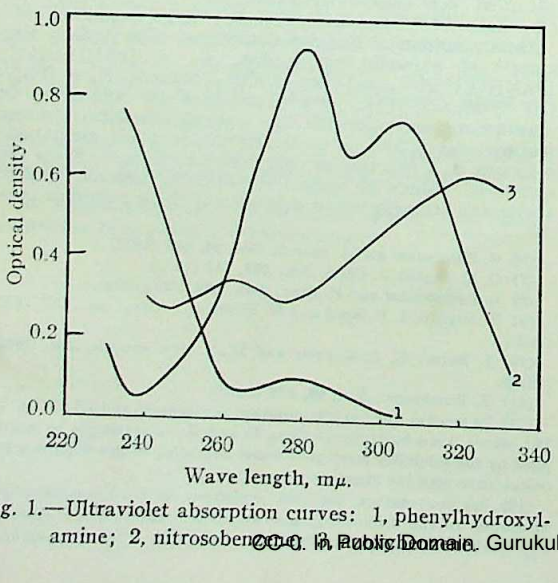

Fig. 1.—Ultraviolet absorption curves: 1, phenylhydroxylamine; 2, nitrosobenzene; 3, azoxybenzene.

An inspection of Fig. 1 will show that Vaughn's method[14] can be used to follow this condensation.

The following relationship will be deduced from Beer's law and the stoichiometry of the reaction.

$$E_1 - E_2 = (\epsilon_a^1 - \epsilon_a^2)(a - x) + (\epsilon_b^1 - \epsilon_b^2)(b - x) + (\epsilon_x^1 - \epsilon_x^2)x$$

$$E_3 - E_4 = (\epsilon_a^3 - \epsilon_a^4)(a - x) + (\epsilon_b^3 - \epsilon_b^4)(b - x) + (\epsilon_x^3 - \epsilon_x^4)x$$

Here, E_i is the optical density of a solution at wave length *i*; *a* and *b* are initial concentrations of phenylhydroxylamine and nitrosobenzene, respectively; *x* is the concentration of azoxybenzene produced; ϵ_a^i, ϵ_b^i and ϵ_x^i are the extinction coefficients of the subscripted materials at wave length *i*. This is a linear or first-order function of *x*; hence a plot of $E_1 - E_2$ (or $E_3 - E_4$) against *x* will show a set of parallel straight lines corresponding to each set of *a* and *b*. Accordingly, plots of $E_1 - E_2$ *vs.* $E_3 - E_4$ with varying *x* will again be represented by a set of parallel straight lines (not curves) each of which corresponds to a run with a set of *a* and *b*.

If the sum of *a* and *b* is constant, *e.g.*, 0.0002 *M*, the variation of the composition of the reaction mixture during the reaction may be represented, just as Vaughn's chart, by a triangular composition diagram of Fig. 2, where P, N and A

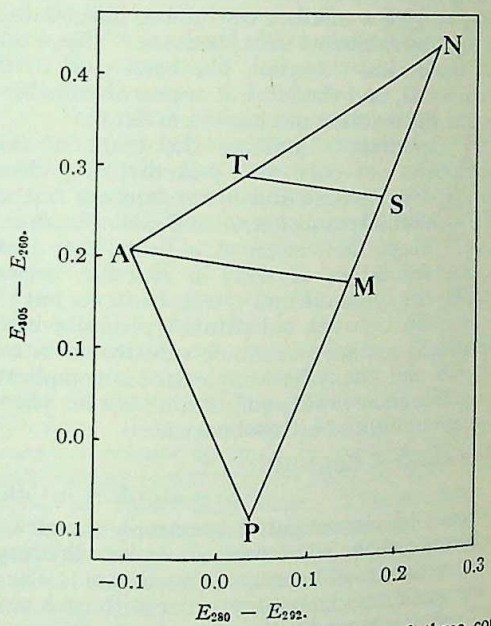

Fig. 2.—Vaughn's chart for the estimation of three components.

represent pure solutions of phenylhydroxylamine (0.0002 *M*), P′, nitrosobenzene (0.0002 *M*), N′, and azoxybenzene (0.0002 $M \times 1/2$), respectively. For example, a reaction course of the equivolume mixture of P′ and N′, represented by the mid-point M of line PN, may be expressed as line MA, since the sum of [PhNO], [PhNHOH] and 2[PhN$_2$O] is constant during the reaction.[14] Analogously, it is apparent that with reactants containing N′ and P′ in a ratio of SP:NS, the reaction course is represented by line ST, where line ST is parallel to line AM and T is an intersection of NA and ST, as is apparent from the above reasoning. This is a modification of Vaughn's chart and seems very useful for the detection of side reactions, since the method determines the concentrations of all reactants and product.

Therefore, methanolic solutions of phenylhydroxylamine (0.0002 *M*), nitrosobenzene (0.0002 *M*) and azoxybenzene (0.0001 *M*) were prepared, their optical densities being determined at 260, 280, 292 and 305 mμ and compared with that of pure methanol by means of a Beckman DU spectrophotometer. Differences of the optical densities, $E_{280} -$

E_{292} and $E_{305} - E_{260}$, were calculated with each compound, the data being plotted in Fig. 2.

Typical Procedure for Rate Measurements.—An appropriate amount of a methanolic solution (0.002 *M*) of nitrosobenzene was introduced into a 200-ml. three-necked flask equipped with an ice-cooled reflux condenser, nitrogen-introducing tube and a tube suitable for withdrawing samples and immersed in a thermostat. Since phenylhydroxylamine is very sensitive to air oxidation, all kinetic experiments were carried out in nitrogen atmosphere. The nitrogen was purified by passing through three washing bottles each containing an aqueous alkaline solution of pyrogallol, then dried over potassium hydroxide and bubbled during the measurement. After bubbling for *ca.* 10 minutes to remove a trace of oxygen, the reaction was initiated by the addition of a methanolic solution (0.0002 *M*) of phenylhydroxylamine. At appropriate time intervals, aliquots (5 ml.) were taken out, poured into a 50-ml. volumetric flask containing an appropriate amount of methanol, diluted accurately to 50 ml. and then cooled to 0°. It was confirmed in preliminary tests that such a procedure would stop the reaction. At the end of the reaction, usually 30–100 minutes, the optical density of the resulting solution was measured at 260, 280, 292 and 305 mμ, and the second-order rate constant was calculated using the method mentioned previously.

The hydrogen-ion concentration was determined by acidimetry, since it was confirmed that the reactants and the product have no appreciable effect on the hydrogen-ion concentration.

Results

Second-order Rate Constants and Temperature Coefficients.—The rates were measured in three media, *i.e.*, 100, 96 and 70% methanol (vol. %), the apparent second-order rate constants being given in Table II with varying molar ratio of both reactants (the molar ratio of phenylhydroxylamine to nitrosobenzene varies from 5 to 1/4). As is shown in the table, the constancy is satisfactory, implying that the condensation involves a rate-determining combination of both reactants. The variation of the rate with temperature is shown in Fig. 3, from which the energy and entropy of activation is calculated to be 10.8 kcal. mole^{-1} and −32.5 cal. deg.$^{-1}$mole^{-1}, respectively.

TABLE II

SECOND-ORDER CONSTANTS FOR THE FORMATION OF AZOXYBENZENE IN PURE METHANOL AT 40°

Initial concentration, *M* $[C_6H_5NHOH]$	$[C_6H_5NO]$	k, l. mole^{-1} min.$^{-1}$
0.00034	0.00166	18.3

.00146	.00054	17.9
.00158	.00042	20.5
	Av.	19.7

Acidity Dependence.—In alkaline solutions oxidation of phenylhydroxylamine to nitrosobenzene was so rapid that accurate determination of the rate was impossible, since the oxidation proceeds during the optical density estimation. On the other hand, in strong acidity nitrosobenzene was converted to an unknown substance. Hence the kinetic experiments were confined to the acidity range from 0.0001 to 0.1 *N*. As the acid source, hydrogen chloride and in a few cases sulfuric acid were used. The variation of the apparent second-order rate constants with acid concentration is given with solvent composition is given in Table III. The data with hydrogen chloride as an acid source agree with those of sulfuric acid of the same normality. No salt effect was observed with added lithium chloride.

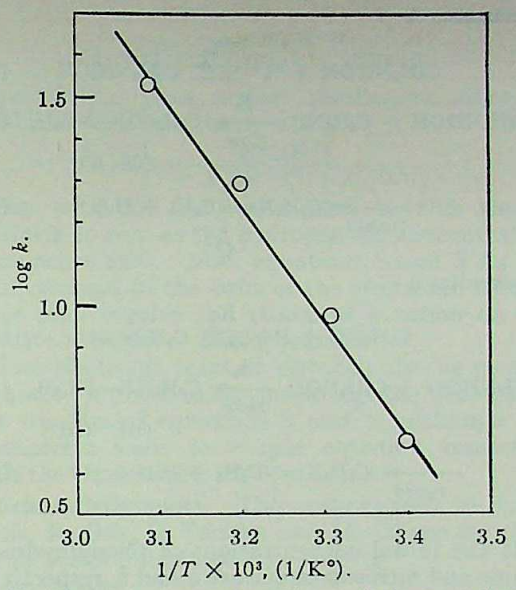

Fig. 3.—The temperature dependence of the second-order constant.

[a] Sulfuric acid-catalyzed. [b] LiCl was added.

Discussion

The results obtained, *i.e.*, the second-order constant and its acidity dependence, may best be explained by assuming two simultaneous mechanisms,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Mechanism A

$$C_6H_5NHOH + H^+ \underset{}{\overset{K_1}{\rightleftharpoons}} C_6H_5\overset{+}{N}H_2OH \quad (1)$$

$$C_6H_5NHOH + C_6H_5NO \xrightarrow[\text{slow}]{k_2} C_6H_5\overset{+}{N}H(OH)-NC_6H_5(O^-) \quad (2)$$

$$\xrightarrow[\text{rapid}]{} C_6H_5N=\overset{+}{N}C_6H_5(O^-) + H_2O \quad (3)$$

Mechanism B

$$C_6H_5NO + H^+ \underset{}{\overset{K_4}{\rightleftharpoons}} C_6H_5\overset{+}{N}OH \quad (4)$$

$$C_6H_5NHOH + C_6H_5\overset{+}{N}OH \xrightarrow[\text{slow}]{k_5} C_6H_5\overset{+}{N}H(OH)-NC_6H_5(OH) \quad (5)$$

$$\xrightarrow[\text{rapid}]{} C_6H_5N=\overset{+}{N}C_6H_5(O^-) + H_2O + H^+ \quad (6)$$

If the initial concentrations of phenylhydroxylamine and nitrosobenzene are a and b, respectively, and that of the azoxybenzene produced at time t is

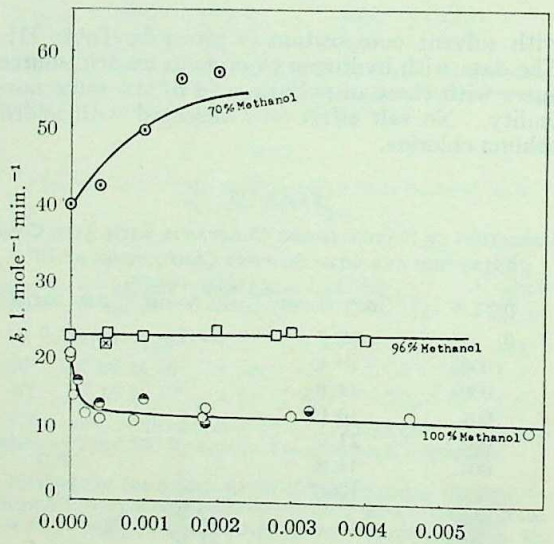

Fig. 4.—k *vs.* acid concentration: ◓ ⊠, sulfuric acid-catalyzed; ◒, LiCl was added; ○ ⊙ □, hydrogen chloride-catalyzed with various solvents.

x, the following relation is required by these mechanisms, where v, k and K are rate, rate constant and equilibrium constant of the subscripted step, respectively.

$$a - x = [C_6H_5NHOH] + [C_6H_5\overset{+}{N}H_2OH]$$

$$b - x = [C_6H_5NO] + [C_6H_5\overset{+}{N}OH]$$

$$[C_6H_5NHOH] = (a - x)\left(\frac{1}{1 + K_1[H^+]}\right)$$

$$[C_6H_5\overset{+}{N}H_2OH] = (a - x)\left(\frac{K_1[H^+]}{1 + K_1[H^+]}\right)$$

$$[C_6H_5NO] = (b - x)\left(\frac{1}{1 + K_4[H^+]}\right)$$

$$[C_6H_5\overset{+}{N}OH] = (b - x)\left(\frac{K_4[H^+]}{1 + K_4[H^+]}\right)$$

$$v_2 = k_2[C_6H_5NHOH][C_6H_5NO] = \frac{k_2(a - x)(b - x)}{(1 + K_1[H^+])(1 + K_4[H^+])}$$

$$v_5 = k_5[C_6H_5NHOH][C_6H_5\overset{+}{N}OH] = \frac{k_5K_4[H^+](a - x)(b - x)}{(1 + K_1[H^+])(1 + K_4[H^+])}$$

Since the over-all rate v is the sum of v_2 and v_5, the apparent second-order rate constant k with varying hydrogen ion concentration should be expressed as

$$k = \frac{k_2 + k_5K_4[H^+]}{(1 + K_1[H^+])(1 + K_4[H^+])} \quad (7)$$

Equation 7 reveals that k approaches k_2 in very weak acidity. The value of k_2 is equal to that of k in a neutral medium, hence k_5 may be calculated from the values of k_2 and k at known acidities using values of K_1 and K_4 in Table I. The values of k_5 thus calculated are shown in Table IV and hold constant over a thousand fold variation in the acid concentration, in agreement with these mechanisms. Using average values of k_5K_4 (Table IV) with the three solvents, the k values were calculated again and are shown in Fig. 4 in comparison with the observed values.

TABLE IV

CALCULATED VALUES OF k_5K_4 AND k_5 AT 40°

[H⁺], N	$k_5K_4 \times 10^{-3}$, l.² mole⁻² min.⁻¹ 100% MeOH	96% MeOH	70% MeOH
0.0001	33[a]

.002	20.6		
.004	26.5		2.88
.005		5.04	
.0086	23.3		
.01	28.8	4.92	3.65
.015			4.13
.018	23.9		
.02		5.31	3.97
.03	25.2	5.15	
.046	26.0		
.062	22.6		
	Av. 24.7	5.10	3.66

k_5 (av.) 2.61×10^4 l. mole^{-1} min.$^{-1}$

[a] At lower acid concentration, the values show a remarkable departure from constancy. This seems unavoidable, since at 0.0001 N, for instance, a 5% decrease of k (from 18.9 to 18.0) results in a 33% decrease of k_5K_4. The k_5K_4 values calculated from the other mechanisms show over a hundred fold variation.

These mechanisms indicate that in neutral solutions a reaction between free phenylhydroxylamine and free nitrosobenzene (eq. 2) predominates, while in acidic solutions a reaction of free phenylhydroxylamine with protonated nitrosobenzene (eq. 5) becomes important, just like the amine–carbonyl condensation.[15] Neither equation 2 nor 5 alone explains the rate–acidity relationship, *i.e.*, the rate constant would decrease with an increase of acidity if equation 2 alone were operating, while the rate would become equal to zero in a neutral solution if equation 5 alone were operating.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Furthermore, the possibilities of the other mechanisms will be discussed below. A rate-determining reaction of protonated phenylhydroxylamine with nitrosobenzene

$$C_6H_5\overset{+}{N}H_2OH + C_6H_5NO \xrightarrow{k_8} C_6H_5N{=}\overset{+}{N}C_6H_5 \\ | \\ O^- + H_2O + H^+ \quad (8)$$

or a rate-determining condensation of both protonated reactants should lead to the rate constant expression

$$k = \frac{k_8K_1[H^+]}{(1 + K_1[H^+])(1 + K_4[H^+])}$$

or

$$C_6H_5\overset{+}{N}H_2OH + C_6H_5\overset{+}{N}OH \xrightarrow{k_9} C_6H_5N{=}\overset{+}{N}C_6H_5 \\ | \\ O^- + H_2O + 2H^+ \quad (9)$$

$$k = \frac{k_9K_1K_4[H^+]^2}{(1 + K_1[H^+])(1 + K_4[H^+])}$$

respectively; hence neither mechanism alone or combined with equation 5, where

$$k = \frac{k_5K_4[H^+]}{(1 + K_1[H^+])(1 + K_4[H^+])}$$

agrees with the fact, since each k value should diminish to zero as the hydrogen ion concentration approaches zero. Also, equations 8 and 9 do not seem rational in the light of the electronic theory, since they involve the attack of a cation on the positive nitrogen of nitrosobenzene.

This electronic point of view can also be used to eliminate a mechanism involving the simultaneous reaction of equations 8 and 2, although the mechanism leads to a rate equation consistent with the experiment.

Acknowledgments.—The authors wish to thank Profs. R. Oda, S. Tanaka and M. Okano for their aid in performing these experiments.

The Kinetics of Solvolysis of Acyl Esters of Salicyclic Acid

BY EDWARD R. GARRETT

RECEIVED DECEMBER 28, 1956

The acid, neutral and alkaline hydrolysis of acetyl-, trimethylacetyl-, β-cyclopentylpropionyl- and diethylacetylsalicyclic acids were studied and the rate constants determined as functions of dissociation and of hydrogen and hydroxyl ion concentration. The Arrhenius parameters of entropy and heat of activation also were determined and mechanisms were considered in light of these values and the structures of the esters. Disagreement with values given in the literature was noted. An unusual increase in "spontaneous" rate was observed with increasing alcohol concentration whereas no such increase was noted with increasing dioxane content.

In order to determine the inhibition of hydrolysis of acyl salicylates by varying alkyl substitution on the acyl group, the acid and base hydrolysis of esters selectively chosen to scan substituent effects, acetyl-, trimethylacetyl-, β-cyclopentylpropionyl- and diethylacetyl salicylic acids were studied. A very complete study of the hydrolysis of acetyl salicylic acid (aspirin) had been made by Edwards.[1,2] However, since these papers had reported an unusually high alkaline hydrolysis heat of activation of 25 kcal./mole, whereas similar acyl phenates had activation energies of an order of magnitude of 12 kcal./mole,[3] the hydrolysis studies of aspirin were repeated and the Arrhenius parameters determined.

It was desired to carry out the hydrolysis studies in solutions as nearly aqueous as possible, but the inadequate water solubility of β-cyclopentylpropionyl- and diethylacetylsalicylic acids necessitated use of water–alcohol mixtures as solvents to maintain sufficient material in solution for spectrophotometric analysis. In order to place the hydrolysis studies of all these esters on comparative grounds, the hydrolysis of aspirin was studied in various water–alcohol mixtures. An unexpected increase in the hydrolysis rates of the anion in the *p*H-independent region was observed. This *p*H-independent hydrolysis of the completely ionized compound (as represented by the plateau of rate *vs.* *p*H at *p*H 5.5–9 in Fig. 1) had been ascribed by Edwards[1,2] to the water attack on the aspirin ion and would imply general acid–base catalysis.[4] In this light ethanol would have to be considered a more active base than water. However, Edwards[1] had also shown by studies in various concentrations of acetate buffers that the "spontaneous" hydrolysis was not subject to general acid–base catalysis.

The extraordinary magnitude of this "spontaneous" or water hydrolysis of aspirin has led to the formulation of cyclic mechanisms involving interaction of both carbonyls and their carbons in a rate-determining step.[5,6]

In order to clarify the anomalous enhancement of "spontaneous" hydrolysis with increasing alcohol content of the solvent and to determine if the rates were dependent on water content or were functions of dielectric constant, the "spontaneous" hydrolysis was studied in various dioxane–water mixtures. Surprisingly, there was small variation in hydrolysis rates.

Calculations and Results

According to Edwards[1,2] the hydrolysis of aspirin, $C_6H_4(OOCCH_3)COOH$, may be expressed by

$$\begin{aligned} &d([C_6H_4(OOCCH_3)COOH] + [C_6H_4(OOCCH_3)COO^-])/dt \\ &= -k_1[H^+][C_6H_4(OOCCH_3)COOH] \\ &- (k_4[H^+] + k_5C_{H_2O} + k_6[OH^-])[C_6H_4(OOCCH_3)COO^-] \\ &= -k\{[C_6H_4(OOCCH_3)COOH] + \\ &\qquad [C_6H_4(OOCCH_3)COO^-]\} \quad (1) \end{aligned}$$

where

$$\begin{aligned} k &= k_1[H^+]/(1 + K'_a/[H^+]) \\ &+ (k_4[H^+] + k_2C_{H_2O} + k_6[OH^-])/(1 + [H^+]/K'_a) \quad (2) \end{aligned}$$

where K_a is the dissociation constant of aspirin and k is the pseudo first-order rate constant at a constant pH. The pseudo first-order rate constants obtained at pH values of 1.1, 2.5 and 5.1 and the determined K_a' values were used to calculate the k_1, k_4 and $k_5C_{H_2O}$ values for acetyl-, trimethylacetyl-, β-cyclopentylpropionyl- and diethylacetylsalicylic acids at 25.0°, 35.0°, 50.3° and 60.3°. These rate constants are given in Table I. The spectrophotometrically determined pK_a and pK_a' are given in Table II. Their relative significance is discussed in the Experimental section. The experimentally determined bimolecular rate constants, k_6, are in Table III.

TABLE II

[a] The acetyl- and trimethylacetylsalicylic acids were studied in 0.5% ethanol; the β-cyclopentylpropionyl- and diethylacetylsalicylic acids were studied in 20% ethanol. [b] The bimolecular rate constants were determined from pseudo first-order rate plots at $[NaOH]_0$ concentrations of 100×10^{-4} M and greater. [c] At this low concentration of alkali, it is expected that catalysis other than hydroxyl would be significant. Thus, the observed k_6 should be higher than the true k_6. [d] The apparent bimolecular rate constants (k_6) for alkaline hydrolysis were 0.116 and 0.114 l./mole/sec. in 20 and 40% ethanol by volume with 10×10^{-4} M [NaOH].

[a] The acetyl- and trimethylacetylsalicylic acids were studied in 0.5% ethanol; the β-cyclopentylpropionyl- and diethylacetylsalicylic acids were studied in 20% ethanol by volume. [b] pH was averaged from five samples taken at room temperature during the hydrolysis, the range in pH values was of the order of 0.1 pH. [c] 0.4708 M H_2SO_4. [d] 0.04708 M H_2SO_4. [e] 0.1178 M H_2SO_4. [f] 0.2354 M H_2SO_4.

the activities as related to the experimentally determined pH values. Anion and acid concentrations are defined in terms of K_a' experimentally derived from the spectrophotometric titrations. The rate constants k_5 and k_6 do not need activity corrections since they are based on anion concentrations similarly derived; the latter, k_6, is determined from hydroxyl concentration given in terms of molarity.

It should also be realized that Edwards' term, $k_4[H^+]$ [anion] is kinetically indistinguishable from k_4K_a' [acid].

The logarithmic profiles of pseudo first-order rate constants against pH at 25° for these esters of salicylic acid as calculated from the derived k_1, k_4, $k_5C_{H_2O}$, k_6 and K_a' values are drawn in Fig. 1. The plotted points are experimentally determined rate constants at their determined pH values and confirm the derived values. Similar profiles may be constructed for other temperatures using the proper autoprotolysis constant, K_w, of the solvent. Such values may be estimated from the literature.[7,8]

Several acid hydrolysis studies were run at the various temperatures and pH values and pseudo first-order rate constants were determined (Table IV). The experimental rate constant data were used to calculate the theoretical pH values determined on the basis of the previously derived k_1 and k_4 values, $[H^+] = (k - k_4K_a)/k_1$; the agreement of the actual and calculated pH values lends support to the validity of the data and methods of calculation.

The Arrhenius plots of the logarithm of the rate constants against the reciprocal of the absolute temperature as per

$$\log k = -(\Delta H_a/2.303R)(1/T) + \log P = S/T + \log P \quad (3)$$

are given in Fig. 2 for k_1, Fig. 3 for k_4, Fig. 4 for $k_5C_{H_2O}$ determined at pH 5.1 and Fig. 5 for k_6. The thermodynamic quantities derived from this function are given in Table V where $\Delta S^{\ddagger}$, the entropy of activation, is calculated from absolute reaction rate theory[9] as

$$\Delta S^{\ddagger} = 2.303R[\log P - \log (k_B T/h)] \quad (4)$$

where k_B is Boltzmann and h is the Planck constant.

The pseudo first-order rate constants for the hydrolysis of aspirin in various percentages by volume of 95% ethanol and dioxane in water mixtures, as well as the apparent pH values are given in Table VI.

[a] The quantities are derived from the logarithmic form of the Arrhenius relation: $\log k = -(\Delta H_a/2.303R)(1/T) + \log P = -S/T + \log P$ where the k is in sec.$^{-1}$ and the k_i in l./mole/sec., the ΔH_a is the heat of activation in kcal./mole, R is the gas constant in cal./degree and T is the absolute temperature. The $\Delta S\ddagger$ entropy of activation is calculated from absolute reaction rate theory: $\Delta S\ddagger = 2.303R\,[\log P - \log (k_B T/h)]$ where k_B is the Boltzman constant and h is Planck's constant. [b] The acetyl- and trimethylacetylsalicylic acids were studied in 0.5% ethanol; the β-cyclopentylpropionyl- and diethylacetylsalicylic acids were studied in 20% ethanol by volume. [c] The values for $k_5C_{H_2O}$ are determined for the pseudo first-order rate constant of the presumed product in sec.$^{-1}$.

the various acyl esters of salicylic acid were determined at 26 ± 1° by a procedure similar to Edwards'[11] by the expression

$$pH = pK_a' - \log\{(a_{HA}C - A_t)/(A_t - a_A\text{-}C)\} = pK_a - \log\{(a_{HA}C - A_t)/(A_t - a_A - C)\} + fZ_1Z_2\sqrt{\mu} \quad (5)$$

where $a_{HA}C$ is the asymptotic absorbance in acid media, $a_A\text{-}C$ is the asymptotic absorbance in alkaline media, a_{HA} and a_A- are the molar absorptivities, respectively, of the undissociated and dissociated acid, μ is the ionic strength, fZ_1Z_2 is the coefficient of the ionic strength correction in the simple Debye–Hückel equation,[11] C is the total concentration of acid, *i.e.*, $C = [HA] + [A^-]$, and A_t is the total absorbance at any pH, *i.e.*, $A_t = a_A\text{-}(C - [HA]) + a_{HA}[HA]$.

The value of f in water is 0.51, but $f \propto 1/D^{3/2}$ where D is the dielectric constant so that $(D_{H_2O}/D_{\%\ Ethanol})^{3/2}\,0.51 = f_{\%\ Ethanol}$ where values of D for various percentages of ethanol at 25° are given in the literature.[12] The ionic strength of the acetate buffers in various ethanol concentrations also was calculated from the pK_a of acetic acid in aqueous alcohol.[13]

Sufficient acyl ester of salicylic acid was weighed in volumetric flasks, dissolved in the appropriate amounts of eth-

anol and diluted with water and concentrated buffer so that the final molarity in ester was 5×10^{-4} M at the desired alcohol concentration. The final buffer concentrations for dissociation constant determinations were similar to Edwards' first fourteen in his Table III.[1] The ester was dissolved in alcohol so that solubilization would be complete prior to the addition of buffer and the hydrolysis kept to a minimum before the immediate pH and spectrophotometric readings.

The pK_a' and pK_a were calculated for all buffers at wave lengths of 268, 272, 276, 280 and 284 mμ by equation 5. The calculated values at a given wave length whose log $[(a_{HA}C - A_t)/(A_t - a_{A^-}C)]$ lay within ±1 limits (usually four) were averaged. The results for the several wave lengths were again averaged to give the pK_a' and pK_a estimates of Table II. The pH-independent isosbestic point of salicylic acid on the Cary model 11 recording spectrophotometer was 300 mμ.

Determination of Rates of Alkaline Hydrolysis.—One-tenth of a millimole of the ester of salicylic acid was dissolved in 100 ml. of nitrogen-purged water (or aqueous alcohol) and maintained at the desired temperature. Twice the desired final alkali concentration was maintained at the same temperature in 50 ml. of water. Two different alkali concentrations were used. Fifty ml. of the acyl ester salicylic acid solution were added to each solution of alkali so that the final solution was 5×10^{-4} M in the acyl ester of salicylic acid and $5–400 \times 10^{-4}$ M in alkali; 5-ml. aliquots of the solutions were taken out at appropriate times and quenched in 5 ml. of HCl of sufficient concentration to neutralize the initial alkali content of the aliquot and with sufficient alcohol content to keep the free acid of the ester in solution. The sampling schedule was adjusted to include at

least 1.5 times the half-life of the hydrolysis. These acidified aliquots were read at 296.5 mμ on a Beckman DU spectrophotometer for the appearance of salicylic acid. This previously had been determined as the isosbestic point for salicylic acid with absorbance independent of pH for this

machine. The molar absorptivity was 354. The rate constants were determined from the slopes of the pseudo first-order plots of log $(A_\infty - A)$ *vs.* time for alkali concentrations $[NaOH]_0$ over $100 \times 10^{-4} M$ where A_∞ is the absorbance of salicyclic acid at total hydrolysis and A is the absorbance at any time t and

$$\log (A_\infty - A) = -k't = -k[NaOH]_0 t/2.303 \quad (6)$$

where

$$k = 2.303k'/[NaOH]_0$$

For lower alkali concentrations, the slopes of bimolecular rate plots were used

$$\log ([NaOH]/[Ester]) = k''t + \text{constant} = k([NaOH]_0 - [Ester]_0) \times t/2.303 + \text{constant} \quad (7)$$

where

$$k = 2.303k''/([NaOH]_0 - [Ester]_0)$$

and

$$[Ester] = [(A_\infty - A)/A_\infty] \times [Ester]_0$$

and

$$[NaOH] = [NaOH]_0 - [Ester]$$

The resultant rate constants and the alkali concentrations used in their determination are given in Table III.

Determination of Rates in Neutral and Acid Media.—The same buffer solutions as used in the determination of pK_a values were used in the determination of pseudo first-order rate constants. The buffer concentrations were 94% of Edwards' concentrations.[1] The experimentally determined constants are given in Tables I and IV and plotted in Fig. 1; 100 ml. of solution, $5 \times 10^{-4} M$ in ester, was used for each study. The rate constants were determined from the slopes of the first-order plots of the appearance of salicylic acid at the pH independent isosbestic point of the Beckman DU at 296.5 mμ as

$$\log (A_\infty - A) = -kt/2.303 + \text{constant} \quad (8)$$

The pH values were determined with the Cambridge pH meter using glass-saturated calomel electrodes at room temperature and are given as the average from five samples taken during an hydrolysis study. The range in pH values was of the order of 0.1 pH unit. Ten to fifteen aliquots were assayed for salicylic acid during the hydrolysis and were so chosen as to at least be equitably distributed throughout 1.5 times the half-life.

The pseudo first-order rate constants for aspirin hydrolysis in varying amounts of 95% ethanol and dioxane were run with the same buffers and are given in Table VI.

Discussion

Arrhenius Parameters of Basic and Acidic Hydrolysis.—The entropies of activation $\Delta S^\ddagger$ as listed in Table V in the alkaline hydrolysis (k_6) of the studied acyl esters of salicylic acid conform to normal expectation in that $\Delta S^\ddagger$ for acetyl- > β-cyclopentylpropionyl- ~ trimethylacetyl- > diethylacetylsalicylic acid. The longer the alkyl chain and the greater its degree of branching, the greater should be the loss in degrees of freedom in formation of the activated state and thus the more negative $\Delta S^\ddagger$.[14]

The heats of activation ΔH_a for the alkaline hydrolysis of aspirin and the other acyl esters of salicylic acid are of the magnitude of 12 kcal./mole which is consistent with the hydrolysis of similar acyl phenates.[3] Thus the more than twice this value reported previously[2] must be an artifact of the method of study.

The assumption of a common intermediate for acid-catalyzed esterification and hydrolysis permits comparison of substituent effects from both reactions.

Loening, *et al.*,[15] have tabulated the Arrhenius parameters for the acid-catalyzed esterifications of many aliphatic acids. The percentage increase in ΔH_a for acid esterification of trimethylacetic acid over acetic acid is 14% and for diethylacetic acid is 24%. The comparable activation values for acid hydrolysis (k_1) of the salicylic esters of these acids are similar percentages of 15% and 30%. Acid-catalyzed esterifications of solely β-disubstituted acids show no significant difference in ΔH_a over acetic acid. The ΔH_a's for the acid hydrolysis of acetyl- and β-cyclopentylpropionylsalicylic acid are also similar. The heats of activation are in the order appropriate to the effect of α-carbon substituents on the positivity of the carbonyl carbon,[16] acetyl- ~ β-cyclopentylpropionyl- < trimethylacetyl- < diethylacetylsalicylic acid.

Neutral Hydrolysis.—Edwards[1] has shown the absence of general acid–base catalysis[17] in the hydrolysis of aspirin at pH 4.7 in aqueous media by varying the concentration of acetic acid–acetate buffers at half-neutralization from 0.05 to 0.3 M in acetate ion and observing no significant rate increase. At this pH the hydrolysis of aspirin has been ascribed almost completely to the "spontaneous" water hydrolysis of the aspirin anion. If this is a true "water" reaction, general acid–base catalysis is to be expected.[4,17] Its absence casts considerable doubt on the mechanism implied in Edwards' kinetic equations.[1]

Amis[4,18,19] has considered the variation of specific rate with dielectric constant. If the aspirin anion reacts with the dipolar molecule, water, the specific rate $k_5 C_{H_2O}/C_{H_2O}$ or the rate divided by the water concentration, plotted against the reciprocal of the dielectric constant[12] for the ethanol–water solutions, should be of negative slope. When the values from Table VI are so treated, the plot is of positive slope and numerically equal to 14. The only sensible value of r of molecular dimensions obtainable from Amis' expressions is on the premise of reaction of a dipolar molecule (water) and a positively charged ion where the rate is still a function of water content. The value of the dipole moment μ was assumed to be 1.8 debye units[4] and resulted in a reasonable value of r, 2.6×10^{-8} cm.

Since the region of pH-independent rate is the region of the anionic form of aspirin, it is difficult to believe this happy result to be naught but fortuitous else the anion must react with two protons in a neutral solution before hydrolysis.

A more consistent mechanism for pH-independent hydrolysis where rate is not significantly affected by increasing dioxane concentration (Table VI) is one which does not involve water in the rate-determining step and may be due to an intramolecular rearrangement similar to the proposals sub-

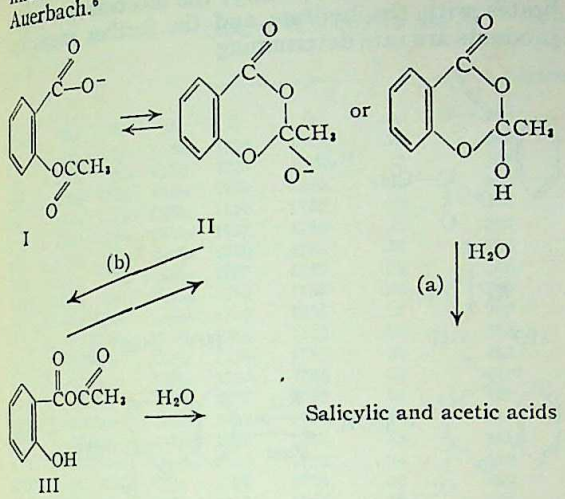
mitted by Chanley, *et al.*,[5,20,21] and Davidson and Auerbach.[6]



Salicylic and acetic acids

The presumed rate-determining step in these proposals is I to II and the subsequent route is either (a) or (b) to the final products. The presence of the anionic form of aspirin (I) is consistent with their argument that cyclization to II is favored by the carboxylate ion being more nucleophilic than carboxyl. The two possible mechanisms proposed for salicyl phosphate hydrolysis[5] are analogous to (a) and (b), the extremely quick hydrolysis of the cyclic intermediate II either in the anionic[5] or neutral form[6] or the intermediate formation of salicoyl phosphate (or salicoyl acetate (III)) which is subsequently hydrolyzed. The latter can be argued against since acetyl phosphate and benzoyl phosphate have half-life periods similar to salicyl phosphate.[5,22]

The higher ΔH_a for $k_5C_{H_2O}$ (Table V) of trimethylacetyl- and diethylacetyl- relative to β-cyclopentylpropionyl- and acetylsalicylic acids may be explained by pronounced steric interference in the formation of the activated cyclic intermediate II. In this closed form (II), the number and length of the alkyls on the β-carbon appears to hinder free rotation about the β-carbon as per Fisher–Taylor–Hirshfelder models and thus steric restrictions on activation are feasible.

The hydrolysis rate attributed by Edwards[1] to hydrogen ion attack on the anion (k_4 in Table V) may be alternatively considered as "spontaneous" hydrolysis of the undissociated acid (Edwards,[1] $k_2C_{H_2O} = k_4K_a$). It would appear that substitution on the fifth atom from the carbonyl oxygen, or Newman's six number,[15,23] raises the activation energy for this hydrolysis of the β-cyclopentylpropionyl- and diethylacetylsalicylic acids by sterically hindering the formation of an activated complex or transition state. However, this is also accompanied by a much smaller decrease in entropy, $\Delta S^{\ddagger}$. Chanley, *et al.*,[5] explain a similarly low $\Delta S^{\ddagger}$ in the hydrolysis of salicyl phosphate by the mutually hindering rotation of phosphate and carboxyl in the open form and thus little loss in degrees of freedom in the cyclic intermediate. Trimethylacetylsalicylic acid has no more restricted rotation of both carbonyls in the open form than does the diethylacetylsalicylic acid. The latter should have more internal energy to lose on activation and thus a more negative $\Delta S^{\ddagger}$.

This implies that the rate-determining step for k_4 or k_4K_a may not be in a step similar to the cyclization[6] (I to II) but in some other simultaneous or subsequent step where the rate-determining step is to a transition state with less restriction of rotation of β-substituted alkyls.[24]

pH-Independent Hydrolysis in Aqueous Ethanol.—The anomalous increase in rate with increasing ethanol content of the solvent in the pH-independent hydrolysis of aspirin is of interest (Table VI). Increase in alcohol content decreases acid-catalyzed hydrolysis as is expected, but the converse occurs in the neutral pH range over which rate is independent of pH. That this is not a dielectric phenomenon is apparent from the small changes in rate in varying dioxane–water mixtures. The alcohol must be specifically involved in the solvolytic mechanism. This is difficult to explain since for solvolysis in alcohol–water mixtures a paraphrase is apt: what alcohol can do, water can do better. Yet a decrease to 40% water in dioxane–water did not show any highly significant kinetic result.

Table VII lists the average of the pseudo first-order rate constant (k_{obs} for the pH-independent region of hydrolysis as given in Table VI and the more rigorously calculated molarities in ethanol and water when the mode of preparation of the solutions is considered).[25]

TABLE VII

AVERAGE pH-INDEPENDENT RATE CONSTANTS (k_{obs}[a] IN SEC.$^{-1}$) FOR THE HYDROLYSIS OF ASPIRIN ANION IN ETHANOL–WATER MIXTURES

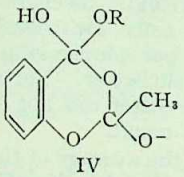
$$k_{OBS} = k_0 + k_{ROH}\,[ROH]/[H_2O].$$

Fig. 6.—Plot of the observed rate constant for *p*H-independent hydrolysis of aspirin anion at 25° against the molar ratio of ethanol to water. The postulated dependence of this plot is the equation $k_{obs} = k_o + k_{ROH}[ROH]/[H_2O]$.

If it is assumed that water and alcohol compete for aspirin anion ion II to form a reacting cyclic intermediate such as



IV

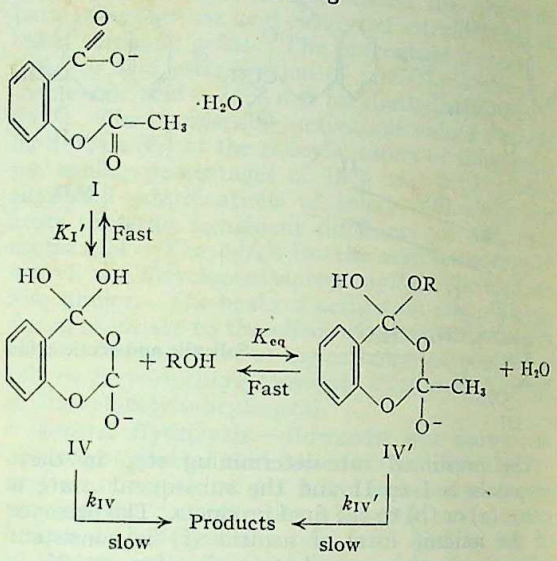
where R is H– or C_2H_5–, then

$$k_{obs} = k_a[H_2O] + k_b[ROH] \qquad (9)$$

However, the data of Table VII do not follow equation 9. At best, a linear representation is valid only for $[C_2H_5OH] > 3.33$ and

$$k_{obs} = 1.43 \times 10^{-6}[C_2H_5OH];\ k_a = 0 \qquad (10)$$

A possible explanation that best fits the data is that the cyclic intermediate in the hydrolysis of an aspirin anion II is formed stoichiometrically as the hydrate IV and $[IV] = K_{I'}[I']$ in a non-rate-determining step. Subsequently, the alcoholate equilibrates with the hydrate and the further steps to products are rate determining



On the basis of this mechanism, the rate expression can be formulated.

$$\begin{aligned} k_{obs}[I'] &= k_{IV}[IV] + k_{IV'}[IV'] \\ &= k_{IV}[IV] + k_{IV'}K_{eq}[IV][ROH]/[H_2O] \\ &= k_{IV}K_{I'}[I'] + k_{IV'}K_{eq}K_{I'}[I'][ROH]/[H_2O] \end{aligned} \qquad (11)$$

Thus

$$k_{obs} = k_0 + k_{ROH}[ROH]/[H_2O] \qquad (12)$$

Equation 11 best fits the data which are plotted accordingly in Fig. 6. The resultant quantitative equation is

$$k_{obs} = 3.65 \times 10^{-6} + 25.5 \times 10^{-6}[C_2H_5OH]/[H_2O] \qquad (13)$$

The Effect of Various Solvents on the Carbonyl Absorption Spectrum of Glycidic Esters

BY HORTON H. MORRIS[1] AND RAYMOND H. YOUNG, JR.

RECEIVED JANUARY 7, 1957

The infrared spectra of a number of glycidic esters show two well-defined absorption bands of approximately equal intensity in the 1800–1700 cm.$^{-1}$ carbonyl stretching region instead of the one to be expected. Of greater interest is the fact that, although the spectra of solutions of the esters in non-hydrogen bonding solvents show the two absorption bands in the carbonyl region, the two bands disappear and are replaced by a single band when the esters are dissolved in a solvent capable of forming hydrogen bonds with the ester. Possible explanations of these effects are advanced.

We have determined the infrared spectra of a number of previously reported[2] glycidic esters and have found that, without exception, the esters give two well-defined absorption bands of almost equal intensity in the 1800–1700 cm.$^{-1}$ carbonyl stretching region instead of the one expected band. The average position of the centers of the two bands for the esters studied are 1729 and 1753 cm.$^{-1}$.

Of even greater interest is the fact that the two bands disappear and are replaced by a single, rather broad band centering at about 1737 cm.$^{-1}$ when the

esters are dissolved in a solvent capable of forming hydrogen bonds, while the spectra of the esters in a variety of non-hydrogen bonding solvents all show the two clearly defined absorption bands. Thus the two bands are present when the esters are dissolved in carbon tetrachloride, carbon disulfide, benzene, cyclohexane, 2-nitropropane, *n*-propyl mercaptan or dimethylaniline; but are replaced by a single band (often fairly broad) when solvents such as chloroform, *n*-butyl alcohol, aniline, methanol or *m*-cresol are used. In those solvents capable of hydrogen bonding with the ester there is a gradual shift of band center position to lower frequencies with increasing hydrogen bonding ability.

It is also of interest that the area under the curves of the esters in CCl_4 solution is found to be approximately equal to the area under the curve of chloroform solutions of the esters. The average value of the extinction coefficient, determined by taking one-half the sum of the extinction coefficients of each of the two bands observed in carbon tetrachloride solution, is approximately equal to that of the single band obtained when the esters are dissolved in chloroform. Thus the average molar extinction coefficient for the two bands in carbon tetrachloride solutions of the esters is 252, while the molar extinction coefficient for the single band given by the esters in chloroform solution is 259.

Table I lists the esters studied and gives the positions of the bands in the carbonyl region when the esters are dissolved in carbon tetrachloride ($\bar{\nu}_1$, $\bar{\nu}_2$) and when they are dissolved in chloroform ($\bar{\nu}_3$). No change in position or intensity of any other band in the spectra with change of solvent has been observed. Table I also gives the difference in frequency ($\Delta\bar{\nu}$) between the two bands, the molar extinction coefficients ($\epsilon_{\bar{\nu}_1}$, $\epsilon_{\bar{\nu}_2}$, $\epsilon_{\bar{\nu}_3}$) as determined for each band, the average molar extinction coefficient for the two bands observed in carbon tetrachloride solutions ($(\epsilon_{\bar{\nu}_1} + \epsilon_{\bar{\nu}_2})/2$) and the areas under the curves (A_{CCl_4}, A_{CHCl_3}) as determined between 1800 and 1600 cm.$^{-1}$ by means of a planimeter. Average values are given at the bottom of each column.

Figure 1 shows the appearance of the bands in the carbonyl region of ethyl α-*n*-propyl-β,β-dimethylglycidate dissolved in various solvents. The curves have been displaced upward for clarity.

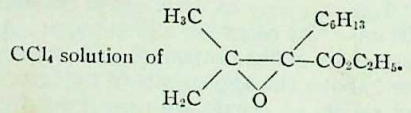

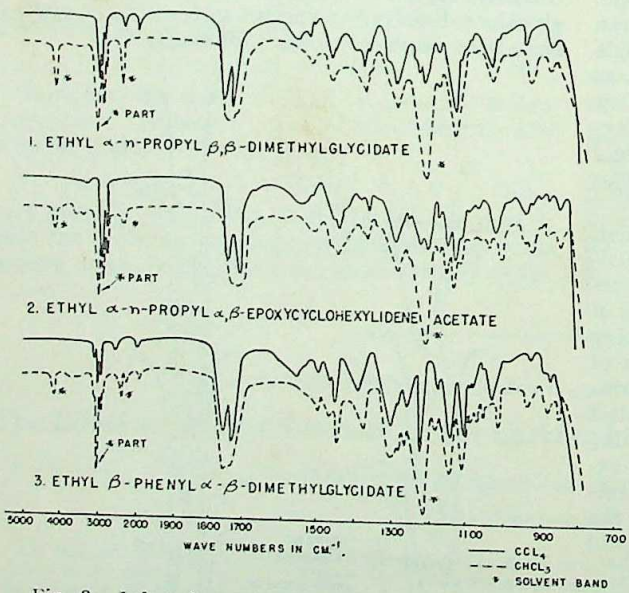

Fig. 3.—Infrared spectra of esters in CCl_4 and $CHCl_3$.

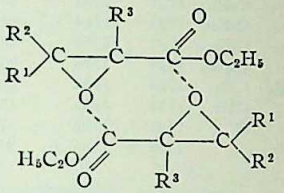
Figure 2 shows the effect on the spectra of the addition of increasing amounts of *n*-butyl alcohol to a carbon tetrachloride solution of ethyl α-*n*-hexyl-β,β-dimethylglycidate.

Figure 3 shows the infrared spectra from 5000–800 cm.$^{-1}$ for ethyl α-*n*-propyl-β,β-dimethylglycidate, ethyl α-*n*-propyl-α,β-epoxycyclohexylidene-acetate and ethyl β-phenyl-α,β-dimethylglycidate in CCl_4 and in $CHCl_3$. The spectra are representative of the types of glycidic esters herein discussed and the spectra of other members of the three homologous series differ only slightly from those shown.

Discussion

It may be possible to explain these observations by assuming dimer formation and hence a coupling between the characteristic stretching vibrations of the two ester carbonyl bonds to cause a frequency splitting, thus giving rise to a pair of absorption bands on either side of the unperturbed frequency. It seems reasonable to assume that two molecules of the ester could orient through dipole–dipole interaction as indicated in the diagram below to form bonds which are strong enough to allow coupling of the two ester carbonyl vibrations.



That the bonding is between the carbon of the ester carbonyl group and the oxygen of the oxirane ring may be indicated by the distance between the two absorption bands (average 24.5 cm.$^{-1}$) observed in CCl_4 solutions of the esters, since the split is a measure of the efficiency of the coupling.[3a] Davison[3b] has shown that in diacyl peroxides (two atoms separating the two carbonyl groups) the split between the two observed carbonyl absorption bands is about 25 cm.$^{-1}$, while anhydrides[4] show a similar pair of absorption bands with a split of about 65 cm.$^{-1}$ resulting from the shorter coupling link.

That the interaction does not involve a linear polymerization and is between two molecules only may be indicated by the fact that no change in the appearance of the two absorption bands occurs upon dilution—an effect to be expected with the type of bonding shown in the diagram, but not to be expected if the bonding were linear.[5]

Intensity measurements and determination of the area under the curves for the esters in CCl_4 and in $CHCl_3$ may also support the dimer picture. The data would seem to indicate that only the ester carbonyl stretching vibration is involved and that a splitting is occurring in non-hydrogen bonding solvents, rather than the juxtaposition of absorption bands caused by two different types of carbonyl vibrations.

The disappearance of the two absorption bands and the appearance of a single band centering approximately at the unperturbed frequency when a solvent capable of forming hydrogen bonds with the ester is added may be an indi-

cation of the relative strength of the bonds involved in dimer formation.

That the frequency of the single band formed in hydrogen-bonding solvents appears to move toward lower frequencies with increasing hydrogen bonding ability of the solvent and that the appearance of the single band in hydrogen bonding solvents is concentration dependent (see Fig. 2) indicates a dissolution of the dimer and the formation of two molecules of the ester, each associated through hydrogen bonding with a solvent molecule.

The bonding which results in dimer formation, as postulated, must be very weak since molecular weight determinations by freezing point depression, as determined in benzene or cyclohexane, give the normal value for a monomeric unit.

It is of interest to note that Schotte[6] has recently recorded the infrared spectra of the diastereomers of $HO_2CCHEtCHMeCO_2H$, m.p. 177–178° (I) and 100–101° (II) and of $HO_2CCHEtCH_2CHMeCO_2H$, m.p. 104.5–5.5 (III) and 83.5–84.5° (IV), and has noted that II and III show a split peak for the carbonyl stretching frequency. He assumed these to have the racemoid configuration. I and IV showed no such split and were presumed to be the mesoid isomers.

Since the esters herein reported are all racemic mixtures, it may be that the proposed dimer is a racemic pair. Molecular models of such a racemic pair and of a pair having a single configuration indicate that the racemic pair may allow a closer approach of the ring oxygens to the carbonyl carbons because of less interference by the alkyl substituents.

The observations might be interpreted in a different way by assuming that two rotational isomers are present in which the carbonyl oxygen is on the same side of the molecule as the ring oxygen in one case and away from the ring oxygen in the other. Since this would represent an equilibrium mixture and since the extinction coefficients of the two observed bands are approximately equal in every case, the unlikely assumption must be made that equal numbers of molecules exist in each of the states for each of the esters. Since resonance splitting does seem to be indicated, we believe that dimer formation offers a better explanation of the data than the assumption of rotational isomerism.

(6) L. Schotte, *Arkiv. Kemi*, **9**, 397 (1956).

Experimental

The infrared spectra were measured with a Baird Associates model 4–55 recording infrared spectrometer employing sodium chloride optics. The same 0.029-mm. cell was used for all determinations. No reference cell was used. The accuracy of the wave length measurement is estimated to be ±5 cm.$^{-1}$ in the region discussed. Polystyrene bands at 1602.5 and 1594.7 cm.$^{-1}$ were recorded on each spectrum for calibration purposes.

Compounds XV, XVI, XVIII and XIX may contain small amounts of impurities. The other esters are considered to be quite pure (see reference 2).

Liquid–Solid Countercurrent Distribution of Fatty Acids with Urea

BY W. N. SUMERWELL

RECEIVED FEBRUARY 7, 1957

The reaction of fatty acids with urea to form inclusion adducts has been used as the basis of a liquid–solid countercurrent distribution method for separating mixtures of fatty acids. The fatty acids and urea, dissolved in an appropriate solvent, served as the moving liquid phase while the precipitated reaction products served as the stationary solid phase. The character of the distribution curve obtained for a given mixture of fatty acids depends on the differences in the distribution coefficients for the individual fatty acids when they are distributed between solid inclusion adducts and organic solvent. The method was found to be effective in the separation of mixtures of fatty acids such as arachidic, stearic, palmitic and oleic acid as well as in the separation of a mixture of the *cis–trans* isomers, oleic and elaidic acids. The method also was applied to a mixture of highly unsaturated salmon egg oil fatty acids (iodine value 350). The results indicate that urea distribution may be a valuable tool in the separation of such unstable compounds.

Introduction

Studies on the formation of urea inclusion adducts as a means of fractionating marine oil fatty acids and their derivatives were begun in this Laboratory several years ago. A preliminary report of this work has been published.[2] The present paper describes the development of a liquid–solid countercurrent distribution procedure based on the differential binding of fatty acids by urea and its application to some synthetic and natural mixtures of fatty acids.

Subsequent to Craig's description of his two-phase liquid–liquid countercurrent distribution technique[3] and its use in the separation of organic compounds, he published a report on a liquid–solid countercurrent system.[4] By this technique, he distributed chrysene and anthracene between cyclohexane and alumina. He defined a coefficient A as the ratio of the weight of solute dissolved in the liquid phase to the weight of solute adsorbed on the solid phase. The position of the maximum concentration of a compound in the distribution system was then calculated by substituting the value of A

in the equation $N - n(A)/(A + 1)$ in the same way that the distribution coefficient is used to calculate the position of maximum concentration in a liquid–liquid countercurrent system.

A different approach to liquid–solid countercurrent distribution can be made if, instead of an adsorbent being used as the solid phase of the system, a precipitated reaction product, produced by a reaction involving the compounds to be distributed, is used. This precipitation reaction, however, must be of a special type in that the relative amounts of any compound in equilibrium between the liquid and solid phases of the system must be governed by a distribution coefficient instead of the solubility product which generally governs precipitation reactions of inorganic compounds. In other words, the solid phase of the system, made up of precipitated reaction products, must act as a solid solution. The requirement would most likely be met by products which are bound by only secondary bonds of the van der Waals and hydrogen bonding variety. Such products could be expected to resemble solutions in their behavior.

Consider a mixture of compounds A_1, A_2, A_3. . .A_j, each of which reacts with a compound B to form the solid reaction products (bound by secondary bonds) P_{A_1B}, P_{A_2B}, P_{A_3B}. . .P_{A_jB}. These reactions are represented by the general equation $A_i + B \rightarrow P_{A_iB}$.

In this system, A_i and B are present in solution in an appropriate solvent and as such constitute the liquid phase. The precipitated reaction products P_{A_iB} constitute the solid phase. From this reaction, distribution coefficients K_1, K_2, K_3 . . . K_j are defined by the general equation

$$K_i = \frac{[A_i \text{ liquid}]}{[A_i \text{ solid}]}$$

where the terms in brackets are the concentrations of A_i in liquid and solid phase, respectively.

It is evident that this equation will hold strictly true only when the volume of the liquid phase and the concentration of B in this phase are held constant. If the values of K_1, K_2, etc., differ sufficiently, then countercurrent distribution should effectively separate A_1, A_2, etc.

Since the binding forces existing between aliphatic compounds and urea are presumably van der Waals forces and in some cases hydrogen bonds, one might expect their adducts to act as solid solutions and to exhibit distribution coefficients. If such is the case, then it should be possible to develop a liquid–solid countercurrent method for the separation of fatty acids using urea, the fatty acids and a suitable solvent.

Preliminary Considerations

The reaction of a fatty acid with urea is represented by the equation xF.A. + yUrea $\rightleftarrows$ F.A.$_x$·Urea$_y$.[5]

In terms of the liquid–solid countercurrent distribution system, the inclusion adducts are the stationary solid phase, whereas the supernatant liquid is the moving phase.

(5) See H. Schlenk, "Progress in the Chemistry of Fats and Other Lipids," Vol. 2, Academic Press, Inc., New York, N. Y., 1952, p. 243, for a review of the urea inclusion compound literature.

To determine whether the amounts of fatty acid in equilibrium between the liquid and solid phases are governed by a distribution coefficient, quantitative measurements using pure palmitic acid as a reactant were made. The reactions were carried out at 30° at three different concentrations of palmitic acid, each in 100 ml. of methanol. In each solution, 19.2 g. of urea was dissolved, which is the amount required to saturate 100 ml. of methanol at 30°. Enough additional urea also was added to each solution to react with the weight of palmitic acid present at a ratio of 12.8 moles of urea per mole of fatty acid.[5] The solutions were held at 30° for 6 hr. Aliquots of the supernatant liquid were then removed and the palmitic acid in solution was extracted and weighed. The data and results of these experiments are given in Table I. It is evident that the palmitic acid does have a definite distribution coefficient in this system.[6]

TABLE I

DISTRIBUTION OF PALMITIC ACID IN A TWO-PHASE METHANOL–UREA SYSTEM

Wt. of palmitic acid, g.	Wt. of urea, g.	Distribution coefficient $K - C$ liquid
1.4200	23.45	0.013
0.6931	21.27	.014
0.3189	20.16	.012

To determine whether sufficient difference exists between the distribution coefficients of long-chain fatty acids to warrant investigation of the urea reaction as a countercurrent method, quantitative measurements employing palmitic, stearic and arachidic acids were made. The reactions were each carried out at 20° in a urea-saturated solution consisting of 70% methanol and 30% ethyl acetate. The K-values obtained were 0.016 for arachidic acid, 0.037 for stearic acid and 0.091 for palmitic acid. Although these values are small, they differ considerably in magnitude and, for this reason, studies on a countercurrent separation were begun.

The concentration of urea in solution at equilibrium should be constant throughout the countercurrent system. This condition can be met through the use of solvents that remain saturated with urea when the reaction has reached equilibrium. In addition, the distribution of different mixtures of fatty acids will, in general, require different concentrations of urea, from one system to another, depending on the chain length and degree of unsaturation of the component fatty acids. This requirement can be met by using a series of solvents with varying urea solubility characteristics.

In the separation of saturated fatty acids at or near room temperature, the solubility of urea can be effectively varied by the use of mixtures of methanol and ethyl acetate. Methyl alcohol when saturated with urea at 20° contains 16.5 g.

(6) The distribution of a fatty acid between solid urea and supernatant solution appears to be similar to the distribution of a compound between an ion exchange resin and supernatant solution. Helferich, THIS JOURNAL, 76, 5567 (1954), has defined the distribution coefficient of a substance in contact with resin as $\bar{c}/c$ where $\bar{c}$ is the concentration of substance in the pore liquid of the resin and c is the concentration in the supernatant solution.

Digitized By Arya Samaj Foundation Chennai and eGangotri

of urea per 100 ml. of solution. Ethyl acetate at 20° contains 0.35 g. of urea per 100 ml. of solution. By varying the proportions of methanol and ethyl acetate, it is possible to prepare saturated urea solutions of any desired concentration between the two limits. A solubility curve for urea in mixtures of methanol and ethyl acetate is shown in Fig. 1.

In the separation of unsaturated fatty acids at lower temperatures, methanol is used as the solvent although the solubility of urea in methanol in the temperature range of −10 to −30° is less than is desirable. Efforts are being made to find a better solvent for work in this range.

It has been found that the solubility of urea in methanol varies linearly with temperature in the range from 20 to −30°. The solubility equation is: $x = 10 + 0.32T$, where T is the centigrade temperature and x is the solubility (g. per 100 ml. of solution) of urea in methanol at that temperature. This equation is useful for computing the concentration of urea in methanol solution at any temperature at which a separation is to be made.

Experimental

Procedure.—Solutions of urea in methanol or a mixture of methanol and ethyl acetate, sufficient in volume for the number of stages (usually, 12 to 30) in the distribution system, were prepared so that the concentration of urea would be the same as that of a saturated solution at the temperature at which the distribution was to be performed.

The distribution was carried out in a series of 500-ml. erlenmeyer flasks, each fitted with a cork stopper holding a short air condenser. Each flask in the series was charged with 10 g. of dry urea (to maintain the solvent at saturation after complex formation). The sample of fatty acids to be distributed, weighing from 5 to 15 g., was placed in the first (0) flask. A 250-ml. volume of the urea solution was added and the mixture was heated until complete solution was obtained. The flask was then cooled to the desired temperature, either in a water-bath or in a refrigerated chest, and allowed to stand until the precipitation of the adducts was complete. The cooling of the reaction mixture should be carried out gradually. Rapid cooling results in less satisfactory separations.

After the reaction in flask 0 has reached equilibrium (about 2 hr.), the supernatant liquid was transferred into flask 1. In most cases, the adduct crystals were well-formed and the liquid layer was decanted easily. If the crystals were small, however, the liquid layer was filtered off with suction. In order that this operation could be accomplished without removing the solid phase from the reaction flask, a rubber stopper was inserted inside the filtering section of a No. 1 Coors büchner funnel. The stopper was ground so that it fitted snugly against the perforated face of the funnel and was bored so that the neck of an erlenmeyer flask fitted into it tightly. A very narrow slit was made on the inside of the stopper so that air could pass into the flask during the filtration. In operation, the stopper was fitted over the flask. The funnel, fitted with filter paper, was placed over the stopper. This assembly was then inverted and attached to a suction flask. In this way, the liquid layer was removed quickly, while the solid phase remained in the flask. Another 250-ml. volume of urea solution was added to flask 0. Flasks 0 and 1 were heated until complete solution was achieved, and they were then cooled to the desired temperature and held until the reaction had reached equilibrium.

The liquid layer in flask 1 was then transferred to flask 2, and the liquid layer in flask 0 was transferred to flask 1. Another 250-ml. volume of urea solution was added to flask 0, and the flasks were heated and then cooled.

This procedure was repeated until the fatty acids in the sample were distributed over the total number of flasks in the system.

To extract the fatty acids from the fractions, each fraction was transferred to a separatory funnel, and 300 ml. of warm water and 10 ml. of concd. HCl were added. The fatty acids were then extracted with 1:1 mixed ether and petroleum ether. The ether extract was dried over magnesium sulfate after which the ether was removed by distillation. Traces of solvent were removed by heating the residual fatty acid fractions in a vacuum oven at 40° for 30 min. The solid fatty acids were crystallized from acetone prior to the determination of their physical constants.

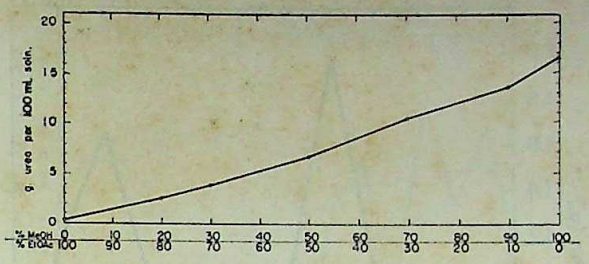

Fig. 1.—Solubility of urea in mixtures of methanol and ethyl acetate at 20°.

Results

1. Distribution of Mixed Stearic, Palmitic and Oleic Acids.—A mixture consisting of 5 g. each of technical-grade stearic, palmitic and oleic acid was distributed over 24 stages at 20° in a urea-saturated solvent made up of 70% methanol and 30% ethyl acetate. The results are shown in Fig. 2.

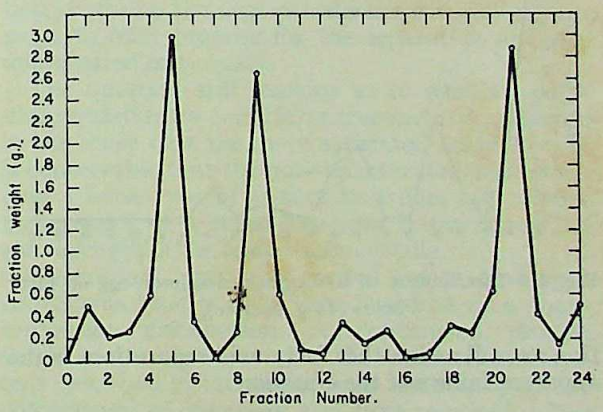

Fig. 2.—Distribution of a mixture of stearic, palmitic and oleic acids (5 g. each).

Fractions 0 through 15 were solids and the remaining fractions were oils. Stearic acid reached a maximum concentration in fraction 5; the physical constants of this fraction were m.p. 69.5°, I value 0.0 and $n^{72}D$ 1.4329. Palmitic acid was concentrated in fraction 9; the constants were m.p. 62.0°, I value 0.6 and $n^{70}D$ 1.4315. Oleic acid was concentrated in fraction 21; the constants were I value 89.5 and $n^{35}D$ 1.4545.

In addition to the major components, arachidic acid was concentrated in fraction 1; the constants of this fraction were m.p. 75.0°, I value 0.0, and $n^{80}D$ 1.4327. Fraction 13 apparently consists of myristic acid contaminated with an unsaturated fatty acid; the constants of this fraction were m.p. 50.5°, I value 2.3 and $n^{70}D$ 1.4305. Fractions 23 and 24 were considered to be largely dienoic fatty acid, owing to their respective refractive index values, $n^{35}D$ 1.4619 and $n^{35}D$ 1.4621.

One of the problems encountered in this separa-

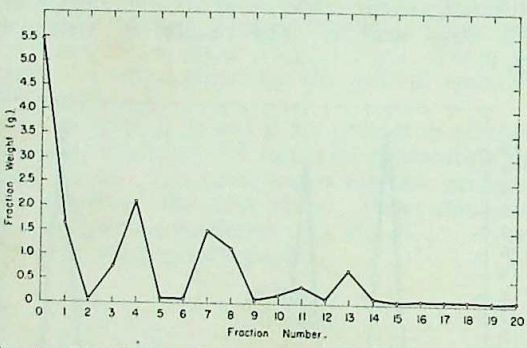

Fig. 4.—Distribution of hydrogenated salmon-egg oil fatty acids (15-g. sample).

tion as well as in other fatty acid separations is the apparent failure of the equation

$$N = n\,\frac{(K)}{K+1} \qquad (1)$$

to predict the point where the maximum of the distribution curve of a particular fatty acid will occur. In this equation, K is the distribution coefficient, N is equal to the number of flasks the maximal concentration has migrated from flask 0, and n is the total number of flasks used in the system. If $K/(K+1)$ is multiplied by 3.5, then the calculated values of N are in fair agreement with the experimental results. Possible explanations for this unexpected behavior might be: (1) large errors in the determined values of K, (2) failure of the reactions to completely reach equilibrium in the time allowed for each crystallization, (3) interaction between mixed fatty acids in the solution has a marked effect on the distribution coefficient of each individual fatty acid. It is felt that explanations 1 and 2 are unlikely to account for such a large discrepancy. Explanation 3, although of unknown significance, probably is the most likely one. The question is likely to remain unanswered until more detailed studies can be carried out. Some light may be thrown on the problem, by further experiments using pure fatty acids and their esters to avoid effects of interaction.

It is of interest to compare the results of urea countercurrent distribution of fatty acids with the results obtained by Ahrens and Craig[7] using a liquid–liquid system containing heptane, methanol, formamide and acetic acid. One difference is in the number of stages required to obtain a satisfactory separation. The liquid–liquid system required from 400 to 600 stages, depending on the nature of the fatty acid mixture, as compared to the 25 stages used for the urea system. The urea system permits larger amounts of fatty acids to be used per distribution as compared with either liquid–liquid countercurrent distribution or the various chromatographic methods which have been used.[8] It also does not require special equipment. However, operation of the urea system is very tedious and time consuming.

Distribution of the *cis–trans* Isomers, Oleic and Elaidic Acids.—It is a well-established fact that the formation of urea–fatty acid complexes is hindered by any distortion in the carbon chain of the fatty acid. It follows that the *cis* isomer of an unsaturated fatty acid should fit less readily in the urea crystal than the *trans* isomer. Thus, the urea countercurrent distribution technique may serve to separate *cis–trans* isomers, such as oleic and elaidic acids.

Elaidic acid was prepared from purified oleic acid by treatment with nitrous acid. The product was crystallized twice from petroleum ether.

A mixture made up of 5 g. each of oleic and elaidic acid was distributed over 12 stages at 20° in urea-saturated methanol. The results are shown in Fig. 3.

Fractions 0 through 5 were solid and the remaining fractions were liquid. Fraction 4 contained the maximum concentration of elaidic acid. The physical constants of this fraction were m.p. 45.5° and n^{70}D 1.4401. Fraction 9 contained the maximum concentration of oleic acid. The physical constants of this fraction were I value 89.3 and n^{35}D 1.4552. The elaidic acid distribution curve was skewed perhaps owing to the stearic acid present as an impurity in the system.

It appears from these results that urea countercurrent distribution may be an efficient method for separating a mixture of *cis–trans* isomers of the long-chain alkene type.

3. Distribution of Hydrogenated Salmon-Egg Oil Fatty Acids.[9]—Salmon-egg oil is characterized by a high content of poly-unsaturated C_{20}-, C_{22}- and C_{24}-fatty acids. Consequently, hydrogenated salmon-egg oil fatty acids should offer suitable raw material for the separation of C_{20} to C_{24} saturated fatty acids.

The hydrogenated sample (I value 6.7) was first separated into saturated and unsaturated fractions by treatment with acetone at −30°. Fifteen

grams of the saturated fraction was then distributed over 21 stages at 18° in a urea-saturated solvent consisting of equal volumes of methanol and ethyl acetate. The results are shown in Fig. 4. All of the fractions obtained from the distribution were solids except for the very small residues in fractions 17 through 20. Over one-third of the sample was found in fraction 0; the physical constants of this fraction were m.p. 73.8°, *I* value 0.0 and $n^{75}D$ 1.4341. Fraction 4, $n^{75}D$ 1.4322, was stearic acid; fraction 7, $n^{75}D$ 1.4302, was palmitic acid; and fraction 13, $n^{75}D$ 1.4285, was mainly myristic acid. Fraction 11, $n^{75}D$ 1.4292, was unidentified.

The results of this experiment suggest that the distribution of saturated fatty acids with more than 18 carbons could be done more successfully at temperatures above room temperature, probably in the range 30° to 35°.

4. **Distribution of Poly-unsaturated Fatty Acids.**—One of the difficult problems in oil chemistry is the separation of natural mixtures of unsaturated fatty acids containing 2 to 6 double bonds, such as those commonly found in marine oils. The preparation of highly unsaturated fatty acid concentrates from marine oils by the urea inclusion method has been reported.[1,10] The mild conditions inherent in the urea procedure are ideally suited for use in the separation of poly-unsaturated fatty acids, although the presence of double bonds in the chain greatly hinders the formation of urea–fatty acid adducts.

To determine whether poly-unsaturated fatty acids could be separated by the urea countercurrent technique, a 15-g. sample of unsaturated salmon-egg oil fatty acid (*I* value 350) was distributed over 18 stages at −30° in urea-saturated methanol. This experiment was exploratory and no attempt was made to characterize the products completely. The results are shown in Fig. 5. It appears from the curve that four fatty acids have been concentrated, one being in each of the fractions 7, 10, 12 and 14. Another fatty acid has perhaps been concentrated in fraction 9 but, if so, it is overshadowed by the large amount of material in fraction 10. The refractive indices of the fractions from this separation are given in Table II, together with the iodine numbers of the principal fractions. Fraction 15, after standing in a vacuum desiccator, was found to contain very fine, silky crystals, melting between 30–32°, in addition to oil. The crystals dissolved readily in the usual organic solvents.

TABLE II

Fraction	Wt., g.	Refractive Index $n^{30}D$	*I* value	Fraction	Wt., g.	$n^{30}D$	*I* value
0	0.000			9	1.503	1.4762	302
1	.020	....		10	1.771	1.4835	341
2	.030	....		11	0.961	1.4865

8	.531	1.4702		17	0.124	1.4928	

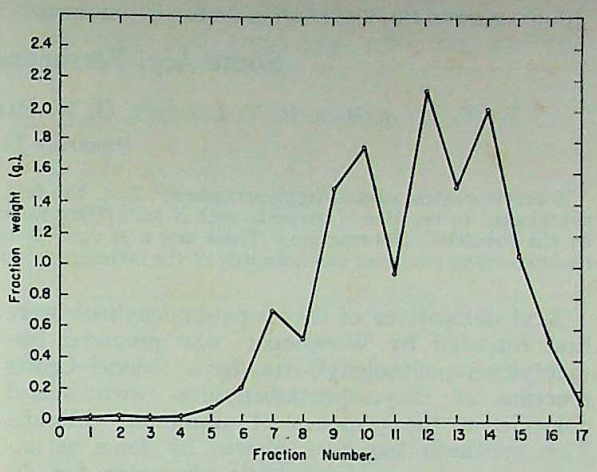

Fig. 5.—Distribution of unsaturated fatty acids from salmon-egg oil (15-g. sample).

The results of this distribution suggest that a larger number of stages should be used in future experiments. Although a considerable amount of work remains to be done toward improving the separation and also in characterizing the distribution products, the urea countercurrent method appears to offer promise for the separation of poly-unsaturated fatty acids.

The question still remains as to whether poly-unsaturated fatty acids form true inclusion adducts in the sense that the more saturated acids do. It is conceivable that the poly-unsaturated acids form only a loose type of adduct that does not require the creation of a crystalline urea lattice along the entire length of the fatty acid molecule.

Experiments are being carried out to develop a continuous type of separation based on urea countercurrent distribution. A continuous process would be greatly superior to the discontinuous system described in this paper from the standpoint of convenience of operation and time required. The experimental technique being used at present employs a 5.5 cm. × 45 cm. column packed with urea and maintained at a temperature suitable for the particular separation under study. The fatty acid sample dissolved in a suitable solvent is placed on the column, and the complexed fatty acids are then eluted with a non-polar solvent, such as hexane. The elution can be facilitated by raising the temperature of the column above the temperature used for forming the complexes.

In conclusion, it should be noted that the phenomenon of inclusion compound formation may become increasingly important in the future in the fields of organic chemistry and biochemistry.[7] In particular, the urea countercurrent technique could be applied to the problem of separating mixtures of petroleum hydrocarbons of the longer chain lengths as well as other types of aliphatic compounds.

Acknowledgment.—The author expresses his grateful appreciation to Mrs. Harriet Starr and Mr. Dave Wieg for their assistance in this work.

Some Acyl Ferrocenes and their Reactions

BY P. J. GRAHAM, R. V. LINDSEY, G. W. PARSHALL, M. L. PETERSON AND G. M. WHITMAN

RECEIVED JANUARY 10, 1957

Formylcyclopentadienyl-(cyclopentadienyl)-iron, the first ferrocene derivative bearing an aldehyde function, has been synthesized by reaction of ferrocene with N-methylformanilide. A number of new diacylferrocenes have also been prepared by the Friedel–Crafts reaction. These new acyl derivatives, as well as the known acetylferrocene and diacetylferrocene, undergo many reactions characteristic of the carbonyl group.

Acyl derivatives of dicyclopentadienyliron were first reported by Woodward[1] who prepared bis-(acetylcyclopentadienyl)-iron by a Friedel–Crafts reaction of dicyclopentadienyliron with acetyl chloride in the presence of aluminum chloride. This synthesis has been viewed by some as important evidence of aromatic character for dicyclopentadienyliron, though others have pointed out that acylation with Friedel–Crafts catalysts occurs with simple alicyclic compounds.[2]

Acetylcyclopentadienyl-(cyclopentadienyl)-iron (II) has been prepared by reaction of dicyclopentadienyliron with acetic anhydride in anhydrous hydrogen fluoride,[3] and in the presence of stannic chloride.[4] Pauson[5] interprets these results and his unpublished synthesis of the monoacetyl derivative with a boron trifluoride catalyst as evidence that dicyclopentadienyliron is more reactive than benzene. Some support is given this conclusion by our synthesis of formylcyclopentadienyl-(cyclopentadienyl)-iron from N-methylformanilide, dicyclopentadienyliron and phosphorus oxychloride, and by our preparation of acetylcyclopentadienyl-(cyclopentadienyl)-iron from dicyclopentadienyliron and acetic anhydride with phosphoric acid catalyst.

Diacyl derivatives of dicyclopentadienyliron reported herein were prepared by the Friedel–Crafts method. The acyl derivatives have been studied to determine effects of the dicyclopentadienyliron ring system on some reactions of the carbonyl group. In most cases, normal functionality was observed.

Formylcyclopentadienyl-(cyclopentadienyl)-iron; Dicyclopentadienylironcarboxaldehyde.—This aldehyde I was synthesized in 55% yield by the reaction of N-methylformanilide with dicyclopentadienyliron in phosphorus oxychloride at 50–55°.[5a] The new aldehyde formed such typical derivatives as a bisulfite addition product, a cyanohydrin, an oxime, an azine, a rhodanone and an acetal. It could be reduced to an alcohol and a hydrocarbon, and it underwent reductive amination. In other respects the aldehyde I displayed unexpected properties.

Under a polarizing microscope, formylcyclopentadienyl-(cyclopentadienyl)-iron was observed to undergo a sharp transition at 45° after which it was isotropic up to a temperature of 124.5°. Between these two temperatures, a liquid crystal region was observed and at 124.5° a sharp change in viscosity indicated the final melting point. Above the transition temperature of 45°, a sharp absorption peak characteristic of hydroxyl groups was observed in the infrared spectrum (Fig. 1). This unexplained hydroxyl absorption did not appear at the expense of carbonyl absorption and was observed only at temperatures above 45°. Chemically, the aldehyde was sensitive to oxidation either in dilute aqueous solutions or in concentrated anhydrous hydrocarbon solutions. The oxidation product, however, was not the carboxylic acid, since no acidic materials could be isolated from the typical amorphous brown oxidation product. When the aldehyde I was treated with Raney nickel and hydrogen at 50°, another unusual reaction was observed in its unexpected conversion to oxydimethylenebis-(dicyclopentadienyliron), $(C_5H_5FeC_5H_4CH_2)_2O$, instead of the expected alcohol, $C_5H_5FeC_5H_4CH_2OH$ (IV).

Acetylcyclopentadienyl-(cyclopentadienyl)-iron.—A new method for the synthesis of acetylcyclopentadienyl-(cyclopentadienyl)-iron (II) has been discovered in which acetylation is accomplished with acetic anhydride at 90° with phosphoric acid catalyst. This suggests that dicyclopentadienyliron is more reactive toward electrophilic substitution than realized heretofore. Some reactions of the monoacetyl derivative II have already been described. These include oxidation to a monocarboxylic acid, conversion to an oxime and reduction to a monoethyl derivative.[6] Acetylcyclopentadienyl-(cyclopentadienyl)-iron has now been found to undergo reductive amination and the Willgerodt reaction. The Willgerodt reaction proceeded smoothly in morpholine to give a stable crystalline thiomorpholide (X) which could be hydrolyzed in methanolic potassium hydroxide to the carboxymethyl derivative XI, and the carboxamide XII. Both the amide and free acid were stable in crystalline form, but aqueous solutions of the acid rapidly turned blue on exposure to air.

Bis-[(3-carboxypropionyl)-cyclopentadienyl]-iron.—Dicyclopentadienyliron reacted with succinic anhydride in the presence of aluminum chloride catalyst to give a bis-(carboxyacyl) derivative (XIII). Attempts to perform a Wolff–Kishner or Clemmensen reduction on this diacyl derivative were unsuccessful. Catalytic reduction apparently stopped at the hydroxyl stage as evidenced by isolation of the corresponding dilactone XIV. The dilactone also was obtained by catalytic reduction of the diethyl ester of bis-[(3-carboxypropionyl)-cyclopentadienyl]-iron (XVIII).

Bis-[(4-aminobutyl)-cyclopentadienyl]-iron.—This new diamine XVI was prepared readily by catalytic reduction of bis-[(3-cyanopropionyl)-cyclopentadienyl]-iron (XV), obtained by reaction of bis-[(3-chloropropionyl)-cyclopentadienyl]-iron with potassium cyanide. The bis-(chloroacyl) derivative was obtained by the method of Woodward[1] from ferrocene and β-chloropropionyl chloride with aluminum chloride catalyst. Bis-[(4-aminobutyl)-cyclopentadienyl]-iron underwent the reactions characteristic of an aliphatic diamine.

Experimental

Formylcyclopentadienyl-(cyclopentadienyl)-iron (I).—A mixture of 112 g. (0.6 mole) of finely ground dicyclopentadienyliron and 107 g. (0.7 mole) of phosphorus oxychloride was heated to 50°, and 81 g. (0.6 mole) of N-methylformanilide was added dropwise with stirring in 1.25 hours. The reaction mixture was cooled slowly to room temperature and allowed to stand for three hours. The resulting mixture was poured onto ice (500 g.) and extracted with diethyl ether for 45 hours in a continuous extractor. The extract was washed with water, 5% aqueous sodium carbonate solution, and again with water. The washed extracts were dried with anhydrous magnesium sulfate and the ether removed by distillation. Crude aldehyde was obtained as a black oil that solidified on standing. It was sublimed at 70° (1 mm.) to give 85.4 g. (66% yield) of formylcyclopentadienyl-(cyclopentadienyl)-iron. A recrystallization from a mixture of *n*-heptane and methylene chloride (3 to 1), gave 71 g. (55% yield) of pure aldehyde as a reddish-brown crystalline solid.

Anal. Calcd. for $C_{11}H_{10}FeO$: C, 61.7; H, 4.71; Fe, 26.1; mol. wt., 214. Found: C, 61.9; H, 4.73; Fe, 26.3; mol. wt., 202.

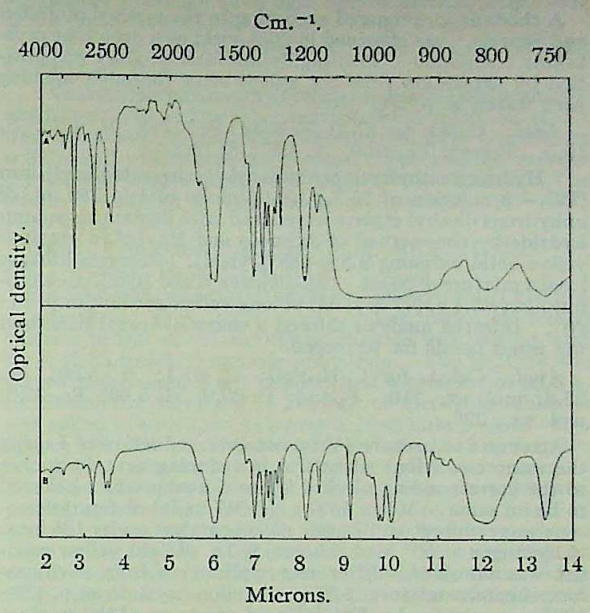

Fig. 1.—Infrared spectrum of formylcyclopentadienyl-(cyclopentadienyl)-iron above (A) and below (B) the transition temperature of 45°.

The aldehyde showed a sharp transition temperature at 45° under polarized light. True melting indicated by a sharp viscosity change occurred at 124.5°. The aldehyde was also prepared with dimethylformamide[7] as the formylating agent. This method required more vigorous conditions (85°, 3.5 hr.), produced considerable tar and gave only 23% yield of aldehyde I in 17% conversion.

Formylcyclopentadienyl-(cyclopentadienyl)-iron (10 g., 0.046 mole) was shaken vigorously with 100 g. of 40% aqueous sodium bisulfite and 15 ml. of ethyl alcohol to obtain 13.3 g. (90% yield) of a yellow bisulfite addition compound. The addition product could not be purified readily by recrystallization and was merely washed with cold water and with chloroform. The analyses indicated some impurities were still present in the product.

Anal. Calcd. for $C_{11}H_{11}FeNaO_4S$: C, 41.5; H, 3.5; Fe, 14.4; S, 10.1. Found: C, 34.7; H, 3.8; Fe, 16.2; S, 10.6.

An oxime III was prepared in 77% yield by reaction of hydroxylamine with I in aqueous methanol at 30°. The oxime was recrystallized from a 2:3 mixture of benzene and heptane, m.p. 133–135°. A transition temperature was noted at 98°.

Anal. Calcd. for $C_{11}H_{11}FeNO$: C, 57.6; H, 4.84; Fe, 24.4; N, 6.11. Found: C, 57.8; H, 5.08; Fe, 24.4; N, 6.37.

A semicarbazone was obtained in 58% yield by reaction of semicarbazide with I in aqueous ethyl alcohol at 60°. The purified semicarbazone, m.p. 203–204° dec., was obtained by recrystallization from a 5:4 mixture of ethyl alcohol and dimethylformamide.

Anal. Calcd. for $C_{12}H_{13}FeN_3O$: Fe, 20.6; N, 15.5. Found: Fe, 20.8; N, 15.5.

An isonicotinylhydrazone, prepared from I according to the method of Fox and Gibas,[8] was obtained in 39% yield after recrystallization from a mixture of isopropyl alcohol and ethyl alcohol (2:1), m.p. 212–213°.

Anal. Calcd. for $C_{17}H_{15}FeN_3O$: Fe, 16.7; N, 12.6. Found: Fe, 17.0; N, 12.5.

An azine, prepared by reaction of I with hydrazine hydrate in methanol at room temperature, was obtained in 47% yield as red-brown crystals after recrystallization from dimethylformamide, m.p. 245°.

Anal. Calcd. for $C_{22}H_{20}N_2Fe_2$: N, 6.61. Found: N, 6.65.

A rhodanone, prepared according to the method of Julian and Sturgis,[9] was obtained in 70% yield as a deep blue crystalline compound. This highly insoluble product was purified by extraction with hot xylene after thorough washing with water, m.p. 245° dec.

Anal. Calcd. for $C_{14}H_{11}FeNO_2$: Fe, 17.0; N, 4.25; S, 19.5. Found: Fe, 16.9; N, 4.37; S, 19.2.

Hydroxymethylcyclopentadienyl-(cyclopentadienyl)-iron (IV).—A solution of 10.7 g. (0.05 mole) of I in 250 ml. of anhydrous diethyl ether was reduced with lithium aluminum hydride by the method of Arimoto and Haven[6] to obtain a yellow solid weighing 9.5 g. (88% yield). Recrystallization from a mixture of 60 ml. of Skellysolve B and 10 ml. of chloroform gave 5.4 g. (47% yield) of long yellow needles, m.p. 74–76°. Infrared analysis showed a sharp hydroxyl band and the usual bands for ferrocene.

Anal. Calcd. for $C_{11}H_{12}FeO$: C, 61.1; H, 5.60; Fe, 25.8; mol. wt., 216. Found: C, 60.9; H, 5.69; Fe, 26.0; mol. wt., 225.

Attempts to prepare IV by catalytic reduction of I using the same conditions successful in reducing acetylferrocene to the corresponding alcohol led to a new product believed to be an ether. When 10.0 g. (0.047 mole) of formylferrocene was reduced with Raney nickel catalyst under 135 atm. of hydrogen at 50° for 1.5 hours, 9.0 g. of light yellow product was obtained. After recrystallization from a chloroform–heptane mixture, 5.35 g. of yellow crystals, m.p. 129–130°, was obtained. The infrared spectrum of the product did not show hydroxyl or carbonyl absorption bands. The spectrum did show the presence of ether links, and a molecular weight determination supports the proposed ether structure, $(C_5H_5FeC_5H_4CH_2)_2O$, oxydimethylenebis-(dicyclopentadienyliron).

Anal. Calcd. for $C_{22}H_{22}Fe_2O$: C, 63.8; H, 5.35; Fe, 27.1; mol. wt., 414. Found: C, 63.7; H, 5.49; Fe, 27.4; mol. wt., 465.

Ferrocenylmethyltrimethylammonium Iodide (V).—A solution of 21.4 g. (0.1 mole) of I in 100 ml. of methanol was heated with 25 g. of dimethylamine in the presence of Raney nickel catalyst at 120° for three hours under 165 atm. pressure of hydrogen. The reaction mixture was filtered through charcoal, diluted with water and extracted with four 75-ml. portions of ether. The combined extracts were washed once with water, dried over magnesium sulfate and filtered. The clear filtrate was treated with a solution of 20 g. of methyl iodide in 50 ml. of anhydrous ether. The yellow precipitate that formed almost immediately was washed with dry ether and dried in a vacuum desiccator over phosphorus pentoxide. The finely divided yellow quaternary methiodide, m.p. 218° dec., weighed 29.1 g. (76% yield) and was readily soluble in water.

Anal. Calcd. for $C_{14}H_{20}FeIN$: C, 43.7; H, 5.23; Fe, 14.5; N, 3.63; I, 32.9. Found: C, 43.9; H, 5.30; Fe, 14.7; N, 3.55; I, 32.9.

This quaternary ammonium iodide was reported recently by Hauser and Lindsay[10] who prepared it by quaternization of dimethylaminoferrocene prepared from ferrocene, formaldehyde and dimethylamine.

Cyanocyclopentadienyl-(cyclopentadienyl)-iron (VI).—Acetic anhydride (40 ml.) was added to 20 g. of the oxime III at room temperature to give a deep red-brown solution. After about 30 minutes, the reaction mixture was poured onto 200 g. of ice, 10 g. of sodium carbonate added, and the red-orange oil that separated was extracted with methylene chloride. The combined extracts were washed with 100 ml. of 5% aqueous sodium carbonate followed by three washings with distilled water. The methylene chloride solution was dried over magnesium sulfate, filtered, and the solvent was evaporated at room temperature under a stream of nitrogen. The resulting viscous red oil decomposed slowly at room temperature to give acetic acid. Analysis indicated the oil was an acetate of the oxime III.

Anal. Calcd. for $C_{12}H_{12}FeNO_2$: Fe, 20.6. Found: Fe, 20.7.

The oxime acetate was placed in a vacuum desiccator over phosphorus pentoxide and pumped to remove the acetic acid produced by slow decomposition. After several days, the oil solidified. The solid residue was sublimed at 100° (1 mm.) for several days until no more brown sublimate was obtained. The crude product (10 g.) was recrystallized from 125 ml. of *n*-heptane to obtain 8.5 g. (46% yield) of pure cyanoferrocene, m.p. 103–104°.

Anal. Calcd. for $C_{11}H_9FeN$: C, 62.6; H, 4.30; Fe, 26.3; N, 6.64. Found: C, 62.6; H, 4.61; Fe, 26.7; N, 6.64.

1-Hydroxy-1-cyanomethylcyclopentadienyl-(cyclopentadienyl)-iron (VII).—The bisulfite addition compound of ferrocenecarboxaldehyde (I) was prepared by adding 21.4 g. (0.1 mole) of I in 35 ml. of ethyl alcohol to 20.8 g. (0.2 mole) of sodium bisulfite in 100 ml. of distilled water. To this slurry was added 9.8 g. (0.2 mole) of sodium cyanide in 100 ml. of water. The mixture was stirred for two hours at about 50°, cooled in ice and filtered. Extraction of the moist product (31 g.) with two 175-ml. portions of benzene and concentration of the extracts gave 17 g. of crude cyanohydrin. After recrystallization from benzene containing a trace of alcohol, 12.5 g. (52%) of cyanohydrin VII was obtained, m.p. 104°, slight decomposition, followed by sharp and complete decomposition at 125°.

It was not possible to prepare the cyanohydrin VII directly from ferrocenecarboxaldehyde and sodium cyanide. Successful preparations of VII were achieved only with the bisulfite addition compound as intermediate.

Anal. Calcd. for $C_{12}H_{11}FeNO$: C, 59.8; H, 4.60; Fe, 23.2; N, 5.81. Found: C, 59.6; H, 4.68; Fe, 23.5; N, 6.03.

2-Cyano-2-carboxyvinylcyclopentadienyl-(cyclopentadienyl)-iron (VIII).—A solution of 21.4 g. (0.1 mole) of I in anhydrous pyridine (50 ml.) was mixed at room temperature with a solution of 26 g. of cyanoacetic acid (0.3 mole) in 20 ml. of pyridine. The mixture was heated 2.5 hours on a steam-bath, cooled and allowed to stand for two days at room temperature. The mixture was diluted with 500 ml. of cold water, cooled in an ice-bath, and acidified with 150 ml. of 6 *N* sulfuric acid. The acidified mixture was extracted with four 150-ml. portions of methylene chloride and the combined extracts were washed three times with 200 ml. of water. The methylene chloride solution was dried with magnesium sulfate and evaporated to an oil which was treated with a solution of sodium carbonate monohydrate (20 g. in 200 ml. of water). The pastey mass that resulted was diluted with 100 ml. of water and filtered. The alkaline filtrate was cooled in an ice-bath and acidified with 6 *N* sulfuric acid to give 5.3 g. (19%) of a purple, gummy precipitate that crystallized on standing. Recrystallization from a mixture of chloroform and carbon tetrachloride gave 3.5 g. of pure VIII, m.p. 158.5–160° dec.

Anal. Calcd. for $C_{14}H_{11}FeNO_2$: C, 59.8; H, 3.95; Fe, 19.9; N, 4.98. Found: C, 59.8; H, 3.95; Fe, 19.7; N, 4.90.

The free acid VIII gave deep purple solutions in acetone or alcohol. Ultraviolet and visible spectra taken on the alcohol solution showed strongest absorptions at 2620, 3200 and 8300 Å.

Sodium Salt.—The solid remaining from the sodium carbonate extraction was dried over phosphorus pentoxide and extracted once with 150 ml. of chloroform to remove unreacted aldehyde. The residue was recrystallized from ethyl alcohol to give 9.4 g. (31% yield) of a dark red sodium salt of VIII.

Anal. Calcd. for $C_{14}H_{10}FeNNaO_2$: Fe, 18.4; Na, 7.59. Found: Fe, 17.9; Na, 8.02.

The sodium salt reacted readily with cupric acetate to give a red insoluble copper salt.

Hydantoin from Formylcyclopentadienyl-(cyclopentadienyl)-iron.—Moist bisulfite addition compound, prepared from 21.4 g. (0.1 mole) of ferrocenecarboxaldehyde (I), was slurried in 150 ml. of ethyl alcohol and added rapidly to a stirred mixture of 29.4 g. (0.45 mole) of potassium cyanide, 86.3 g. (0.9 mole) of ammonium carbonate, 150 ml. of distilled water and 50 ml. of ethyl alcohol. The reaction was stirred vigorously at 55° for 1.5 hours and cooled to room temperature. The alcohol was distilled from the mixture, and the residue was cooled and filtered to give 19 g. of an olive-brown hydantoin. The crude hydantoin was washed with hot benzene and hot methanol. The gray residue (11 g.) was purified by solution in 4% aqueous sodium hydroxide solution followed by filtration and acidification to give 9.0 g. (32% yield) of an olive product. One recrys-

tallization from 1,2-dimethoxyethane and one from aqueous dimethylformamide afforded a pale yellow-brown crystalline product, m.p. 192–197° dec.

Anal. Calcd. for $C_{13}H_{12}FeN_2O_2$: C, 54.9; H, 4.26; Fe, 19.7; N, 9.86. Found: C, 54.3; H, 4.48; Fe, 19.7; N, 9.64.

5-Ferrocenylmethylenebarbituric Acid.—A solution of 6.4 g. (0.05 mole) of barbituric acid and 3.0 g. of anhydrous potassium acetate in 150 ml. of glacial acetic acid was filtered and heated to 95°. To it was added portionwise in about two minutes 10.7 g. (0.05 mole) of aldehyde I. The reaction mixture, which became deep blue immediately, was allowed to cool slowly to room temperature. The mixture was filtered and the crystalline violet precipitate was washed once with glacial acetic acid and three times with methanol. The washed product weighed 11.1 g. after drying over phosphorus pentoxide. An additional 2.0 g. of product (total yield 80%) was obtained by dilution of the filtrate with water to cause precipitation. After filtration, drying and sublimation of the residue, volatile impurities such as formylferrocene and ferrocene were removed by sublimation. The compound did not melt below 360°.

Anal. Calcd. for $C_{15}H_{12}FeN_2O_3$: C, 55.6; H, 3.73; N, 8.64. Found: C, 55.1; H, 3.76; N, 8.95.

Acetylcyclopentadienyl-(cyclopentadienyl)-iron (II).—A mixture of 93 g. (0.5 mole) of dicyclopentadienyliron, 250 ml. of acetic anhydride and 20 ml. of 85% phosphoric acid was heated at 100° for 10 minutes. The reaction mixture was cooled slightly and poured onto ice. After standing overnight, the mixture was neutralized with 200 g. of sodium carbonate monohydrate in 200 ml. of water. The resulting brown pasty mass was cooled in an ice-bath and filtered. The tan product was washed four times with 100-ml. portions of water and filtered. The granular product was dried in a vacuum desiccator over phosphoric anhydride. Sublimation of the crude product at 100° (1 mm.) gave 81.5 g. (71.4% yield) of an orange crystalline product II, m.p. 85–86° (lit.[3] 85–86°) after recrystallization from *n*-heptane.

1-Aminoethylcyclopentadienyl-(cyclopentadienyl)-iron (IX).—A mixture of 22.8 g. (0.1 mole) of the monoacetyl derivative II, 125 ml. of absolute ethyl alcohol, 30 g. of liquid ammonia and 10 g. of Raney nickel catalyst was heated for 3 hr. at 100° and 135 atm. hydrogen pressure. The red orange solution was mixed with 2 g. of Celite and filtered to remove catalyst. The filtrate was poured into 500 ml. of cold water and extracted with diethyl ether. About 600 ml. of extracts were combined, washed three times with water, and dried with anhydrous magnesium sulfate. The drying agent was removed by filtration, the filtrate was diluted with one liter of anhydrous ether, and the solution was treated with dry hydrogen chloride. After about 15 minutes, the pink amine hydrochloride was collected by filtration, washed with diethyl ether, partially air-dried, slurried with 100 ml. of chloroform at room temperature, and filtered. Further washing with chloroform on the büchner funnel gave a pale yellow solid weighing 5.9 g. after drying in a vacuum desiccator over phosphoric anhydride. Recrystallization from 75 ml. of anhydrous ethyl alcohol gave 3.3 g. of a lemon-yellow hydrochloride, m.p. 163–165° dec.

Anal. Calcd. for $C_{12}H_{16}ClFeN$: C, 54.2; H, 6.07; N, 5.27. Found: C, 54.4; H, 6.19; N, 5.37.

Thiomorphylamidomethylcyclopentadienyl-(cyclopentadienyl)-iron (X).—A mixture of 9.5 g. of the monoacetyl derivative II, 1.9 g. of sulfur and 5.2 ml. of morpholine was heated at 130° for 2.5 hours. The viscous black reaction mixture was extracted with hot methanol, and the extracts were diluted with water to give a dark brown precipitate of thioamide X. Successive recrystallizations from benzene–hexane and water–methanol mixtures gave orange needles, m.p. 128.5–129°, yield 4.5 g. (30%).

Anal. Calcd. for $C_{16}H_{19}FeNOS$: C, 58.3; H, 5.83; N, 4.26; S, 9.74. Found: C, 58.9; H, 6.01; N, 4.48; S, 9.79.

Carboxymethylcyclopentadienyl-(cyclopentadienyl)-iron (XI).—A solution of 5.0 g. of the thioamide X in 50 ml. of 10% methanolic potassium hydroxide was refluxed 17 hours. The reaction mixture was poured into 800 ml. of cold water and was thoroughly extracted with ether. Neutralization of the aqueous layer with concentrated hydrochloric acid gave a fine yellow precipitate. Recrystallization from decolorizing carbon and dilute methanol gave light yellow needles, m.p. 150–152°,[11] yield 2.5 g. (60%).

Anal. Calcd. for $C_{12}H_{12}FeO_2$: C, 59.1; H, 4.96. Found: C, 59.1; H, 5.17.

Carboxymorphilomethylcyclopentadienyl-(cyclopentadienyl)-iron (XII).—The ether extracts from synthesis of XI were combined, washed with water, dried over magnesium sulfate and evaporated to dryness. The residue was recrystallized from a mixture of benzene and hexane. The amide crystallized as fine yellow needles, m.p. 148–149°, yield 0.3 g. (6%).

Anal. Calcd. for $C_{16}H_{19}FeNO_2$: C, 61.3; H, 6.12; N, 4.47. Found: C, 61.1; H, 6.10; N, 4.57.

Bis-[(3-carboxypropionyl)-cyclopentadienyl]-iron (XIII).—A mixture of 96 g. (0.72 mole) of anhydrous aluminum chloride in 200 ml. of methylene chloride was treated with 36 g. (0.36 mole) of succinic anhydride. The mixture was stirred and shaken a few minutes and a solution of 33.3 g. (0.18 mole) of ferrocene in 200 ml. of methylene chloride was added in small portions over a 10-minute period. Hydrogen chloride gas was evolved and the heat of reaction brought the mixture to 35°. The dark violet, viscous solution was allowed to stand 7 hours at room temperature, poured onto ice, and filtered. The air-dried solid (yield 46 g.), was extracted once with 800 ml. of boiling water and twice with 150 ml. of boiling water. The combined extracts were cooled in an ice-bath and filtered to obtain 19.7 g. (38% yield) of crystalline bis-[(3-carboxypropionyl)-cyclopentadienyl]-iron, m.p. 164–166° dec.[11]

Anal. Calcd. for $C_{18}H_{18}FeO_6$: C, 56.0; H, 4.69; Fe, 14.5; neut. equiv., 193. Found: C, 56.3; H, 4.94; Fe, 14.9; neut. equiv., 193.

The acid XIII was converted to the corresponding diethyl ester XVIII by slowly distilling a solution of 21.3 g. of the acid, 1.5 g. of sulfuric acid, 200 ml. of ethyl alcohol and 250 ml. of toluene through a small still. After slow distillation for 4 hours, the remaining solution was cooled to room temperature and washed with 75 ml. of 10% aqueous sodium carbonate solution. The toluene solution was dried over magnesium sulfate, filtered and evaporated at room temperature to obtain 23 g. (94%) of red-brown crystals. Crystallization from ethyl alcohol gave 20.3 g. of shiny orange-brown platelets of bis-[3-carbethoxypropionyl)-cyclopentadienyl]-iron (XVIII), m.p. 134–136°.

Anal. Calcd. for $C_{22}H_{26}O_6Fe$: C, 59.7; H, 5.92; Fe, 12.6. Found: C, 59.8; H, 6.04; Fe, 12.8.

Bis-[(5-oxotetrahydro-2-furyl)-cyclopentadienyl]-iron (XIV).—A mixture of 17.1 g. (0.06 mole) of (XIII), 200 ml. of ethyl alcohol and 1 g. of ruthenium dioxide was heated for 3 hours at 85° under 165 atm. of hydrogen pressure. The reaction mixture was heated on a steam-bath and filtered through charcoal. Evaporation of the alcohol gave a tan, gummy residue that was converted to 7.5 g. of fine yellow powder by extraction with methanol. Recrystallization from 50 ml. of chloroform gave 4.3 g. of a yellow crystalline product. This was dissolved in 30 ml. of boiling chloroform, diluted with 25 ml. of methanol and evaporated until crystallization began. The mixture was cooled slowly to obtain 3.7 g. (17.5%) of golden yellow crystals of pure bis-[(5-oxotetrahydro-2-furyl)-cyclopentadienyl)-iron, m.p. at 165° dec.

Anal. Calcd. for $C_{18}H_{18}FeO_4$: C, 61.0; H, 5.12; Fe, 15.8. Found: C, 61.2; H, 5.12; Fe, 15.9.

The lactone also was obtained by hydrogenation of the ester XVIII with Raney nickel catalyst at 75° and 135 atm. of hydrogen pressure.

Bis-[(3-cyanopropionyl)-cyclopentadienyl]-iron (XV).—A solution of 10 g. of bis-[(3-chloropropionyl)-cyclopentadienyl]-iron (prepared by the method of Woodward[1] in 34% yield) and 4.0 g. of potassium cyanide in 150 ml. of ethyl alcohol was refluxed for 4 hours. The reaction mixture was filtered and the filtrate was cooled in an ice-bath to obtain 5.4 g. of an orange-red crystalline material, m.p. 118–121°. Recrystallization from toluene followed by recrystallization from ethyl alcohol gave orange crystals, m.p. 133–134°.

(11) Variations in decomposition temperatures have been noted in ferrocene derivatives having carboxyl functions. The decomposition temperature of bis-{(3-carboxypropionyl)cyclopentadienyl}-iron varies with heating rate. This may account for some discrepancy between [illegible] Reinhart, Curby and Sokol (p. 3420).

Anal. Calcd. for $C_{18}H_{16}N_2O_2Fe$: C, 62.1; H, 4.63; Fe, 16.0. Found: C, 61.9; H, 4.83; Fe, 16.4.

Bis-[(4-aminobutyl)-cyclopentadienyl]-iron (XVI).—A solution of 8.2 g. (0.023 mole) of XV in 100 ml. of ethyl alcohol was hydrogenated over Raney nickel catalyst at 65° and 135 atm. of hydrogen pressure. The solution was filtered to remove catalyst, dried over magnesium sulfate and diluted with 500 ml. of ether. Dry hydrogen chloride gas was passed in to produce a dark red oil that slowly crystallized. The product was filtered, washed with ethyl alcohol and dissolved in 50 ml. of water. Addition of an aqueous solution of sodium carbonate precipitated 5.3 g. of an orange solid which was recrystallized from heptane to give fine orange crystals, m.p. 137–138°.

Anal. Calcd. for $C_{18}H_{28}N_2Fe$: N, 8.53; Fe, 17.0; neut. equiv., 164. Found: N, 8.87; Fe, 17.8; neut. equiv., 162.

Bis-[(1-hydroxyethyl)-cyclopentadienyl]-iron (XVII).—To a cooled solution of 3 g. of lithium aluminum hydride in 150 ml. of tetrahydrofuran, 30 g. of bis-(acetylcyclopentadienyl)-iron was added slowly. After the reaction was complete, 25 g. of ethyl acetate was added to the yellow solution. A mixture of ether, ethyl alcohol and the calculated quantity of water to destroy the aluminum complexes was added to the mixture. The solution was filtered with aid of Celite, and the filter cake was washed thoroughly with ether. Evaporation of the filtrates gave 27.8 g. (92%) of crude, yellow diol. Recrystallization from hexane gave yellow crystals, m.p. 69–71°.

Anal. Calcd. for $C_{14}H_{18}O_2Fe$: Fe, 20.4. Found: Fe, 20.6.

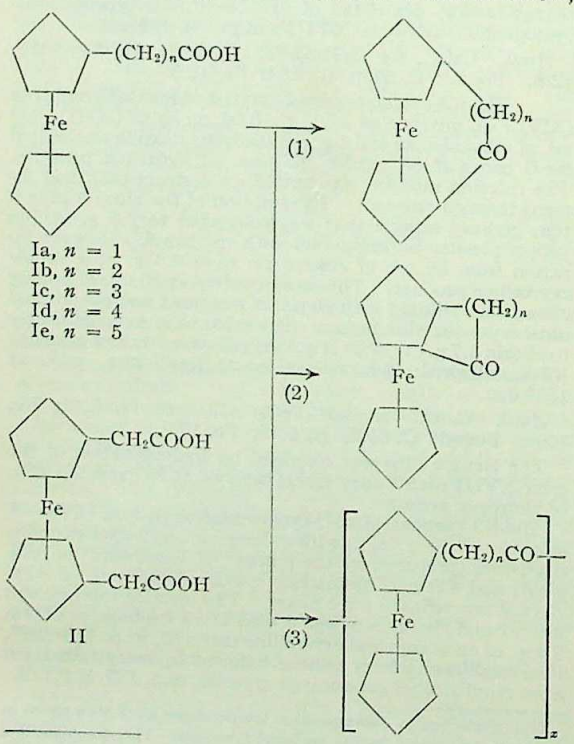
Organic Chemistry of Ferrocene. II. The Preparation of ω-Ferrocenyl Aliphatic Acids[1]

BY KENNETH L. RINEHART, JR., RONALD J. CURBY, JR., AND PHILLIP E. SOKOL

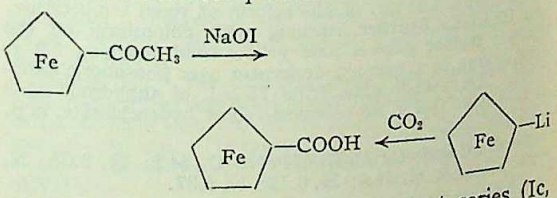
RECEIVED JANUARY 28, 1957

Five ω-ferrocenyl aliphatic acids have been synthesized; these are ferrocenylacetic acid, β-ferrocenylpropionic acid, γ-ferrocenylbutyric acid, δ-ferrocenylvaleric acid and ε-ferrocenylcaproic acid. Synthetic methods employed include the Willgerodt reaction of ferrocenyl ketones, carbethoxylation of acetylferrocene and Friedel–Crafts acylations of ferrocene.

As a portion of a general investigation of the spatial requirements for intramolecular reaction of substituted ferrocenes *vs.* intermolecular reaction by these compounds, a study has been undertaken of the relative tendency of ferrocene-substituted aliphatic acids (I) to undergo heteroannular and homoannular ring closure (routes 1 and 2 below, respectively) and polymer formation (route 3).[1,2] The present paper deals with the synthesis of the ω-ferrocenylmonocarboxylic acids ferrocenylacetic acid (Ia), β-ferrocenylpropionic acid (Ib), γ-ferrocenylbutyric acid (Ic), δ-ferrocenylvaleric acid (Id) and ε-ferrocenylcaproic acid (Ie) and the dicarboxylic acid 1,1′-ferrocenediacetic acid (II).



A number of substituted ferrocenecarboxylic acids (I, $n = 0$) have been previously prepared, both by the hypohalite oxidation of the corresponding acetylferrocenes[3–6] and by the carboxylation of ferrocenyllithium compounds.[7,8] As neither of these methods is readily applicable to the synthesis of the present acids, alternative routes have been investigated, adapted to the preparation of the individual compounds.



The higher homologs of the present series (Ic, Id, Ie) were easily prepared in sizable quantities by hydrogenation of the corresponding ω-keto acids (IIIa, IIIb, IIIc). The keto acids, in turn, were prepared by Friedel–Crafts acylation of fer-

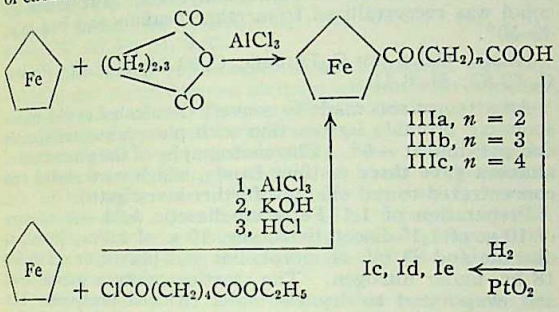
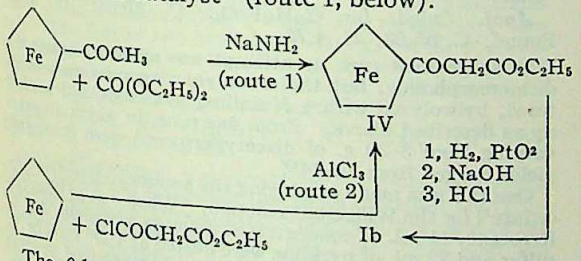
rocene with a limited amount of appropriate acid derivatives under conditions designed to give principally monoacylation.[3] Thus, ferrocene and succinic anhydride gave β-ferrocenoylpropionic acid (IIIa), and ferrocene and glutaric anhydride gave γ-ferrocenoylbutyric acid (IIIb), while ferrocene and δ-carbethoxyvaleryl chloride gave δ-ferrocenoylvaleric acid (IIIc). Yields from the anhydrides approximated 90%, while that from the half-ester acid chloride was 70%. Hydrogenation of each keto acid was effected in good yield.

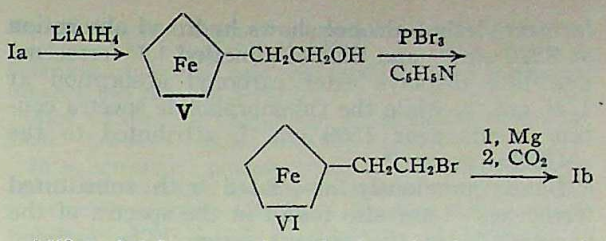


A similar procedure has been employed for the synthesis of β-ferrocenylpropionic acid by Woodward and Csendes,[9] who acylated ferrocene with carbethoxyacetyl chloride (route 2, below) to give the β-keto ester ethyl ferrocenoylacetate (IV) in good yield. Since carbethoxyacetyl chloride is inconvenient to prepare,[10] alternative routes have been investigated in the present study. The most convenient proved to be the carbethoxylation of acetylferrocene, employing diethyl carbonate and sodium amide catalyst[11] (route 1, below).

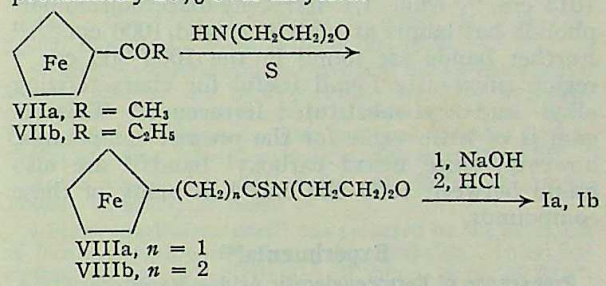


The β-keto ester IV was not isolated but was hydrogenated, then hydrolyzed directly to β-ferrocenylpropionic acid. No attempt was made to establish optimum conditions, but the ready availability of the starting materials render this approach particularly attractive.

Two alternative routes to β-ferrocenylpropionic acid were investigated but proved considerably less successful. One, the Willgerodt reaction of propionylferrocene, gave the acid, but in only very low yield, as described in the next paragraph. The second, below, was abandoned when the attempted conversion of β-ferrocenylethyl alcohol (V) to the corresponding bromide VI gave a complex mixture of products.



The Willgerodt reaction[12] was employed with success in the preparation of both ferrocenylacetic acid[13] and β-ferrocenylpropionic acid, from acetylferrocene (VIIa) and propionylferrocene (VIIb), respectively. The usual conditions[14] for the Kindler variation[15] of the Willgerodt reaction were modified slightly by the addition of dioxane to lower the reflux temperature, as the intermediate thiomorpholide was found to decompose at the normal reflux temperatures. Ferrocenylacetothiomorpholide (VIIIa) was obtained in 40% yield from one run and could be hydrolyzed in alkali to the corresponding acid. In other runs the thiomorpholide was not isolated, and the crude reaction mixture was hydrolyzed to give ferrocenylacetic acid in approximately 20% over-all yield.



No attempt was made to isolate β-ferrocenylpropionothiomorpholide (VIIIb), but the yield of β-ferrocenylpropionic acid from hydrolysis of the crude reaction mixture was only 4%, reflecting the usually lower yields of product obtained from higher alkyl aryl ketones compared to those from methyl aryl ketones.[12]

The dicarboxylic acid 1,1′-ferrocenediacetic acid was prepared by the same procedure in 13% over-all yield and was characterized as its dimethyl ester.

Infrared spectra are consistent with those anticipated for compounds of the structures given.[16] Thus, the spectra of the acids contain carboxyl carbonyl bands in the 1712–1705 cm.$^{-1}$ region, while those of the ketonic compounds, with carbonyl adjacent to the ferrocene nucleus, have bands between 1667–1663 cm.$^{-1}$.[17] The spectrum of

(17) Exceptions to these values are found in the spectra of ferrocenylacetic acid and ε-ferrocenylcaproic acid, which show carboxyl carbonyl absorption at 1698 and 1694 cm.$^{-1}$, respectively, when determined in mulls. However, spectra of these compounds in chloroform solution have carboxyl bands at the normal positions. Also exceptional are the mull spectra of δ-ferrocenoylvaleric acid, which has two carboxyl bands, at 1723 and 1702 cm.$^{-1}$, and two ketone bands at 1658 and 1638 cm.$^{-1}$, and, to a lesser extent, the mull spectrum of β-ferrocenoylpropionic acid, with two ketone bands, at 1657 and 1640 cm.$^{-1}$. In these compounds, too, the abnormalities are absent from [illegible]

Digitized by Arya Samaj Foundation Chennai and eGangotri

ferrocenylethyl alcohol shows hydroxyl absorption at 3220 cm.$^{-1}$ and that of dimethyl 1,1′-ferrocenediacetate displays ester carbonyl absorption at 1740 cm.$^{-1}$, while the thiomorpholide spectra contain bands near 1500 cm.$^{-1}$, attributed to the —CSN= group.[18]

Bands previously associated with substituted ferrocenes[3,19] are also found in the spectra of the compounds in the present series. The carbon–hydrogen stretching band[19] is found between 3090 and 3040 cm.$^{-1}$, usually near 3060 cm.$^{-1}$, for every compound and carbon–hydrogen bending bands[19] in the narrow region 828–820 cm.$^{-1}$. All of the compounds with one unsubstituted cyclopentadienyl ring have bands near 1110 and 1005 cm.$^{-1}$ (9–10 μ rule),[20] although in some cases the 10 μ band is very weak. Thus the *absence* of *both* bands would be strong indication of substitution on both rings. However, the *presence* of one or more bands in these positions cannot be taken conclusively as proof of an unsubstituted ring. For example, in the present series dimethyl 1,1′-ferrocenediacetate has a band at 1015 cm.$^{-1}$, while 1,1′-ferrocene-diacetodithiomorpholide has bands at both 1111 and 1006 cm.$^{-1}$.[21] Further bands are found in the 1000–900 cm.$^{-1}$ region previously found useful for characterizing alkyl- and acyl-substituted ferrocenes.[3] This region is of little value for the present compounds, however, since broad carboxyl bands[22] are also found between 1000–900 cm.$^{-1}$ in many of these compounds.

Experimental[23]

Preparation of Ferrocenylacetic Acid.—A mixture of 20 g. of acetylferrocene, 7 g. of sulfur, 50 ml. of dioxane and 150 ml. of morpholine was heated at reflux for 18 hr. under nitrogen. The reaction mixture was filtered and evaporated to small volume under reduced pressure, then transferred to an alumina column and eluted in two fractions with benzene. From the first fraction was obtained 10.2 g. (35%) of **ferrocenylacetothiomorpholide**, m.p. 126–128°, and from the second fraction 1.0 g. (5%) of recovered acetylferrocene. Ferrocenylacetothiomorpholide, recrystallized from ether, had m.p. 130–131°.

Anal. Calcd. for $C_{16}H_{19}FeNOS$: C, 58.29; H, 5.80; N, 4.25. Found: C, 58.71, 58.52; H, 5.86, 5.75; N, 4.55.

The crude thiomorpholide was heated under reflux for 4 hr. with 2 *N* aqueous sodium hydroxide, then filtered, washed with ether and acidified with hydrochloric acid. The precipitated acid was extracted into ether, and the ether extracts were washed with water, dried and evaporated to small volume. Addition of pentane gave 5.5 g. (73% from the thiomorpholide) of precipitated ferrocenylacetic acid. The yellow acid, recrystallized from ether–pentane, darkened 125–135° and sintered 135–140°.

Anal. Calcd. for $C_{12}H_{12}FeO_2$: C, 59.05; H, 4.96. Found: C, 59.40; H, 5.34.

In subsequent runs the thiomorpholide was not isolated, but the reaction mixture from the Willgerodt procedure was filtered, then hydrolyzed directly with refluxing 4 *N* aqueous sodium hydroxide. The basic mixture was acidified and extracted with ether. The organic acid was extracted from ether with sodium carbonate and reprecipitated upon acidification. The ether–carbonate extraction sequence was repeated to give the pure acid; yields from six runs employing this procedure varied from 14 to 26%.

β-Ferrocenylethyl alcohol was prepared in quantitative yield from ferrocenylacetic acid by reduction at room temperature with lithium aluminum hydride. The yellow alcohol was recrystallized from ether–pentane and had m.p. 49–50°.

Anal. Calcd. for $C_{12}H_{14}FeO$: C, 62.64; H, 6.13. Found: C, 62.87; H, 6.41.

An attempt was made to convert the alcohol to the corresponding bromide by reaction with phosphorus tribromide and pyridine at −5°. Chromatography of the product over alumina gave three distinct bands, which were eluted and concentrated to red oils, not further investigated.

Preparation of 1,1′-Ferrocenediacetic Acid.—A mixture of 10 g. of 1,1′-diacetylferrocene, 10 g. of sulfur, 18 ml. of dioxane and 83 ml. of morpholine was heated at reflux for 18 hr. under nitrogen. The reaction mixture was filtered and evaporated to dryness under reduced pressure. The residue was dissolved in chloroform and reprecipitated with pentane. This process was repeated to give an analytical sample (0.32 g., 2%) of 1,1′-ferrocenediacetodithiomorpholide, which darkened 175–190°, sintered 200°.

Anal. Calcd. for $C_{22}H_{28}FeN_2O_2S_2$: C, 55.93; H, 5.96; N, 5.93. Found: C, 56.12; H, 6.10; N, 6.04.

The purified material was combined with the residue from the evaporated chloroform–pentane filtrates and hydrolyzed with sodium hydroxide as described above for the preparation of ferrocenylacetic acid. The yield of 1,1′-ferrocenediacetic acid was 1.4 g. (13%). The yellow acid, recrystallized from ether–pentane, darkened below 137° and sintered 140–143° with decomposition.

Anal. Calcd. for $C_{14}H_{14}FeO_4$: C, 55.64; H, 4.67. Found: C, 55.53; H, 4.75.

In subsequent runs no attempt was made to isolate the dithiomorpholide, but the crude reaction mixture was filtered, hydrolyzed with 4 *N* sodium hydroxide and worked up as described above. From five runs, in which amounts varying from 3–30 g. of diacetylferrocene were employed, yields ranged from 10–14%.

One run was made employing the ammonia–pyridine procedure[24] for the Willgerodt reaction. When 3 g. of diacetylferrocene, 11 ml. of concentrated aqueous ammonia, 4 g. of sulfur and 32 ml. of pyridine were heated at 165° for 4 hr. in a sealed tube, only 20 mg. of poorly characterized product could be obtained and the procedure was not further explored.

Dimethyl 1,1′-ferrocenediacetate was prepared in 75% yield by the reaction of 1,1′-ferrocenediacetic acid with diazomethane. The product was eluted from a Celite column with benzene and concentrated to the brown liquid diester. The infrared spectrum shows strong ester carbonyl absorption at 1740 cm.$^{-1}$.

Anal. Calcd. for $C_{16}H_{18}FeO_4$: C, 58.20; H, 5.49. Found: C, 58.43; H, 5.81.

Preparation of β-ferrocenylpropionic acid was effected *via* the β-keto ester obtained by carbethoxylation[11] of acetylferrocene. A solution of sodium amide[25] was prepared from 2.3 g. of sodium and 100 ml. of liquid ammonia. After the blue color had disappeared a solution of 10 g. of acetylferrocene in 100 ml. of absolute ether and 25 ml. of diethyl carbonate was added. The resulting mixture was stirred for 2 hr. under reflux, then poured over ice and acetic acid. The ether phase was washed with sodium carbonate, concentrated under reduced pressure and purified by elution with benzene from a Celite column. Benzene was removed in vacuum to give a red oil.

(19) E. R. Lippincott and R. D. Nelson, THIS JOURNAL, **77**, 4990 (1955).

(20) This rule was proposed by Rosenblum,[3] who attributed sharp infrared bands at 9 and 10 μ to the presence of one or more unsubstituted cyclopentadienyl rings in the ferrocene molecule. Lippincott and Nelson[19] assign bands near 9 μ to ring breathing and bands near 10 μ to C–H bending parallel to the plane of the ring.

(21) It may be noted that 1,1′-dimethyl-2-ferrocenecarboxylic acid and the corresponding 3-carboxylic acid,[3] in which both rings are substituted, also have bands at 1104 cm.$^{-1}$.

A portion (4.0 g.) of the crude residue was dissolved in acetic acid and hydrogenated at four atmospheres pressure over 800 mg. of platinum oxide catalyst. After 48 hr. the mixture was filtered, diluted with water and extracted with ether. The ethereal solution was washed with sodium carbonate and concentrated. The residue was hydrolyzed with refluxing aqueous potassium hydroxide. The cooled basic solution was extracted with ether, then acidified to give crude β-ferrocenylpropionic acid, which was purified by passing the sodium salt through Celite, re-precipitation with acid and recrystallization from ether–pentane. A total of 1.73 g. was obtained of yellow-orange, crystalline β-ferrocenylpropionic acid, m.p. 115–116°,[26] together with an additional 340 mg. of less pure material.

Anal. Calcd. for $C_{13}H_{14}FeO_2$: C, 60.49; H, 5.47. Found: C, 60.44; H, 5.62.

The ether extract of the saponification mixture was concentrated and eluted from an alumina column with benzene. A small amount of ethylferrocene[27] was obtained, together with 580 mg. of recovered acetylferrocene.

A second portion of the crude β-keto ester was saponified with ethanolic potassium hydroxide at room temperature, then diluted with water. The orange aqueous layer was washed with ether, then acidified. The precipitated acid was extracted into ether, but apparently was decarboxylated readily as only acetylferrocene, m.p. 84–85°,[28] could be isolated from the ether solution.

A third portion of the crude β-keto ester was transferred to an alumina column. In addition to recovered acetylferrocene, a small amount of red oil[29] was obtained; the infrared spectrum of this material showed typical ferrocene bands at 3100 and 826 cm.$^{-1}$[19] and carbonyl absorption, consistent with that of a β-keto ester, at 1739 and 1665 cm.$^{-1}$.[30,31]

Propionylferrocene was prepared by the Friedel–Crafts acylation of ferrocene with propionic anhydride. To a mixture of 34.5 g. of aluminum chloride and 300 ml. of methylene chloride was added a solution of 44.3 g. of ferrocene and 15.6 g. of propionic anhydride in 300 ml. of methylene chloride. The mixture was stirred for 2 hr. at room temperature, then decanted over ice and worked up in the usual manner. The methylene chloride solution was concentrated and the residue dissolved in benzene and transferred to an alumina column, which was eluted with benzene. The first of two bands gave 21.4 g. (48%) of recovered ferrocene, while the second band yielded 15.3 g. (53%) of propionylferrocene as a red oil, which crystallized from pentane at Dry Ice temperature, m.p. 38–39°.

Anal. Calcd. for $C_{13}H_{14}FeO$: C, 64.49; H, 5.83. Found: C, 64.66; H, 6.08.

Propionylferrocene was converted to β-ferrocenylpropionic acid by the Willgerodt procedure described above for the preparation of ferrocenylacetic acid, but the yield of the substituted propionic acid was small (*ca.* 4%), and the material was impure (m.p. 112–114°). The infrared spectrum was, however, nearly identical with that of β-ferrocenylpropionic acid, obtained from the carbethoxylation sequence above.

β-Ferrocenoylpropionic acid[32] was prepared, by the procedure described above for the synthesis of propionylferrocene, from 7.4 g. of ferrocene, 2.0 g. of succinic anhydride and 5.8 g. of aluminum chloride.[33] The crude acid was extracted from methylene chloride with sodium carbonate, filtered through Celite and re-precipitated with dilute hydrochloric acid; yield 5.0 g. (87%). A sample of orange β-ferrocenoylpropionic acid, recrystallized from methanol–benzene, had m.p. 166.5–167.5°.

Anal. Calcd. for $C_{14}H_{14}FeO_3$: C, 58.78; H, 4.93; Fe, 19.52. Found: C, 58.74; H, 5.20; Fe, 19.24.

In an alternative procedure the order of addition of reagents was ferrocene (74.7 g.), aluminum chloride (58.8 g.), succinic anhydride (20.0 g.). Reaction was allowed to proceed for 20 hr. at room temperature. The yield of pure keto acid from this procedure was 11.8 g. (21%).

γ-Ferrocenylbutyric acid was prepared by hydrogenation of β-ferrocenoylpropionic acid, as described above for the preparation of β-ferrocenylpropionic acid. The diluted reaction mixture was extracted with ether, and the ether phase was in turn extracted with sodium carbonate. γ-Ferrocenylbutyric acid precipitated in yellow crystals on acidification of the carbonate extracts and was purified by repeated ether–carbonate extractions; yield 0.88 g. (93%, from 1.0 g. of keto acid), m.p. 115–116°.

Anal. Calcd. for $C_{14}H_{16}FeO_2$: C, 61.79; H, 5.93. Found: C, 61.79; H, 5.73.

γ-Ferrocenoylbutyric acid was prepared by the procedure described above for the preparation of β-ferrocenoylpropionic acid. From 33 g. of ferrocene, 10 g. of glutaric anhydride[34] and 26 g. of aluminum chloride the yield of γ-ferrocenoylbutyric acid was 24.1 g. (92%), m.p. 136–137°.

Anal. Calcd. for $C_{15}H_{16}FeO_3$: C, 60.05; H, 5.36; Fe, 18.59. Found: C, 59.75; H, 5.35; Fe, 18.52.

δ-Ferrocenylvaleric acid was prepared from γ-ferrocenoylbutyric acid by the hydrogenation procedure employed above for the preparation of γ-ferrocenylbutyric acid. From 1.0 g. of the orange keto acid was obtained 0.80 g. (84%) of yellow δ-ferrocenylvaleric acid, m.p. 109–110°.

Anal. Calcd. for $C_{15}H_{18}FeO_2$: C, 62.95; H, 6.34. Found: C, 62.69; H, 6.54.

δ-Ferrocenoylvaleric acid[32] was prepared by the acylation of ferrocene with δ-carbethoxyvaleryl chloride. Ethyl hydrogen adipate (b.p. 130–131° (2 mm.), m.p. 28–29.5°; lit.[35] b.p. 140–145° (2 mm.), m.p. 28–29°) was prepared by the procedure of Brown, *et al.*,[35] from diethyl adipate, adipic acid and ethanol and converted to the acid chloride (b.p. 70–73° (0.7 mm.); lit.[35] b.p. 120° (15 mm.)) by thionyl chloride.

Acylation was effected by the procedure described for the synthesis of propionylferrocene and employed 34.7 g. of δ-carbethoxyvaleryl chloride, 67.5 g. of ferrocene and 52.0 g. of aluminum chloride. After the reaction mixture had been worked up, the methylene chloride solution, containing ferrocene and keto ester, was allowed to stand for 60 hr. with 1 *N* ethanolic potassium hydroxide. Addition of water gave the sodium salt of δ-ferrocenoylvaleric acid in the aqueous layer. The orange acid precipitated on addition of glacial acetic acid and was extracted into ether, and recovered upon concentration; yield 43.5 g. (71%). An analytical sample, recrystallized from ether–pentane, had m.p. 83.5–84.5°.

Anal. Calcd. for $C_{16}H_{18}FeO_3$: C, 61.17; H, 5.78. Found: C, 61.48; H, 5.33.

In a second run the yield of keto acid was 65%.

ε-Ferrocenylcaproic acid[32] was prepared from δ-ferrocenoylvaleric acid by the hydrogenation procedure employed above for the preparation of γ-ferrocenylbutyric acid. From 5.0 g. of keto acid the yield of ε-ferrocenylcaproic acid was only 3.3 g. (70%) due to mechanical loss on bumping. The melting point behavior of ε-ferrocenylcaproic acid indicates polymorphism. Sharp yellow crystals, obtained from ether–pentane, had m.p. 92–93°; after re-solidification this material melted 85–86°. Microcrystals, obtained after grinding and prolonged drying, had m.p. 83–84°; after re-solidification this material melted 91.5–92.5°.

Anal. Calcd. for $C_{16}H_{20}FeO_2$: C, 64.03; H, 6.72. Found: C, 64.07; H, 6.57.

Acknowledgments.—The authors wish to express

(26) Woodward and Csendes[9] also have found m.p. 115–116° for this acid.

(27) K. L. Rinehart, Jr., Sung Moon and K. L. Motz, in preparation.

(28) The high degree of purity of this material [lit.[2] m.p. 86–87°] is in agreement with the formulation of the acidic product as ferrocenoylacetic acid.

(29) The oil did not yield readily to crystallization, presumably due to impurities. Woodward and Csendes[9] found ethyl ferrocenoylacetate to have m.p. 50–51°.

Fluorocarbon Derivatives. I. Derivatives of Sulfur Hexafluoride[1]

BY FRIEDRICH W. HOFFMANN[2] AND THOMAS C. SIMMONS WITH R. B. BECK, H. V. HOLLER, T. KATZ, R. J. KOSHAR, E. R. LARSEN, J. E. MULVANEY, F. E. ROGERS, B. SINGLETON AND R. S. SPARKS

RECEIVED NOVEMBER 15, 1956

The electrofluorination of dialkyl and cyclic sulfides and dialkyl disulfides in anhydrous hydrogen fluoride by the Simons process was investigated. Dialkyl sulfides were found to yield the corresponding di-perfluoroalkyl sulfur tetrafluorides, $(R_F)_2SF_4$ (I), together with degradation products. Dialkyl disulfides failed to give the corresponding di-(perfluoroalkyl) disulfur decafluorides, $(R_FSF_4)_2$, but yielded instead I and cleavage products.

Introduction

Direct as well as cobalt trifluoride fluorination of both methyl mercaptan and carbon disulfide result in the formation of trifluoromethyl sulfur pentafluoride, CF_3SF_5[3] (II). Clifford, El-Shemy, Emeleus and Haszeldine[4] obtained the same compound by electrochemical fluorination of dimethyl sulfide in anhydrous hydrogen fluoride (Simons process)[5] together with bis-(trifluoromethyl) sulfur tetrafluoride, $(CF_3)_2SF_4$ (III), the fully fluorinated analog of the starting material. II and III, which can be regarded as mono- and di-(perfluoroalkyl) derivatives of sulfur hexafluoride, respectively, seem to be the only representatives of these two classes of compounds reported in the literature.

The successful conversion of dimethyl sulfide to III and to the cleavage product II suggested that the relatively mild conditions prevailing in the Simons cell might permit the preparation of higher homologs of the two series of sulfur hexafluoride derivatives, $(R_F)SF_5$ (I) and $(R_F)_2SF_4$, (IV), respectively, from the corresponding dialkyl sulfides. Therefore, the behavior of several open-chain and cyclic sulfides and of three dialkyl disulfides during low-voltage electrolysis in anhydrous hydrogen fluoride was studied in the course of a program for the investigation of new sulfur- and nitrogen-containing fluorocarbon derivatives. This investigation resulted in the synthesis of several open-chain and one cyclic fluorocarbon derivatives of sulfur hexafluoride. The physical constants and analyses of these new compounds are listed in Table I.

After the Experimental part of our investigation had been completed, Severson, Brice and Coon[6] reported the preparation of $(C_4F_9)_2SF_4$ (X), $C_4F_9SF_5$ (IX) and $\overline{CF_2CF_2OCF_2CF_2SF_4}$ (XI) by the Simons process. These compounds also had been obtained in our study.

Experimental

Apparatus.—The large scale runs were performed in a cell of 3600-ml. capacity and a nominal rating of 50 amperes (cell A). The cell casing was constructed of nickel with an electrode pack of alternating anodes and cathodes (9 each, spaced 1/8 inch apart) of 8.9 × 17.8 × 0.16 cm. nickel sheeting and was provided at the bottom with a valve for the removal of insoluble liquid fluorinated product. Any gaseous reaction product, or low boiling materials entrained in the effluent hydrogen, were condensed in attached traps cooled with Dry Ice–acetone and liquid nitrogen. The effluent from the cell was passed through a low temperature reflux condenser and subsequently through a bed of sodium fluoride pellets in order to remove hydrogen fluoride from the gas stream before condensation in the attached cold traps.

Small cell runs were carried out in either of two nickel cells provided with Kel-F windows for observation of the electrolyte during the reaction. One of the cells (cell B), of 900-ml. capacity, had a cathode area of 250 sq. cm., the cell body served as the anode and the cell was rated at 10 amperes. The other small cell (cell C), of 1000-ml. capacity, was equipped with four anodes and four cathodes (14.0 × 12.7 × 0.16 cm. each) arranged alternatingly and was rated at 25 amperes. Cells A and C were provided with a mantle through which a refrigerant could be circulated. The coolant for the cell condensers and jacket was obtained from a Mayer Junior Chil-er (Mayer Refrigerating Engineers) model J-4, using a brine of ethylene glycol and water.

The power for cell A was supplied by a Sorenson Nobatron model E-6-100a and for cells B and C by a Mallory Rectopower, model 6RS25-1.

Materials.—The organic starting materials used in the electrofluorination were commercial products or were synthesized by conventional methods.

The hydrogen fluoride employed was commercial grade anhydrous hydrogen fluoride (Mathieson Chemical Corp. and Pennsylvania Salt Manufacturing Co.) which was distilled before use through a 122-cm. Monel column of 12.7 cm. inside diameter and packed with nickel Heli-pak (Podbielniak, Inc.).

The sodium fluoride pellets used for the removal of entrained hydrogen fluoride from the effluent gas stream were obtained as NaF·HF pellets (Harshaw Chemical Co.) and converted to NaF by the passage of dry air or nitrogen over the pellets at 450° for 10 hr.

Operation of the Cells.—Drying of the distilled anhydrous hydrogen fluoride (which contained approximately 0.5% of water) was accomplished by electrolyzing the cell charge of hydrogen fluoride at 5.5 to 6.0 volts. During the drying of the hydrogen fluoride some care had to be exercised to avoid undesirable explosions due to the formation of oxygen difluoride. The tendency for explosions was greatest during low flow rates of the effluent gases and could be prevented by increasing the gas flow with dry nitrogen.

The cells normally were operated at the reflux temperature of the electrolyte. However, cooling the cell charge was found to be desirable before addition of organic starting material, before emptying the cell after completion of a run, during temporary shut-downs over the week-ends, and in case of a leak or clogging of the exit gas lines. In general, the runs in cell A were carried out with 4 to 7 mole % of solute at 5.2–5.8 volts for extended periods on a 24-hr. day basis for 5 days per week with intermittent shut-downs of 65–70 hr. over the week-ends. If at all possible, cells B and C were also operated on this semi-continuous basis. During the course of all runs in cell A, hydrogen fluoride and organic starting materials were added intermittently in order to maintain an approximately constant concentration. Further addition of starting material was based on a measure of the hydrogen produced (as measured by a wet test meter) in the electrofluorination. The experimental data given in the original paper by Simons[5] on the electrofluorination process show that the replacement of one atom of hydrogen by fluorine proceeds with the consumption of two faradays and the formation of 1 mole of hydrogen with approximately 90% efficiency. In calculating the faradays required for fluorinating organic sulfur compounds and, thus, the hydrogen produced, it was assumed that the initial attack occurred at the sulfur atom and that this addition of fluorine would require only one faraday per fluorine atom. For example, the complete fluorination of one mole of dipropyl sulfide will require on this basis the passage of at least 32 faradays and result in the production of 358.4 liters of hydrogen (S.T.P.).

In runs performed in cells B and C the starting material was added in one portion to the hydrogen fluoride charge, and the electrofluorination was continued until the electrolyte was depleted of starting material.

Purification of Liquid Cell Products.—Liquid products obtained from the electrochemical cell were washed with water, dilute aqueous sodium bicarbonate solution and again with water. The heavy layer of insoluble, fluorinated product was separated and refluxed with 30–50% aqueous potassium hydroxide to remove hydrolyzable impurities. The insoluble fluorinated material was then washed with water, left in contact with Drierite or magnesium sulfate and the dried material was finally fractionated through a modified Todd column of approximately 40 plates. Center fractions of constant boiling point and refractive index were taken for analysis and determination of physical properties. The purity of the sample was checked by infrared and NMR analysis.

Gaseous products were passed over sodium fluoride pellets to remove entrained hydrogen fluoride and dried by passage over phosphorus pentoxide. If the gaseous cell effluents were found to attack mercury, they were purified further by passing through 30% aqueous potassium hydroxide solution. The purified gaseous material was then fractionally distilled in a low temperature column of approximately 25 plates. Molecular weights were determined by the vapor density method employing a gas density balance.[7]

Electrochemical Fluorinations.—The experimental conditions employed in the various runs are listed in Table II together with the weight-yields of the main products. In some of the runs, only portions of the cell products were worked up; in these cases, the amounts of products indicated in the table were calculated from the data obtained by fractionation of aliquots of the crudes.

Only the isolation of the major products from the insoluble, liquid cell drainings and the cold trap condensates is described in detail in the following for the various sulfur-containing starting materials.

Diethyl Sulfide.—The crude, liquid cell drainings (36.5 g.) were stabilized with aqueous alkali and refluxed under the column with overhead removal of the volatile material which was recondensed in an attached Dry Ice–acetone cold trap. Fractionation of the material remaining in the distillation flask yielded after a forerun of 5 g., b.p. 31–70.0°, 12.5 g. of di-(perfluoroethyl)-sulfur tetrafluoride (VI), b.p. 70.0–70.2°, $n^{25}D$ 1.2753.

The volatile material (14.5 g.) from the cell drainings was combined with the Dry Ice condensate (70 g.) from the cell effluents. The mixture was stabilized with alkali (89% recovery) and fractionated in a low temperature still to yield 20 g. of sulfur hexafluoride, b.p. −65 to −60°; 46 g. of pentafluoroethyl-sulfur pentafluoride (V), b.p. 13.5°, molecular weight 244 (calcd. 246); and 4 g. of pot residue. The identities of both V and VI were confirmed by nuclear magnetic resonance (NMR) analysis.

Di-*n*-propyl Sulfide.—The electrofluorination of 826 g. of di-*n*-propyl sulfide (Eastman Kodak, white label) gave during 215 hr. of operation 2052 l. of hydrogen at an average current of 23.5 amp. The run yielded 536 g. of HF-insoluble liquid product, 695 g. of Dry Ice–acetone trap condensate and 215 g. of condensate in the liquid nitrogen trap.

The combined Dry Ice and liquid nitrogen condensates were vaporized, passed over sodium fluoride, dried and separated into four arbitrary fractions: (1) b.p. −140 to −70°, approximately 200 g.; (2) b.p. −70 to 0°, 227 g.; (3) b.p. 0–25°, approximately 60 g.; (4) b.p. above 25°, 430 g.

Cut 1 was found to attack mercury. Therefore, a portion of 95 g. was passed through 30% aqueous potassium hydroxide solution to remove the reactive, unidentified contaminants; 59% of purified condensate was recovered. Low temperature distillation of the purified material yielded approximately 7 g. of crude carbon tetrafluoride, b.p. −140 to −80° (reported[8] b.p. 129°), molecular weight 78–86 (calcd. 88); 28 g. of crude sulfur hexafluoride, b.p. −80 to −60°, molecular weight 120–144 (calcd. 146) (identified by infrared analysis).[9]

Low temperature distillation of 219 g. of fraction 2 yielded 136.2 g. of sulfur hexafluoride, b.p. −62 to −57° (reported[10] b.p. −63.9°), molecular weight 138–147; and 52.8 g. of hexafluoropropane, b.p. −36 to −33° (reported[8] b.p. −38°) molecular weight 185 (calcd. 188). Fraction 3 of the original distillation did not yield any identifiable material.

Fraction 4 was stabilized with aqueous potassium hydroxide, dried with Drierite (88.4% recovery) and distilled to give the cuts: (4a) b.p. 27–42°, 42 g.; (4b) b.p. 42.0–

[a] Sulfur hexafluoride was obtained in all runs. [b] No effective separation was possible. [c] Mixture of XV, VI, IX and $C_3F_7SF_4CF_3$.

42.5°, $n^{25}D$ 1.2594, 312 g.; (4c) b.p. 43–46.0°, 21 g. Elemental and NMR analysis of cut 4b led to its identification as perfluoropropyl sulfur pentafluoride, $C_3F_7SF_5$ (VII), which was also the main component of the cuts 4a and 4c.

The fractionation of the purified cell drainings (493 g.) yielded after a forerun of 42 g. of material, b.p. 43–116°, 360 g. of di-(perfluoropropyl) sulfur tetrafluoride (VIII), colorless liquid, b.p. 116.0–116.5°, $n^{25}D$ 1.2856–1.2858; and 29.3 g. of less pure VIII, b.p. 117.0–118.0°, $n^{25}D$ 1.2868. An analytical cut of VIII, b.p. 116.0°, gave a NMR spectrum which confirmed its identity.

Di-*n*-butyl Sulfide.—From 1746 g. of di-*n*-butyl sulfide (Eimer & Amend, Highest Purity) were obtained 1530 g. of liquid cell products, 2330 g. of Dry Ice–acetone condensate and 600 g. of liquid nitrogen condensate.

Distillation of portions of the material condensed at −78° showed that its composition changed during the run and depended apparently on a variety of factors, such as cell voltage, flow rate of effluent gas and cell temperature. Dry Ice condensate (900 g.) collected during the first half of the run was separated into a gaseous and a liquid fraction (boiling above room temperature). A portion of 195 g. of the low boiling material (about 57% of the total amount of crude Dry Ice condensate) subjected to a low temperature distillation at 761 mm. gave 10.2 g. of unidentified product, b.p. −23 to −4°, average molecular weight 154; 173.3 g. of perfluorobutane, b. 1–3°, molecular weight 223–235 (calcd. 238); and 13.2 g. material, b. 3–15°. The weights of the three fractions correspond to 4.7, 88.4 and 6.3%, respectively, of the total charge.

A portion of 110 g. of low boiling material from the Dry Ice condensate collected at a later stage of the electrofluorination gave the following fractions: (1) b.p. 1–2°, 48.5 g., molecular weight 230–238; (2) b.p. 10–24°, 36.4 g., molecular weight 226–196; (3) b.p. above 24°, 20 g. The weights of the fractions 1 to 3 correspond to 44, 33.1 and 18.2%, respectively, of the total charge. The NMR spectrum indicated fraction 1 to be pure *n*-decafluorobutane (XIII), while fraction 2 gave a spectrum consistent with that expected for a mixture of nonafluorobutane (XIV) isomers (reported[11] C_4F_9H, b.p. 14–15°).

The higher boiling material from the various Dry Ice–acetone condensates was combined (1006 g.), and a portion of 268 g. was fractionated through an 18-in. heated column (packed with Heli-pak) to give after a forerun of 5.4 g., b.p. 61–68°, 95.1 g. of crude nonafluorobutyl sulfur pentafluoride (IX), b.p. 68–71°, $n^{20}D$ 1.2740–1.2728; and 25.0 g. of pot residue, $n^{20}D$ 1.2740. The NMR spectrum of the crude IX suggested the presence of approximately 25% of the cyclic compound perfluorothiophane tetrafluoride, $\ulcorner CF_2(CF_2)_2SF_4 \urcorner$ (XV), as a contaminant. One hundred thirty-seven grams of condensate was collected in a cold trap attached to the still. Redistillation of this material showed it to consist mainly of XIV isomers.

The total amount of mixture of IX and XV obtained by rectification of the Dry Ice condensate was 406 g. A separation of this mixture by careful redistillation was not possible.

Distillation of the purified liquid cell drainings (1416 g.) yielded 659 g. of bis-(nonafluorobutyl) sulfur tetrafluoride (X), b. 90.5–98.5° (100 mm.), $n^{25}D$ 1.2940–1.2948. A middle cut of this material was taken and redistilled at atmospheric pressure to give an analytical sample, b.p. 154.0°, $n^{25}D$ 1.2943. The lower boiling portion of the liquid cell product gave a cut of 318 g. of impure IX, b.p. 67–76°, $n^{25}D$ 1.2720–1.2709. An analytical cut, b.p. 70.5–70.7°, $n^{25}D$ 1.2709, gave a NMR spectrum similar to that for the mixture of IX and XV obtained from the Dry Ice condensate.

Low temperature distillation of the gaseous products condensed in the liquid nitrogen trap led to the identification of sulfur hexafluoride and XIII by infrared analysis.

Di-*n*-butyl Sulfoxide.—Rectification of the stabilized cell drainings (9.5 g. of crude material) yielded 3 g. of colorless distillate, b.p. 69.0–71.0°, $n^{25}D$ 1.2768–1.2770, identified by its NMR spectrum as impure IX, and 4 g. of colorless distillate, b. 155°, $n^{25}D$ 1.2945, identified as X. Low temperature distillation of the Dry Ice–acetone condensate (28 g.) led to the identification of sulfur hexafluoride and XIII.

Thiophane.—Fractionation of 60 g. of insoluble cell drainings, obtained from 100 g. of thiophane, b. 118–120°, gave 8 g. of forerun, b.p. up to 68.0°; 17.0 g. of colorless distillate, b. 68.0–72.5°, $n^{21.5}D$ 1.2768–1.2762; 11 g. of higher boiling material at 72.5–120°; and 16 g. of distillation residue. The material, b. 68.0–72.5°, was redistilled and a middle cut taken at 70.0°, $n^{25}D$ 1.2766, for analysis.

Anal. Calcd. for $C_4F_{12}S$: C, 15.59; F, 74.0; S, 10.41. Found: C, 15.4; F, 74.6; S, 10.0.

Although the analysis of this cut is in fair agreement with the values calculated for perfluorothiophane tetrafluoride (XV), its NMR spectrum showed considerable contamination with VI, IX and possibly $C_3F_7SF_4CF_3$. A cut, b.p. 72.5–73.5°, $n^{21.5}D$ 1.2758, of the higher boiling distillate showed the same NMR resonance peaks as the analytical samples of XV, but with variations in the intensities.

The pot residue was not further investigated.

Thioxane.—Electrofluorination of 78 g. of thioxane (Carbon & Carbide Chemicals Co.) yielded 55 g. of liquid

(11) A. F. Benning and J. D. McHard, U. S. Patent 2,519,760 (1950).

Digitized by Arya Samaj Foundation Chennai and eGangotri

cell drainings and 1 g. of Dry Ice–acetone condensate. Distillation of the liquid product gave in addition to 25.0 g. of lower boiling cuts 19.0 g. of colorless liquid, b.p. 78.2–78.8°, $n^{25}D$ 1.3019, and left 11 g. of residue. The main fraction was identified as perfluorothioxane tetrafluoride (XI), but infrared analysis indicated the presence of an acid fluoride impurity. The material, therefore, was refluxed for 3 hr. with excess ammonium hydroxide and redistilled to yield the pure XI, b.p. 80.0–80.5°, $n^{25}D$ 1.3015, as indicated by its infrared and NMR analysis. No identification of the Dry Ice condensate or of the lower boiling fractions was attempted.

Di-*n*-butyl Disulfide.—In this run, 1900 g. of HF-insoluble, liquid cell drainings, 2010 g. of Dry Ice condensate and 1044 g. of liquid nitrogen condensate were obtained from 1964 g. of di-*n*-butyl disulfide (Fisher, Highest Purity). Rectification of the stabilized liquid product gave after a forerun of 71.3 g., b. 45–70°, a fraction of 833 g. of crude IX, b. 70–72°, $n^{25}D$ 1.2704, and a fraction of 179.5 g. of X, b.p. 61–62° (21 mm.), $n^{25}D$ 1.2960. The NMR spectrum of the crude IX indicated 10–15% contamination with XV. A careful fractionation of the crude material gave a constantly boiling cut of IX, b.p. 70.5°, $n^{25}D$ 1.2701, which on the basis of its NMR spectrum was free from the cyclic compound XV.

A portion of the liquid nitrogen condensate was screened and found to contain approximately 60% of sulfur hexafluoride and 20% of decafluorobutane (XIII) together with products which attacked mercury and reacted with 20% aqueous potassium hydroxide solution. The remainder of this condensate was not investigated.

Careful rectification of the Dry Ice condensate gave a fraction of XIII, b.p. −12 to −11° (462 mm.), and a cut, b.p. 2–4° (462 mm.), consisting of a mixture of isomeric C_4F_9H (XIV). The NMR spectrum of the XIII showed it to contain approximately 15% of the isomeric decafluoroisobutane, $(CF_3)_3CF$ (XVI). The higher boiling portion of the −78° condensate consisted to a large extent of IX but was not processed further.

Di-*t*-butyl Disulfide.—Electrofluorination of 849 g. of di-*t*-butyl disulfide (Eastman Kodak, Practical Grade, b.p. 198–204°) gave 178 g. of HF-insoluble, liquid product, 502 g. of Dry Ice–acetone condensate and 323 g. of liquid nitrogen condensate. The rectification of the alkali-treated liquid product did not yield any constantly boiling fraction. NMR analysis of several arbitrary cuts indicated complex mixtures of fluorocarbons and derivatives of sulfur hexafluoride containing both normal and branched chains. Low temperature distillation of the gaseous products gave sulfur hexafluoride and decafluorobutane. The NMR analysis of the decafluorobutane fraction showed that the major component was XIII contaminated with 10–15% of XVI.

A second run with 713 g. of di-*t*-butyl disulfide at a lower voltage resulted in the formation of 522 g. of liquid cell drainings, 734 g. of Dry Ice condensate and 317 g. of condensate collected in the liquid nitrogen trap. In spite of the larger amount of liquid cell product from this run, we were unsuccessful in isolating any pure material. The results of the NMR analyses of several arbitrary cuts were similar to those obtained with the material from the run performed at 5.5–5.6 v.

Di-(β-diethylaminoethyl) Disulfide.—Di-(β-diethylaminoethyl) disulfide (62 g., 0.235 mole), b.p. 117° (35 mm.) to 119° (50 mm.), $n^{25}D$ 1.4977–1.4981, yielded 81 g. of liquid cell product and 16 g. of Dry Ice condensate which boiled above room temperature and gave upon fractionation a series of small, unidentified cuts in the range from 23 to 58°. Rectification of the liquid product gave after a forerun of 12.6 g., b.p. 60–120°, a fraction of 30 g. of $(C_2F_5)_2NCF_2CF_2SF_5$ (XII), b.p. 122–124°, $n^{25}D$ 1.2921, and left 15 g. of distillation residue which was not further investigated.

Small amounts of partly fluorinated tar-like products deposited in the cell in all runs. The tars isolated from the electrochemical fluorinations of di-*n*-butyl sulfide and di-*t*-butyl disulfide were analyzed and found to have the approximate compositions $C_{10}H_{11}F_{10}S$, $C_{11}H_6F_{10}S$ and $CH_2F_2S_2$, respectively.

Pyrolysis of Perfluorobutyl Sulfur Pentafluoride.—Perfluorobutyl sulfur pentafluoride (173 g., 0.3 mole) was passed at a rate of approximately 0.25 mole per hour through a metal tube packed with aluminum oxide–aluminum fluoride pellets heated to 650–700°. The effluent gases were condensed in attached Dry Ice–acetone and liquid nitrogen traps. Distillation of the combined condensate (147 g.) gave 44 g. of distillate, b.p. −130 to −75°; 74 g. of material boiling below 25°; and 29 g. of liquid, boiling above 25°. Further fractionation of the higher boiling liquid fraction yielded three distinct cuts: (1) b.p. 56–58°, $n^{20}D$ 1.2513, 3 g.; (2) b.p. 80–83°, $n^{20}D$ 1.2610, 3 g.; (3) b.p. 102–104°, $n^{20}D$ 1.2670, 4 g.; which were identified tentatively by their physical constants as perfluorohexane (reported[12] b.p. 57.23°, $n^{22}D$ 1.2515); perfluoroheptane (reported[13] b.p. 82.51°, $n^{20}D$ 1.26019) and perfluoroöctane (reported[14] b.p. 103.5°, $n^{25}D$ 1.2830) respectively.

Reaction of Perfluorodibutyl Sulfur Tetrafluoride with Aluminum Chloride.—Di-(perfluorobutyl) sulfur tetrafluoride (100 g., 0.183 mole) was cautiously added to 15 g. of anhydrous sublimed aluminum chloride in a 500-ml. flask equipped with stirrer. The temperature of the stirred mixture was slowly raised to 80° where a violent reaction occurred. When the reaction subsided, the material was heated to 100° and held at this temperature for 5 hr. Distillation of the reaction product after drying over Drierite gave 15 g. of a greenish yellow liquid, b.p. 96–97°, $n^{20}D$ 1.3489. Infrared analysis indicated that this material contained a C_4F_9-group and that its spectrum was very similar to that of $(C_4F_9)_2SF_4$ with some major differences in the long wave lengths. Elemental analysis gave 49.2% fluorine and 30.52% chlorine.

Summary of Results

The stability of alkyl sulfides and saturated cyclic sulfur compounds in anhydrous hydrogen fluoride makes these compounds suitable starting materials for conversion by the Simons process to the corresponding fully fluorinated analogs. Similarly to the behavior of dialkyl ethers the sulfides form in hydrogen fluoride more or less colored solutions which exhibit a high degree of conductivity. The conductivity of these sulfide solutions is undoubtedly the result of the formation of a salt-like addition compound between sulfide and hydrogen fluoride of the type $(R_2S—H)^+ F^-$, which ionizes readily in the liquid hydrogen fluoride.

While a considerable part of the sulfide is degraded with rupture of the sulfur–carbon and even the carbon to carbon bonds during the electrolysis, some of the starting material is converted without apparent change of the original skeleton to the fully fluorinated analog. The partial degradation of the starting material was observed in all electrolytic runs to varying degrees and was noticed to increase with increasing voltage; it is definitely responsible for the relatively low conversion of a given organic compound to the fully fluorinated analog.

The sulfur-containing fluorocarbon analogs obtained from dialkyl sulfides were in all runs of the types R_FSF_5, $(R_F)_2SF_4$ and $R_F'SF_4$, where R_F represents a C_nF_{2n+1} group and R_F' represents C_nF_{2n} and is part of a heterocyclic system incorporating the sulfur atom. In no case could any sulfur derivatives of a lower oxidation state be obtained. Although the absolute amount of bis-(heptafluoropropyl) sulfur tetrafluoride (VIII) was, in the run with dipropyl sulfide, larger than that of heptafluoropropyl sulfur pentafluoride (VII), the relative yield of VII on a molar basis was higher than that of VIII. In the runs starting with diethyl and di-*n*-butyl sulfide the yields of R_FSF_5 exceeded by far those of $(R_F)_2SF_4$, even on an absolute weight basis. Cleavage of the carbon–sul-

fur bonds was thus rather pronounced in all these runs. Whether this cleavage occurs by a rupture of one of the C–S bonds in the original or only partly fluorinated sulfide or whether it is the result of a degradation of the $(R_F)_2SF_4$ cannot be decided on the basis of our experiments; but the formation of partly fluorinated tar-like products in all cell runs might well be interpreted by an at-random attack on the carbon-to-sulfur and carbon-to-carbon bonds of the sulfide at any time during the electrolysis. Rupture of the C–S bond in the original sulfide should lead to gaseous monofluorohydrocarbon derivatives which, however, were not found, at least not in amounts sufficient for identification. The lack of solubility in the hydrogen fluoride and the great stability of the bis-(perfluoroalkyl) sulfur tetrafluorides argues against its degradation in the cell. The presence of the sulfur in its highest valence state in all products, except perhaps the cell tars, suggests that the oxidation of the sulfur occurs in the initial stages of the electrofluorination of the sulfides and disulfides before the fluorination of the carbon chain is completed. In contrast to this observation, Haszeldine and Nyman[15] were able to isolate from an electrofluorination run of thioglycolic acid in addition to $SF_5CF_2CO_2H$ the incompletely fluorinated product $SF_3CF_2CO_2H$ which demonstrates that in this case the substitution reaction on the carbon is completed before the oxidation of the sulfur atom is accomplished.

It was hoped that fluorocarbon derivatives of the type $(R_FSF_4)_2$, the symmetrical bis-(perfluoroalkyl) derivatives of disulfur decafluoride, S_2F_{10}, might be obtainable by the electrofluorination of dialkyl disulfides in hydrogen fluoride. However, in the runs performed with di-*n*-butyl disulfide and di-*t*-butyl disulfide, no indications for the formation of a derivative of S_2F_{10} were obtained. The results of these two runs were rather surprising insofar as in addition to the expected cleavage product, R_FSF_5, the second major, higher boiling reaction product was the SF_6 derivative of the type $(R_F)_2SF_4$. In the run starting with di-*n*-butyl disulfide, the main reaction product was identical with the compound obtained from di-*n*-butyl sulfide.

That the effect of the electrofluorination on a given carbon skeleton of an organic compound is far deeper reaching than that of a simple replacement of hydrogen by fluorine becomes obvious in the examination of the NMR spectra of the gaseous cleavage products from the runs with di-*n*-butyl and di-*t*-butyl disulfide. The decafluorobutane fraction, b.p. about 0°, was in both cases a mixture of the two possible isomers, *n*-C_4F_{10} and $(CF_3)_3CF$, containing 10–15% of the branched isomer. The observed rearrangement of a tertiary carbon arrangement as in $(C)_3{\equiv}C$ to a normal chain does not have a counterpart in the organic radical or carbonium ion chemistry and seems to be unique, but nevertheless general, in the chemistry of fluorocarbons. This type of rearrangement was also observed in the cleavage of substituted pyridines during electrochemical fluorination (see paper II of this series).[16] It is noteworthy that the ratio of normal to branched isomers seemed to be the same, regardless of the structure of the parent compound.

A unique side-reaction, involving an interesting cyclization, was demonstrated by the presence of 20–25% of an impurity in the $C_4F_9SF_5$ (IX) fraction (from di-*n*-butyl sulfide and disulfide) which was identified as perfluorothiophane tetrafluoride (XV) on the basis of the similarity of the additional peaks in the NMR spectrum of the crude IX with those expected and also found in the reaction product obtained from thiophane. A similar cyclization was observed previously[17] in the electrofluorination of $(C_2H_5)_2NCOF$ which resulted in the formation of perfluoro-3-ethyloxazolidine, $C_2F_5\overline{NCF_2CF_2OCF_2}$. It is interesting to note that the IX obtained by electrofluorination of di-*n*-butyl disulfide contained ony 10% of the cyclic impurity XV.

The NMR analysis of the higher boiling products from the electrofluorination of di-*t*-butyl sulfide indicated all of these fractions to be complex mixtures of normal and branched chain fluorinated compounds. Only a small part of the high boiling material consisted of sulfur-containing compounds, the majority was a mixture of fluorocarbons. The presence of fluorocarbons in these fractions, b.p. 70–85° (18 mm.), would require that these fluorocarbons contain at least six to twelve carbon atoms; in other words, they are coupling products of fragments of various chain lengths.

The fluorination of the cyclic 1,4-thioxane and thiophane indicates that a part of the starting material survives the electrolysis without cleavage of the original bonds. The NMR spectrum of the liquid product obtained in the electrofluorination of thiophane, on the other hand, showed absorption peaks which were attributed to the cyclic compound XV and the three possible cleavage products retaining the sulfur atom, *i.e.*, IX, VI and $C_3F_7SF_4CF_3$. The formation of these cleavage products demonstrates the susceptibility of each of the carbon–carbon bonds and of the sulfur-to-carbon bond toward cleavage. The stability of the various bonds in the five-membered ring system appears to be lower than in the six-membered ring of the 1,4-thioxane since the yield of the cyclic, completely fluorinated product is much higher from thioxane than from thiophane.

Since the electrofluorination runs carried out in the 10 and 25 ampere cells (B and C) employed relatively small amounts of starting materials, only the main products were obtained in amounts sufficiently large for identification. From the run with di-*n*-butyl sulfoxide, again only products with the sulfur in its highest oxidation state could be isolated. The products were identical with the two SF_6 derivatives obtained from di-*n*-butyl sulfide, and disulfide. The small-scale eletrofluorination of bis-(2-diethylaminoethyl) disulfide yielded a substantial amount of the perfluoroalkyl sulfur pentafluoride, $(C_2F_5)_2NCF_2CF_2SF_5$, formed by scission of the original S–S bond confirming, thus, the results from the runs with the isomeric dibutyl disulfides.

The pyrolysis of IX at 650–700° gave small amounts of perfluoroöctane, perfluoroheptane and perfluorohexane with extensive decomposition of the starting material. Recent reports[6,18] on the pyrolysis of similar compounds under less drastic conditions demonstrated the possible free radical nature of these reactions.

The reaction of X with aluminum chloride was violent and could not be controlled effectively to obtain sufficient quantities of product for study.

A paper is in preparation by members of the Spectroscopy Group, Physical Measurements Branch, which will contain a more detailed discussion of the infrared spectra of the compounds reported in this paper. A study of the NMR spectra of these compounds was published recently by Muller, *et al.*[19]

Acknowledgments.—We are indebted to members of the Analytical Research Branch for the elemental analyses, the Spectroscopy Group for determination of the NMR and infrared spectra and to members of the Physical Measurements Branch for determination of some of the physical constants reported.

Fluorocarbon Derivatives. II.[1] Cyclic Nitrides

BY THOMAS C. SIMMONS AND FRIEDRICH W. HOFFMANN[2] WITH R. B. BECK, H. V. HOLLER, T. KATZ, R. J. KOSHAR, E. R. LARSEN, J. E. MULVANEY, K. E. PAULSON, F. E. ROGERS, B. SINGLETON AND R. E. SPARKS

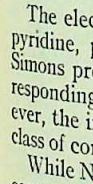
RECEIVED NOVEMBER 15, 1956

The electrofluorination of some secondary and tertiary cyclic amines in anhydrous hydrogen fluoride by the Simons process[3] was investigated. Pyridine, C-substituted pyridines and morpholine yielded the corresponding fully fluorinated, secondary cyclic nitrides, while N-substituted piperidines and 1-methylmorpholine gave the corresponding tertiary fluorocarbon nitrides. In all cases, considerable amounts of cleavage products also were formed; some of them were isolated in pure state and identified.

Introduction

The electrofluorination of cyclic amines, such as pyridine, piperidine and 1-alkylpiperidines by the Simons process has been reported to yield the corresponding cyclic fluorocarbon nitrides[4,5]; however, the information given in the literature on this class of compounds is rather scanty.

While N-alkyl-substituted piperidines and related compounds, such as N-substituted morpholines, will be converted by electrofluorination in anhydrous hydrogen fluoride to the corresponding, unreactive, cyclic tertiary nitrides (I with X = O or CF_2, and Y = C_nF_{2n+1}), unsubstituted pyridine, piperidine, morpholine, as well as their C-substituted derivatives, are expected to yield the corresponding secondary cyclic nitrides (I with X = O or CF_2, and Y = F). The secondary nitrides, by virtue of their NF group, may possibly undergo chemical reactions allowing thus the introduction of cyclic fluorocarbon nitride groups into other molecules.



I

Only two secondary cyclic fluorocarbon nitrides appear to have been described in the literature, *i.e.*, perfluoropiperidine, obtained either by electrofluorination of pyridine or piperidine[5] or by fluorination of pyridine with cobaltic fluoride[6] and perfluoro(2,6-dimethylpiperidine) prepared by Haszeldine[7] from 2,6-dimethylpyridine with cobalt trifluoride.

The purpose of this investigation was to study the general behavior of cyclic amines in the Simons cell and to characterize the resulting electrofluorination products. Pyridine, 4-alkyl-substituted pyridines and morpholine were chosen as starting materials for the preparation of secondary nitrides. N-methylmorpholine and 1,1′-dipiperidylmethane were expected to yield the corresponding tertiary fluorocarbon nitrides. The physical constants and analyses of the purified secondary and tertiary nitrides obtained in this study are listed in Table I.

Experimental

Electrochemical Fluorinations.—With the exception of N-methylmorpholine, which was electrofluorinated in the 10-amp. cell (B), all other runs were performed in the 50-amp. cell (A) in the manner described previously.[1] The experimental conditions for the electrochemical fluorination runs and the major reaction products are listed in Table II. The crude liquid and gaseous products were subjected to the same preliminary purification with alkali or sodium fluoride, as described for the runs using dialkyl sulfides and disulfides[1] as starting materials.

The hydrogen fluoride employed was commercial grade, anhydrous material (Mathieson Chemical Corp. and Pennsylvania Salt Manufacturing Co.) which was distilled and dried electrolytically[1] before use. The organic starting materials were commercial products with the exception of 1,1′-dipiperidylmethane, b.p. 77.0–79.5° (2.6–2.7 mm.), $n^{25}D$ 1.4810, which was prepared by the method of Knoevenagel[8] from piperidine and formaldehyde.

Only the isolation of the major reaction products from the HF-insoluble liquid cell drainings and the cold trap condensates is described in the following for the various runs employing nitrogen-containing heterocyclic compounds as

[a] The amounts given are those of crude material.

starting materials. In runs where only portions of some of the cell crudes were worked up, the total weight of product given in Table II was calculated on the basis of the data obtained by processing the aliquots.

Pyridine XII.—The electrofluorination of 2370 g. of pyridine (Eastman Kodak, Karl Fischer Reagent) during 508 hr. of operation produced 5799 l. of hydrogen; 548 g. of liquid cell drainings; 3940 g. of Dry Ice–acetone condensate; and 698 g. of liquid nitrogen condensate.

The condensates collected at −78° throughout the run were combined and kept for removal of entrained hydrogen fluoride over sodium fluoride pellets in a refrigerator at about −15°. For distillation, this material was decanted from the sodium fluoride into a precooled round-bottom flask. A portion of 3759 g. was distilled in four batches through a 12-in. vacuum-jacketed column packed with nickel Heli-pak (Podbielniak, Inc.) and the following arbitrary cuts were taken: (1) b.p. up to 45°, 2774 g.; (2) b.p. 45–62°, 674 g.; (3) higher boiling residue, 69 g.

Fraction 1 consisted mainly of perfluoro-*n*-pentane (X). A portion of 681 g. of this fraction was distilled in a low temperature still at 486 mm. and yielded 526 g. of crude X, b. 17–23°, molecular weight 284–293 (calcd. 288). A higher boiling residue (1a) of 68 g. of liquid material remained in the flask; 14% loss during distillation and handling. Careful refractionation of the crude X at 460 mm. pressure gave an analytical sample, b.p. 16°, molecular weight 288 (reported b.p. 29.32°,[9] 29.3°)[10]; this sample melted at −128 to −124° with a plateau at −126 to −125° (reported[9] f.p. −125.65°).

Fraction 2 and the higher boiling residues 3 and 1a were combined (811 g.) and distilled through an 18-in. vacuum-jacketed column packed with nickel Heli-pak to give after 8.2 g. of forerun, b.p. 35–45°, 677.9 g. of crude perfluoropiperidine (II), b. 45–52.5°, and left 78 g. of higher boiling liquid. In an attached Dry Ice–acetone trap was collected 7.2 g. of low boiling material, presumably impure X which was discarded.

Careful refractionation of a 600-g. portion of the crude II through a modified Todd column of approximately 40 plates gave at atmospheric pressure after a small forerun of X and an intermediate fraction (b.p. up to 49.5°) 268.6 g. of pure II, b.p. 49.5–9.9°, $n^{20}D$ 1.2754–1.2759. Redistillation of a portion of this material furnished an analytical sample, b.p. 49.5°, $n^{20}D$ 1.2752, d_{25} 1.7043 (reported, b.p. 49–50°, $n^{25}D$ 1.279, d_{25} 1.738[6]; b.p. 48, $n^{20}D$ 1.281, d_{20} 1.744[5]).

All the material boiling above 52.5° from the previous rectifications was combined and the mixture (670 g.) was fractionated through the Todd column. A major fraction (306 g.), b.p. 67–71°, $n^{25}D$ 1.2756–1.2719, exhibited an infrared spectrum indicating the presence of residual hydrogen. This finding and the elemental analysis of the material suggest it to be a mixture of II and isomeric monohydrides of II.

Anal. Calcd. for $C_5F_{11}N$: C, 21.21; F, 73.82; N, 4.97. Found: C, 21.2; F, 72.1; N, 5.0. Calcd. for $C_5F_{10}HN$: C, 22.65; F, 71.68; N, 5.28.

Further distillation of the remaining material under reduced pressure yielded a constantly boiling fraction of 93 g. of a colorless, mobile liquid, b.p. 71–72° (51 mm.), which was tentatively identified by its analysis and nuclear magnetic resonance (NMR) spectrum as perfluoro-1,1′-dipiperidyl (III). The analytical sample was taken at 72° (51 mm.).

The liquid nitrogen trap condensate was evaporated and

the gas passed successively through large drying tubes filled with sodium fluoride pellets and Drierite, respectively. The recondensed gas was then distilled in a low temperature still to yield 491 g. of nitrogen trifluoride contaminated with approximately 5% of carbon tetrafluoride, as determined by mass spectrometric analysis. This material boiled at −128 to −122° and showed a molecular weight range of 70 to 72 (calcd. 71) (reported for NF_3,[11] b.p. −129.07°).

1,1'-Dipiperidylmethane (XIII).—This run, performed in Cell A with an electrode pack of alternating iron cathodes and nickel anodes, yielded 130 g. of insoluble cell drainings; 1465 g. of Dry Ice–acetone condensate; and 260 g. of condensate in a liquid nitrogen trap. The latter condensate was screened and found to consist mainly of nitrogen trifluoride, b.p. −129 to −126°, molecular weight 74 (calcd. 71).

Distillation at atmospheric pressure of a portion of 136 g. of the Dry Ice condensate, after passing over sodium fluoride pellets, gave 69.3 g. of X, b. 28–30°, and left 62.1 g. of material boiling above 30°. In an attached cold trap was collected 7 g. of lower boiling material, presumably X, which was discarded. The remainder of the Dry Ice condensate was treated in the same manner. The material boiling above 30°, was combined with the liquid cell drainings and the mixture stabilized in the usual manner with aqueous potassium hydroxide. The dried, crude liquid product (470 g.) was then fractionated at atmospheric pressure to yield 97 g. of a mixture of X and II, b. 32–37.5°; 115 g. of II, b.p. 47.5–51°, $n^{20}D$ 1.2754; 75 g. of a mixture of II and perfluoro-1-methylpiperidine (IV); 143 g. of IV, b. 63–66°, $n^{25}D$ 1.2752–1.2754; and 21 g. residue (4% distillation loss). An analytical sample of IV was taken at 66°, $n^{25}D$ 1.2754, d_{25} 1.7426 (reported[4] 65–65.5° (730 mm.), $n^{24}D$ 1.275, d_{24} 1.760). The identity of IV was confirmed by its NMR spectrum.

4-*n*-Propylpyridine (XIV).—Commercial XIV (Reilly Tar & Chemical Corp.) was fractionated through a 3-ft. heated column packed with glass helices and the fraction b. 185.5–187.5° collected.

The electrofluorination of 1695 g. of XIV in cell A with an electrode pack of alternating nickel anodes and iron cathodes gave 1795 g. of liquid cell drainings, 295 g. of Dry Ice–acetone condensate, and 300 g. of liquid nitrogen condensate. The condensate in the liquid nitrogen trap consisted mainly of nitrogen trifluoride which was identified by its infrared spectrum.[12,13] The material condensed at −78° boiled in the range from −50 to +17° and might have contained C_3 and C_4 cleavage products; it was not investigated further.

The liquid cell drainings were stabilized in the usual manner and a 1237-g. portion of the dried material (1515 g., 84.4% recovery) was fractionated through the Todd column to give 15 g. of forerun, b.p. 35–58°, and 30 g. of a colorless liquid distillate, b.p. 58–59°, $n^{20}D$ 1.2578, possibly C_6F_{14} (reported for perfluoro-2-methylpentane,[14] b.p. 57.7°, $n^{25}D$ 1.2564). Further fractionation of the remaining crude product gave in addition to several intermediate, unidentified cuts 754 g. of perfluoro-3-ethylhexane (VI), b.p. 102–103°, and 85.7 g. of perfluoro-4-*n*-propylpiperidine (V), b.p. 121–124°; both yields are based on the total amount (1515 g.) of crude stabilized cell drainings.

The NMR spectrum of an analytical sample of VI, b.p. 103.0°, $n^{25}D$ 1.2744, confirmed its identity. A middle cut of V, b.p. 123.5°, was taken for elemental and NMR analysis.

4-Isopropylpyridine (XV).—Commercial XV (Reilly Tar & Chemical Corp.) was used without further purification as starting material in this run which yielded 1980 g. of HF-insoluble liquid product; 282.1 g. of Dry Ice–acetone trap condensate; and 280 g. of material condensed by liquid nitrogen. The condensate collected at −195° was mostly nitrogen trifluoride. No attempt was made to work up the Dry Ice condensate from this run.

A portion of 1538 g. of the crude, liquid cell product was stabilized in the usual manner and the dried recovered material (1378 g., 89.6% recovery) was fractionated at atmospheric pressure to yield the following main fractions: (1) crude perfluoroheptanes, colorless liquid, 74 g., $n^{20}D$ 1.2713; (2) crude VI, 452 g., b. 100–104°, $n^{20}D$ 1.2780; (3) colorless liquid, 305 g., b.p. 109–111°, $n^{20}D$ 1.2880; (4) crude perfluoro-4-isopropylpiperidine (VII), 226 g., b.p. 122–128°, $n^{20}D$ 1.3010; and 108 g. pot residue (4.2% distillation loss). The forerun, several intermediate cuts and the residue were not further investigated.

Fraction 1, which boiled in the range expected for perfluoroheptanes, is possibly a mixture of C_7F_{16} isomers (reported for perfluoro-2,2,3-trimethylbutane,[15] b.p. 82°, $n^{30}D$ 1.2676 with $\Delta n/\Delta t = -0.00045$, $n^{20}D$ 1.2712 calcd.).

The NMR spectrum of fraction 2 showed it to contain the expected perfluoro-2-methyl-3-ethylpentane only as a minor component; the major part of this fraction gave a spectrum identical with that of VI obtained by electrofluorination of XIV. The spectrum was taken on an analytical cut, b.p. 101.5°, $n^{25}D$ 1.2783. The calculated total yield of this material in the crude cell drainings was 582 g.

Fraction 3 could not be identified with certainty. The rather complex NMR spectrum seems to indicate the presence of a compound having the structure $(CF_3)_2CFCF(C_2F_5)CF_2CF_2NF_2$ or $(CF_3)_2CFCF(C_2F_5)CF_2NFCF_3$.

Anal. Calcd. for $C_8F_{19}N$: C, 20.4; F, 76.6; N, 2.97. Found: C, 22.1; F, 76.0; N, 1.8.

Analytical sample, b.p. 110°, $n^{20}D$ 1.2885, $n^{25}D$ 1.2864, d_{25} 1.8635, MR_D found 45.26, AR_F 1.22, MR_D calcd. 45.04 (using AR_F 1.22).

Fraction 4 (260 g. total yield) (analytical sample, b.p. 124.5°, $n^{20}D$ 1.3010) was identified by its NMR spectrum as VII.

Morpholine (XVI).—XVI (675 g.) (Eastman Kodak, Yellow Label) yielded 644 g. of condensate in the Dry Ice–acetone cooled trap and 93 g. of material condensed by liquid nitrogen. No HF-insoluble liquid cell drainings were obtained in this run.

The condensate collected at −78° was evaporated from the traps and the gas bubbled through 10% aqueous potassium hydroxide to remove small amounts of acidic impurities. The washed gas was passed successively through small columns of sodium fluoride pellets and granular Drierite, respectively, and recondensed with Dry Ice–acetone. Fractionation of the condensate through a low temperature still gave after a small forerun 96.9 g. of perfluorodiethyl oxide (XI), b.p. 3.0–4.5° (730 mm.) (reported[16] b.p. 1.0°), molecular weight 248 (calcd. 254), which was identified by its NMR spectrum. A subsequent cut, b.p. 4.5–30°, of 100 g. consisted of a mixture of XI and perfluoromorpholine (VIII). Further distillation of the remaining charge yielded 260 g. of a colorless liquid, b.p. 30.3–33.0° (730 mm.), b.p. 17–21° (455 mm.), molecular weight 248–253 (calcd. 249), which was identified by its analysis and NMR spectrum as VIII. No attempt was made to identify the contents of the liquid nitrogen trap.

1-Methylmorpholine (XVII).—XVII (80 g., 0.79 mole) (Eastman Kodak, Yellow Label) yielded 7 g. of HF-insoluble, liquid product and 55 g. of Dry Ice–acetone condensate which was found to boil above room temperature. No liquid nitrogen-cooled trap was attached to the cell in this run.

Fractional distillation of 55 g. of the combined products, after treatment with calcium sulfate and sodium fluoride, through a 25-cm. column packed with nickel Heli-pak gave 33.7 g. perfluoro-1-methylmorpholine (IX), b.p. 50.0–52.0°, $n^{25}D$ 1.2679–1.2659 (analytical sample, b.p. 51.1–51.3°, $n^{25}D$ 1.2659), which was identified by its elemental analysis and NMR spectrum. A small forerun and the column hold-up were not investigated further.

Summary of Results

The results of the electrochemical fluorination of the cyclic amines were comparable in many respects to those obtained in the electrofluorination of alkyl sulfides. The starting materials formed in the electrolyte colored solutions which exhibited a high degree of conductivity. These amine–hydrogen fluoride solutions showed boiling points considerably higher than anhydrous hydrogen fluoride al-

lowing, in general, the cell temperatures to rise during the electrolysis to 25–35° and in some cases even to 40° (in the runs with XIV and XV).

The electrofluorination runs gave, with the exception of the run with dipiperidylmethane, the fully fluorinated analogs and in all cases fluorinated cleavage products of the organic starting materials. The electrochemical fluorination of pyridine (XII) yielded, as expected, perfluoropentane (X), nitrogen trifluoride contaminated with about 5% of carbon tetrafluoride and as the main product perfluoropiperidine (II). The formation of perfluoro-1,1′-dipiperidyl (III) from XII is noteworthy. Condensations of this type occur possibly in all electrofluorinations but, in general, the resulting products are not formed in small runs in amounts sufficient for isolation and identification.

The electrofluorination of 4-*n*-propylpyridine (XIV) yielded some of the fully fluorinated analog V which according to its NMR spectrum appeared to be free of isomers. The NMR analysis of the perfluoro-3-ethylhexane (VI) fraction which had been formed in this run by rupture of the two carbon-to-nitrogen bonds indicated the absence of isomers but showed contamination with a small amount of other impurities.

The isomeric 4-isopropylpyridine (XV) gave in an analogous manner perfluoro-4-isopropylpiperidine (VII) which, however, appeared to contain V as a contaminant. The NMR analysis of the cleavage product C_8F_{18} from this run indicated the major component to be VI with some perfluoro-2-methyl-3-ethylpentane, $(CF_3)_2CFCF(C_2F_5)_2$, present as an impurity. A similar conversion of a branched carbon skeleton to a straight chain has been observed in the electrochemical fluorination of *t*-butyl disulfide[1] which yielded as one of the cleavage products a perfluorobutane fraction consisting of approximately 85–90% of perfluoro-*n*-butane and 15–10% of perfluoroisobutane.

The only material which failed to give the perfluorinated analog was dipiperidylmethane (XIII). Only the cleavage products II, IV and X were obtained. It is interesting to note that in this run as well as in the electrofluorination of XIV, where the electrode pack consisted of alternating iron cathodes and nickel anodes, none, or at best only a relatively small yield, of the fully fluorinated analogs was formed. The amount of tarry materials obtained in the cells during these runs was correspondingly large. The electrochemical fluorination of XV employing an all-nickel electrode pack gave a larger yield of perfluorinated analog than the run with XIV using alternating iron and nickel electrodes (260 g. as compared to 85.7 g.). This observation was rather surprising since one might expect the more branched carbon skeleton of XV to be more susceptible to degradation than that of XIV.

The electrofluorination of morpholine (XVI) resulted in a relatively good yield of perfluoromorpholine (VIII) and a considerable amount of perfluorodiethyl oxide (XI) indicating extensive cleavage of the C–N bonds of the starting material. Similar results were obtained with 1-methylmorpholine (XVII) which yielded, as expected, the fully fluorinated analog IX and the cleavage product XI.

A detailed discussion of the NMR and infrared spectra of the various compounds obtained in this study will be published by members of the Spectroscopy Group, Physical Measurements Branch, of these laboratories in a forthcoming paper.

Acknowledgments.—We wish to express our appreciation to Dr. R. D. Dresdner of the University of Florida, Gainesville, for his valuable advice in the construction and operation of the electrochemical cells. The authors are also indebted to Mr. C. A. Rush and Mr. J. H. Rothstein for performing the analyses reported in this paper.

Neighboring Carbon and Hydrogen. XXIX. $\rho-\sigma$ Analysis of Acetolysis of Substituted Neophyl Arylsulfonates

By R. Heck and S. Winstein

Received December 8, 1956

In acetolysis of neophyl *p*-bromobenzenesulfonate, ionization is exclusively anchimerically assisted, only neighboring phenyl participating. Rates of aryl-assisted ionization of a series of substituted neophyl *p*-bromobenzenesulfonates have been measured and correlated with the aid of the Hammett $\rho-\sigma$ relation. Omitting the *p*-MeO group, log *k* of acetolysis is approximately linear in σ with a slope ρ of -3.65. The value of log *k* for the *p*-MeO substituent falls substantially above the line through the other points. By using σ^+-values of Brown and Okamoto which reflect a blend of inductive and resonance influences of the substituents more appropriate for an electron-demanding reaction, the *p*-MeO group may be treated along with the other substituents. The slope of the log *k* *vs.* σ^+ line is -2.96.

In connection with another investigation,[1] it became necessary to prepare *p*-benzhydrylneophyl alcohol (IX). The synthetic route employed involved preparation of the *p*-bromo- and *p*-carbomethoxyneophyl alcohols (III) and (V). Since these were available and the *p*-carbomethoxyneophyl alcohol was converted easily to the *p*-methyl analog, we were prompted to extend the previous study[2] of the effect of substituents on solvolysis rate of neophyl arylsulfonates. The results obtained and their analysis with the aid of Hammett's $\rho-\sigma$-relation[3] are given in the present article

Substituted Neophyl Bromobenzenesulfonates.—All of the *p*-bromobenzenesulfonates required in the present study were prepared by the usual method from the corresponding alcohols. The preparation of several of the required alcohols began with the bromination of α,α-dimethylphenylacetic acid (I) which was available from the nitrile obtained by the alkylation of benzyl cyanide with sodamide and methyl iodide. From the bromination was obtained the α,α-dimethyl-*p*-bromophenylacetic acid (II). Lithium aluminum hydride reduction of the latter yielded *p*-bromoneophyl alcohol (III).

To confirm the *p*-position of the bromine atom in the brominated acid II and alcohol III, oxidation to *p*-bromobenzoic acid was carried out. Oxidation of the bromophenylisobutyric acid II with boiling alkaline potassium permanganate proceeded very slowly and yielded only a trace of pure *p*-bromobenzoic acid. However, much more satisfactory results were obtained by treatment of the bromoneophyl alcohol III with thionyl chloride and oxidizing the product with alkaline permanganate. Evidently, the reaction of the alcohol III with thionyl chloride proceeds with Wagner–Meerwein rearrangement, the aryl group migrating so that tertiary chloride and related olefins are produced. Oxidation of the whole crude reaction mixture gave a substantial yield of pure *p*-bromobenzoic acid.

p-Bromoneophyl alcohol (III) was converted to the aryllithium derivative, though in poor yield, by reaction with two equivalents of *n*-butyllithium in ether solution. Carbonation yielded *p*-carboxyneophyl alcohol (IV) which was converted to *p*-carbomethoxyneophyl alcohol (V) with diazomethane. Reduction of this ester with lithium aluminum hydride yielded *p*-hydroxymethylneophyl alcohol (VI). Hydrogenolysis of the latter over palladium-on-charcoal led to *p*-methylneophyl alcohol (VII).

The reaction of 3 equivalents of phenyllithium with *p*-carbomethoxyneophyl alcohol (V) gave *p*-diphenylhydroxymethylneophyl alcohol (VIII), hydrogenolysis of the latter leading to *p*-benzhydrylneophyl alcohol (IX).

The remaining new alcohol, *m*-methylneophyl alcohol, was prepared by the lithium aluminum hydride reduction of the corresponding acid. This acid, α,α-dimethyl-*m*-tolylacetic acid, was prepared by the hydrolysis of the nitrile which, in turn, was obtained by alkylating *m*-methylbenzyl cyanide with sodamide and methyl iodide.

Acetolysis.—All of the bromobenzenesulfonates investigated in the present work obeyed good first-order kinetics in acetolysis, the measured first-order rate constants being summarized in Table I, which also includes a comparison of the rates with those of three neophyl derivatives previously investigated.[2,4]

In order to verify[4,5] the course of acetolysis of the reference compound, neophyl *p*-bromobenzenesulfonate (X), the products of solvolysis of 0.05 *M* material in acetic acid, 0.06 *M* in lithium or sodium acetate, were investigated. Treatment of the reaction product with lithium aluminum hydride and

[a] Three times recrystallized bromobenzenesulfonate was employed. [b] From the $n^{25}D$, using $n^{25}D$ 1.5364 for XIII and 1.5057 for XIV.[6] [c] From ultraviolet absorption, using ϵ 14,000 for XIII and 77 for XIV in isooctane.[6]

subsequent chromatography gave rise to olefin and alcohol fractions.

In quantitative hydrogenation, a sample of the olefin product consumed the correct quantity of hydrogen calculated for a mixture of β,β-dimethylstyrene (XIII) and 1-phenyl-2-methyl-2-propene (XIV). Also, the hydrogenation product proved to be pure isobutylbenzene, the infrared spectrum being identical with that of a pure standard. The analysis of the olefin product for conjugated and unconjugated components, XIII and XIV, respectively, could be based on either ultraviolet absorption spectrum or refractive index, both methods agreeing well. As summarized in Table II, the olefin proved to be 51% conjugated (XIII) and 49% unconjugated (XIV).

The alcohol product, m.p. 25–26°, was essentially pure rearranged tertiary alcohol XVI, the authentic synthetic material having m.p. 25.5–26.5°. There was some indication from the infrared spectrum of a trace of unrearranged material in the alcohol product. The alcohol product displayed an infrared spectrum nearly identical with that of authentic benzyldimethylcarbinol (XVI), except for the presence of slightly high absorption at 1000–1075 cm.$^{-1}$ and slightly low absorption at 1125–1250 cm.$^{-1}$. Since neophyl alcohol has a very strong band at 1030 cm.$^{-1}$ and is relatively transparent at 1125–1250 cm.$^{-1}$, it seems probable that a small amount of neophyl alcohol is present in the acetolysis product. By preparing a synthetic mixture containing 1.6% neophyl alcohol in the tertiary alcohol and comparing its spectrum with that of the solvolysis product, it was possible to estimate that the product alcohol contained 0.5–0.75% neophyl alcohol.

While the indications are that the over-all solvolysis product contains *ca.* 0.2% neophyl alcohol, it is not clear what its mode of formation is. Some of it may arise during lithium aluminum hydride treatment of the reaction product, since the latter would contain 0.1% of unreacted neophyl bromobenzenesulfonate after ten solvolysis half-lives

(6) S. J. Lapporte, unpublished work.

(28 hr.). Some of the unrearranged neophyl product may arise from second-order reaction of neophyl bromobenzenesulfonate with acetate ion. For these reasons, it is not possible, without more controls, to associate the neophyl alcohol with any definite competing reaction path such as anchimerically unassisted solvolysis of neophyl bromobenzenesulfonate.

The present observations on the nature of the products further strengthens the previous conclusion,[2,5] based on rate and $\Delta S^{\ddagger}$, that neophyl bromobenzenesulfonate solvolyzes essentially exclusively with anchimerically assisted ionization. It seems likely that anchimerically unassisted solvolysis would lead to a product containing at least a substantial proportion of unrearranged material. The virtual absence of such a material indicates the proportion of solvolysis by an anchimerically unassisted route must be extremely small.

ρ-σ Correlation.—As is brought out in Table I, the relative solvolysis rates at 75° of the neophyl bromobenzenesulfonates studied in the present and previous[2] work cover a range of 4500. The *p*-methoxyl substituent enhances rate by a factor of 88.5 and the *p*-carbomethoxy group depresses rate by a factor of 52. Even in the latter case, aryl-assisted ionization can be assumed to dominate the acetolysis; with anchimerically assisted ionization depressed by a factor of only *ca.* 50, one would not yet expect other processes, so negligible in solvolysis of neophyl bromobenzenesulfonate, to be too serious. On this basis, one can expect sufficient uniformity of mechanism of solvolysis of the series of neophyl bromobenzenesulfonates to warrant application of the Hammett relation[3] (1) to the rate data.

As is clear from Fig. 1, the plot of log k *vs.* σ is roughly linear, with the point for *p*-OCH_3 lying

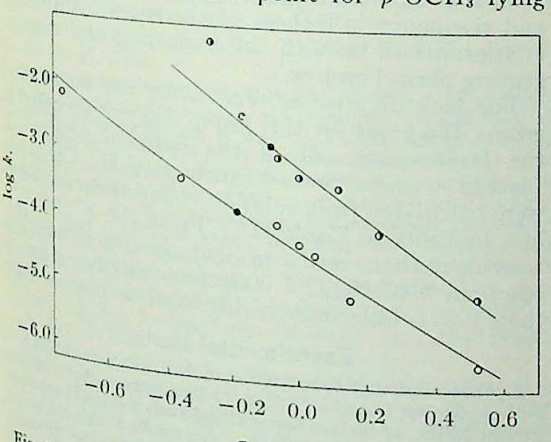

Fig. 1.—Plot of log k for acetolysis of neophyl *p*-bromobenzenesulfonates at 75° *vs.* σ: ◑, 1 + log k *vs.* σ; ○, log k *vs.* σ^+; ●, *p*-$(C_6H_5)_2CH$ group.

substantially above the line outlined by the other points. As summarized in Table III, after omitting the *p*-OCH_3 group, the remaining points fit the Hammett linear relation (1) with a slope ρ equal to −3.65, the probable error of the fit being 0.085 in log k. In line with the nature[5] of the anchimerically assisted rate-determining ionization step, ρ is negative and relatively large in magnitude. This is expected for an electron-demanding reaction.

TABLE III

SUMMARY OF LEAST SQUARES FITS OF LOG k OF ACETOLYSIS OF NEOPHYL *p*-BROMOBENZENESULFONATES TO THE HAMMETT ρ-σ RELATION AT 75°

Substit. constant[a,b]	log k^0	ρ	r^c
σ^{3b}	−4.037	−3.650	0.085[d]
σ^+	−4.281	−2.959	.125

[a] For *p*-$COOCH_3$, σ and σ^+ equal to +0.522 employed; σ^+ values of Brown and Okamoto were used: *p*-OCH_3, −0.764; *p*-CH_3, −0.306; *m*-CH_3, −0.0652; *m*-OCH_3, −0.0465; *p*-Br, 0.148. [b] The least squares lines yield σ = −0.082 and σ^+ = −0.184 for the *p*-$(C_6H_5)_2$ CH group. [c] Probable error in log k. [d] Omitting the *p*-OCH_3 group from the least-squares line.

The upward curvature of the log k *vs.* σ plot for the point corresponding to the *p*-methoxyl group is to be expected, since one cannot expect the blend[7-10] of inductive and resonance influences reflected by σ to be appropriate for a strongly electron-demanding reaction. Such failure of the Hammett ρ-σ-relation is common, for example, in solvolysis of benzhydryl halides[11] or brominolysis of benzeneboronic acids.[12] It is common also in connection with other rearrangement reactions similar to the present example. A few such rearrangements are listed in Table IV for comparison with the present work.

Table IV includes examples of aryl migration to carbon or oxygen, as well as a number of cases of migration to nitrogen. The latter include the Beckmann, Lossen, Hofmann and Stieglitz rearrangements, as well as Schmidt reactions of benzoic acids and 1,1-diarylethenes. Some of the applications of the Hammett relation are to rate data. When the substituent is in the migrating phenyl group, the Hammett relation is supposed to account for the modification of the inductive and anchimeric effects[5] of the phenyl group by the substituent. When the substituent is on a nonparticipating phenyl, the Hammett relation is supposed to account for the modification of the inductive and any conjugative effects[5] of the phenyl group.

Some of the applications of the Hammett relation in Table IV are to relative migration aptitudes. If we take anchimerically assisted ionization of 2,2-diphenylethyl[5,13] toluenesulfonates XV and XVI for illustration, the meaning of the plot of log of relative migration aptitude *vs.* σ may be clarified

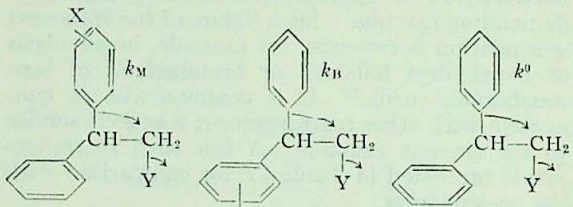
TABLE IV

SUMMARY OF APPLICATION OF HAMMETT'S RELATION TO CERTAIN REARRANGEMENTS

Reaction series	Ref.	$-\rho_M$	$-(\rho_M - \rho_B)$	$-\rho_B$
$XC_6H_4C(CH_3)_2CH_2OBs$, AcOH, 75.0°		3.7		
$XC_6H_4CH(C_6H_5)CH_2OTs$, AcOH, 99.5°	13	4.2		2.0
$XC_6H_4CH(C_6H_5)CH_2OH$, P_2O_5, xylene	14		2.3	
$XC_6H_4C(CH_3)_2OOCOC_6H_4NO_2$, AcOH, 25.0°	15	5.1		
$(XC_6H_4)(C_6H_5)C{=}NOC_6H_2(NO_2)_3$, CCl_4, 90.8°	16	4.3		1.9
$XC_6H_4CONHOCOC_6H_5$, aq. NH_3, 30°	17	2.6		
$XC_6H_4CONHBr$, aq. NaOH, 30°	18	2.5		
XC_6H_4COOH, HN_3, H_2SO_4, $Cl_2C{=}CHCl$, 40°	19a	2.0		
$XC_6H_4CN_2(C_6H_5)(CH_3)$, H_2SO_4, C_6H_6	20		2.8	
$(XC_6H_4)(C_6H_5)C{=}CH_2$, HN_3, H_2SO_4	19b		2.1	
$(XC_6H_4)(C_6H_5)_2CNHOH$, PCl_5, C_6H_6	21		1	

in the following way. To the extent that the Hammett relation will account successfully for the rates of the anchimerically assisted rate-determining ionizations, we may write relation (2) for k_M, where the substituent is in the migrating phenyl (XVM), and relation (3) for k_B, where the substituent is in the phenyl group which remains



XV M X XV B XVI

behind (XVB). In these relations, k^0 is half the rate constant of ionization of 2,2-diphenylethyl toluenesulfonate (XVI).

$$\log k_M = \log k^0 + \rho_M\sigma \quad (2)$$

$$\log k_B = \log k^0 + \rho_B\sigma \quad (3)$$

$$\log (k_M/k_B) = (\rho_M - \rho_B)\sigma \quad (4)$$

The relative migration aptitude of the substituted phenyl group, defined equal to the ratio k_M/k_B, is then given by relation 4. The latter is a linear relation between log of relative migration aptitude and σ, the proportionality constant being $(\rho_M - \rho_B)$. The situation is similar for cases where aryl does not participate in the rate-determining step but migrates at a later stage of the reaction. For such cases, k_M, k_B and k^0 are rate constants for the reaction steps involving aryl shift.

In most of the applications of the Hammett relation in Table IV, considerable tendency for curvature in the log k or log (k_M/k_B) *vs.* σ plot is evident. In such cases, the values of ρ listed are either for electron-withdrawing substituents or for a range of substituents including none more electron-supplying than p-CH_3. Within a factor of *ca.* 2, the various ρ_M values, some of them quite rough, are similar for all the rearrangements listed.

By choosing new σ values[7,9,10] which do reflect a blend of inductive and resonance influences more appropriate to electron-demanding reactions, one can hope to treat the present reactivity data more satisfactorily with relation 1. The set of σ values, labeled σ^+ values, which we have employed for this purpose is one derived by Brown and Okamoto[9,22] from rates of hydrolysis of substituted phenyldimethylcarbinyl chlorides in aqueous acetone. The plot of log k of acetolysis of the neophyl bromobenzenesulfonates *vs.* σ^+ is shown in Fig. 1, from which it is evident that the point for p-OCH_3 comes closer to fitting on the same line with the other substituents. The σ^+ value employed for p-OCH_3 somewhat over-corrects the present situation, since the p-OCH_3 point now falls below the line. The least-squares fit of the data to relation 1, including the p-OCH_3 point, is summarized in Table III. By using σ^+ values, the fit of the data including the p-OCH_3 point is comparable to that obtained using σ values but omitting p-OCH_3.

In principle, the fit of the other rearrangements in Table IV by the Hammett relation might be improved by the use of σ^+ instead of σ-values. However, the available data are too scanty in most cases to make a thorough recalculation worthwhile. In general, the σ^+ values seem to correct too far to account well for the p-OCH_3 group. If sufficient data were available, it would probably be desirable, in accounting for relative migration aptitudes, to use different σ values in equations 2 and 3, since it is unlikely that the same blend of inductive and resonance influences of the substituent group is appropriate in both the migrating and non-migrating phenyl groups.

For lack of σ or σ^+ values for the benzhydryl group, the point for this group was not included in the least-squares fit of the data to relation 1. Instead, σ and σ^+ values for the p-$(C_6H_5)_2CH$ group were calculated from relation 1, and these are listed in a footnote to Table III. From the σ^+ value, it is evident that, in the present electron-demanding reaction, p-$(C_6H_5)_2CH$ is electron-supplying, less so than p-CH_3 but considerably more so than m-CH_3.

Experimental Part

β-p-Bromophenylisobutyric Acid.—A mixture of 133 g. of β-phenylisobutyric acid, 135 g. of bromine and 0.2 g. of iron wire in 150 cc. of carbon tetrachloride was refluxed overnight. After being cooled, the solution was washed with cold dilute acid and then water. Finally, the product was extracted with a solution of 50 g. of sodium hydroxide in 500 cc. of water. Acidification of the basic extract and cooling gave rise to the crude acid. Four crystallizations from aqueous methanol yielded 118 g. of acid, m.p. 124–125.5°.

Anal. Calcd. for $C_{10}H_{11}O_2Br$: C, 49.40; H, 4.56. Found: C, 49.42; H, 4.79.

The oxidation of β-p-bromophenylisobutyric acid with boiling basic potassium permanganate solution proceeded very slowly, and only a trace of pure p-bromobenzoic acid was obtained.

p-**Bromoneophyl Alcohol.**—A 46-g. quantity of the above acid in 200 cc. of ether was added slowly with stirring to 7.5 g. of lithium aluminum hydride in 500 cc. of ether. After the addition, the solution was refluxed for 1 hr., cooled and treated with cold dilute hydrochloric acid. The ether solution was washed with water and aqueous sodium bicarbonate. Then it was dried and concentrated. Distillation yielded 36.5 g. of crude alcohol, b.p. 120–123° (2.0 mm.), n^{25}D 1.5598. Recrystallization from pentane yielded 33.3 g. of material, m.p. 44–47°, m.p. 46–47.5° after a second crystallization.

Anal. Calcd. for $C_{10}H_{13}OBr$: C, 52.42; H, 5.72. Found: C, 52.46; H, 5.94.

A 1.0-g. quantity of the alcohol was refluxed 1 hr. with 10 cc. of thionyl chloride. The excess thionyl chloride was removed under vacuum, and the remaining oil was refluxed overnight with a solution of 4 g. of potassium permanganate and 2 cc. of 5% sodium hydroxide in 80 cc. of water. Cold dilute sulfuric acid was added and boiling was continued for 10 minutes. After the mixture was cooled to 0°, an excess of aqueous sodium bisulfite was added and the solid was filtered off. Recrystallization from benzene gave 0.30 g. (34%) of *p*-bromobenzoic acid, m.p. 248–250°, mixed m.p. 248–250°.

p-**Carboxyneophyl Alcohol.**—*n*-Butyllithium was prepared from 10.5 g. of lithium ribbon and 90 g. of butyl bromide in 300 cc. of ether at −10° as described by Gilman.[23] To this solution, cooled to 0°, was added a solution of 48 g. of *p*-bromoneophyl alcohol in 150 cc. of ether with stirring during *ca.* 10 min. The mixture was then stirred for 30 minutes at room temperature and poured onto an excess of Dry Ice. When the Dry Ice had disappeared and the solution had come to room temperature, cold dilute hydrochloric acid was added. The ether phase was separated and the aqueous solution was extracted with ether. The combined extracts were washed with water and the product was extracted with a solution of 30 g. of sodium bicarbonate in water. Acidification gave the crude acid. Two crystallizations from aqueous methanol yielded 5.8 g. of material, m.p. 155–157°. Another crystallization raised the m.p. to 158–159°.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.26. Found: C, 67.80; H, 7.23.

p-Carbomethoxyneophyl alcohol was prepared from 7.0 g. of the above acid and an excess of ethereal diazomethane. The product, b.p. 135–140° (1.5 mm.), obtained by distillation, was recrystallized twice from ether–pentane to yield 5.0 g. of material, m.p. 42–43.5°.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75. Found: C, 69.25; H, 7.80.

p-**Diphenylhydroxymethylneophyl Alcohol.**—Phenyllithium was prepared from 1.4 g. of lithium ribbon and 15 g. of bromobenzene in 200 cc. of ether. To this stirred solution was added dropwise 5.0 g. of *p*-carbomethoxyneophyl alcohol in 50 cc. of ether. After the addition, the solution was refluxed for 2 hr. Then cold water was added with cooling. The aqueous phase was separated and extracted twice with ether. The combined ether solutions were washed with water, dried and concentrated. The residual oil crystallized on standing overnight. Two crystallizations from ligroin–benzene gave 6.0 g. of the glycol, m.p. 114–116.5°.

Anal. Calcd. for $C_{23}H_{24}O_2$: C, 83.10; H, 7.28. Found: C, 83.10; H, 7.25.

p-**Benzhydrylneophyl Alcohol.**—A solution of 6.0 g. of *p*-diphenylhydroxymethylneophyl alcohol in 50 cc. of pure methanol was shaken with 0.2 g. of 10% palladium-on-charcoal and 3 drops of 2 *N* hydrochloric acid under 35 p.s.i. of hydrogen for *ca.* 24 hr. The solution was filtered through Celite and poured into dilute aqueous sodium bicarbonate. The product was extracted with two portions of ether. The extracts were washed with water, dried and concentrated. The oil obtained was crystallized twice from ether–pentane. This gave 3.0 g. of alcohol, m.p. 75.5–77°.

Anal. Calcd. for $C_{23}H_{24}O$: C, 87.30; H, 7.64. Found: C, 87.17; H, 7.44.

p-**Hydroxymethylneophyl Alcohol.**—A solution of 4.5 g. of *p*-carbomethoxyneophyl alcohol in 50 cc. of ether was added cautiously to 3 g. of lithium aluminum hydride in 100 cc. of ether. A precipitate formed immediately. It was necessary to reflux the solution for 20 hr. in order to complete the reduction. Cold dilute sulfuric acid was added cautiously and the aqueous phase was separated and extracted with ether. The combined extracts were washed with water and aqueous sodium bicarbonate. The solution was dried and the ether was evaporated. The residue was recrystallized three times from ether–pentane. The product, 2.1 g., formed long colorless needles, m.p. 58–59°.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.39; H, 9.02.

p-**Methylneophyl Alcohol.**—The above glycol, 2.0 g., was dissolved in 25 cc. of pure methanol and hydrogenated at 35 p.s.i. using 0.2 g. of 10% palladium-on-charcoal as catalyst. The hydrogenation was complete in 3 hr. The resulting solution was filtered through Celite, and the filtrate was evaporated on a steam-bath. Vacuum distillation yielded 1.5 g. of alcohol, b.p. 87–88° (1.5 mm.), n^{25}D 1.5193.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.44; H, 9.82. Found: C, 80.25; H, 9.84.

α,α-**Dimethyl-***m*-**methylbenzyl Cyanide.**—Sodamide was prepared in 500 cc. of liquid ammonia from 20 g. of sodium, ferric chloride being used as catalyst. The 500 cc. of dry benzene was added while the ammonia was evaporated. The benzene finally was boiled in order to expel the last traces of ammonia. To the warm solution, 48 g. of *m*-methylbenzyl cyanide[24] was added with stirring and slight cooling. A vacuum was applied to the warm solution to remove the ammonia formed. Then 130 g. of methyl iodide was added as rapidly as possible to the still warm, stirred solution, slight cooling being necessary to keep the reaction mixture from boiling too vigorously. The hot solution was stirred 10 minutes more and cooled. A little methanol was added to destroy any remaining sodamide and then ice-water. The benzene layer was separated, washed with water, cold dilute hydrochloric acid, water and finally with aqueous sodium bicarbonate. The solution was dried and concentrated. The dark brown product was fractionated under vacuum through a center-rod column (*ca.* 20 plates). The pure nitrile, 32 g., boiled at 119–120° (15 mm.).

Anal. Calcd. for $C_{11}H_{13}N$: C, 82.97; H, 8.23. Found: C, 82.81; H, 8.20.

α,α-**Dimethyl-***m*-**tolylacetic Acid.**—The above nitrile, 15 g., was refluxed for 2 hr. with 12 g. of potassium hydroxide in 50 cc. of ethylene glycol. After being cooled, the solution was poured onto ice and hydrochloric acid. The oil which separated could be induced to crystallize, three crystallizations from pentane yielding 10.4 g. of material, m.p. 70.5–73°. Another crystallization raised the m.p. to 73–74°.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92. Found: C, 73.86; H, 7.85.

m-**Methylneophyl Alcohol.**—The reduction of 8.0 g. of α,α-dimethyl-*m*-tolylacetic acid with 2.0 g. of lithium aluminum hydride in ether proceeded readily. The usual isolation yielded 7.0 g. of the pure alcohol, b.p. 91–94° (2.5 mm.), n^{25}D 1.5210.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.44; H, 9.82. Found: C, 80.45; H, 9.56.

Bromobenzenesulfonates.—The *p*-bromobenzenesulfonates were prepared from the corresponding alcohols by the usual pyridine method. Most of the esters were recrystallized from benzene–ligroin. Table V summarizes the melting points and analyses of the five new *p*-bromobenzenesulfonates employed in the present work. The equivalent weights observed in acetolysis were close to the theoretical values except in the *p*-benzhydryl case, for which acetolysis indicated a purity of only 85%.

1,1-**Dimethyl-2-phenylethanol.**—This alcohol was prepared by the reaction between ethyl phenylacetate and methylmagnesium iodide. The crude alcohol was chromatographed carefully on alumina and recrystallized 4 times from pentane at −80°. The pure alcohol has the properties: m.p. 25.5–26.5°, n^{25}D 1.5128, b.p. 59–60° (1.5 mm.).

Acetolysis of Neophyl *p*-**Bromobenzenesulfonate.**—A solution of 50.0 cc. of 1.00 *M* lithium acetate and 750 cc. of dry acetic acid was heated to 75.0°, and 15.0 g. of the pure *p*-bromobenzenesulfonate,[4] m.p. 80.5–81.5°, three times recrystallized from ligroin, was added. The solvolysis solution was kept at 75.0° for 28 hr., and then it was

cooled and poured into water. The products were extracted with 5 portions of pentane, and the extracts were washed with water and aqueous sodium bicarbonate. The extract was dried and the solvent was distilled off carefully through a Vigreux column. The crude products were reduced with 1.5 g. of lithium aluminum hydride in ether. The products were isolated by adding water to the solution and decanting the ether solution from the insoluble salts. The solids were extracted several times with ether and the extracts were washed with water, dried and concentrated. Chromatography on 200 g. of alumina separated the products into olefin and alcohol. The olefins, 3.2 g. (59.6%), $n^{25}D$ 1.5207, were eluted with pentane and the alcohols, 1.90 g. (31.1%), $n^{25}D$ 1.5128, b.p. 65–68° (1.5 mm.), were eluted with ether.

The olefin fraction in isooctane displayed an ϵ 6912 at λ 244 mμ in ultraviolet absorption. A 0.8843-g. sample of the olefin product was hydrogenated in acetic acid at 27.5° and 752 mm., using 10% palladium-on-charcoal as catalyst. A total of 169 cc. of hydrogen (99%) was absorbed in 90 minutes. The hydrogenated product was isolated by pouring the acetic acid solution into water and extracting with pentane. The pentane extracts were washed with aqueous sodium bicarbonate and dried. The solvent was evaporated, and the residue was refluxed with sodium metal until the metal remained bright. A final distillation gave 0.45 g. of product, b.p. 172°, $n^{25}D$ 1.4837. The infrared spectrum of this material was identical with that of isobutylbenzene,[6] $n^{25}D$ 1.4841.

The alcohol fraction from the chromatography of the solvolysis product had m.p. 25–26°, mixed m.p. with 1,1-dimethyl-2-phenylethanol, 25–26°. The infrared spectrum indicated the presence of 0.5–0.75% of neophyl alcohol in the tertiary alcohol. Definite absorption was observed at 1000–1075 cm.$^{-1}$ where neophyl alcohol absorbs strongly, and slightly low absorption was observed at 1125–1150 cm.$^{-1}$ where neophyl alcohol is relatively transparent. The infrared spectrum of the solvolysis product was intermediate between a synthetic mixture containing 1.6% neophyl alcohol in the tertiary alcohol and the pure tertiary alcohol.

In a second solvolysis carried out as above with slightly less pure *p*-bromobenzenesulfonate, a 61.5% yield of olefin was obtained and a 30.3% yield of alcohol. The olefin fraction, $n^{25}D$ 1.5200, displayed ϵ 6880 at λ 244 mμ in ultraviolet absorption. The alcohol, m.p. and mixed m.p. 24.5–25.5°, b.p. 65–68° (2 mm.), $n^{25}D$ 1.5120, had an infrared spectrum consistent with the presence of more than 99% tertiary alcohol and *ca.* 1% neophyl alcohol.

In a control experiment, a solution of 1.5 g. of the tertiary alcohol, 1 cc. of acetic anhydride, 1 cc. of 1.00 *M* lithium acetate in dry acetic acid and 100 cc. of dry acetic acid was heated to 75.0° for 30 hr. The reaction mixture was worked up in the usual way, and the recovered product was reduced with 0.5 g. of lithium aluminum hydride in ether. The excess hydride decomposed with water, and the ether solution was decanted from the salts. The salts were extracted several times with fresh ether. The combined extracts were washed with water, dried and concentrated. Distillation gave 1.3 g. of product, b.p. 65° (1.5 mm.), $n^{25}D$ 1.5130, m.p. 24–25.5°. A comparison of the −OH band at 3350 cm.$^{-1}$ of the product with that of pure tertiary alcohol showed the product to contain a small amount of non-hydroxylic material, probably olefin. Otherwise, the infrared spectra of the two materials were very similar.

Mechanisms of Elimination Reactions. XVIII. Reactivities of Some 2,3-Norbornane Derivatives[1,2]

BY STANLEY J. CRISTOL AND ERHARD F. HOEGGER

RECEIVED JANUARY 18, 1957

Rate constants have been determined for the second-order reaction of sodium 1-pentoxide in 1-pentanol with *endo-cis*- and *trans*-2,3-dichlorononorbornane at 101.3 and 116.2°, and with *exo*-2-*p*-toluenesulfonyl-*endo*-3-chlorononorbornane at 0 and at 12°. The relative reactivities toward elimination of the elements of hydrogen chloride from these boat-form cyclohexane rings have been interpreted on the basis of an elimination process involving a carbanion intermediate.

Elimination of the elements of hydrogen chloride from 11,12-dichloro-9,10-dihydro-9,10-ethanoanthracene with alkali has been shown[3] to be very sluggish and to be relatively non-stereospecific, *cis* elimination being preferred over *trans* by a factor of about 8, in contrast to the generally observed large preference of *trans* over *cis* elimination.[4] The striking lack of stereospecificity was rationalized[3] by the assumption that normal *trans* elimination (in acyclic systems or in cyclic systems without severe hindrance to rotation or ring conversion) utilizes a concerted *trans* coplanar transition state[4,5]; this transition state is forbidden to *cis* groups in ordinary small rings or to either *cis* or *trans* groups in bicyclo[2,2,2]octane derivatives without excessive torsional strain. Norbornane, or bicyclo[2,2,1]-heptane is locked by the 1,4-methano bridge in a boat-form cyclohexane ring in the same way as the 1,4-ethano bridge affects the cyclohexane ring in

the bicyclo[2,2,2]octane molecule. Accordingly, it would be anticipated that 2,3-dichloronorbornane isomers would be relatively inert and that *trans* elimination would not be markedly faster, and might be slower, than *cis* elimination. That this was true was observed in either a qualitative or a rough quantitative fashion in such compounds in three different laboratories.[6-8] In view of these results, it seemed worthwhile to get quantitative information about these isomers.

The preparations of *endo-cis*-2,3-dichloronorbornane and the *trans* isomer has been described,[7,8] and treatment with alkali has been shown to give 2-chloronorbornene.[7] We chose to use 1-pentanol as solvent for the kinetic study, and sodium 1-pentoxide as base, because of the moderately high temperatures involved. Appropriate details of the procedures used in determining rate constants are given in the Experimental section. The rate data are given in Table I for the reactions of these two isomers with sodium 1-pentoxide.

It may be noted from the data of the table that just as in the case of the dichlorodihydroethanoanthracenes, *cis*-dehydrochlorination is preferred over *trans*-dehydrochlorination in these rigid boat-form compounds where the eclipsed bonds cannot readily attain the requisite geometry for *trans* coplanar elimination. These data are not directly comparable with the data on the bicycloöctanes because of the different solvents used (ethanolic dioxane and *n*-amyl alcohol), but it may be fairly stated that in both cases, the favoring of *cis* elimination does not follow from factors increasing its rate, but rather from factors markedly decreasing the rate of *trans* elimination.[3] At the present time we are not in a position to discuss the preference of *cis* elimination over *trans* in the two systems, nor the differences in amount of this preference between the two systems. These may be the result of effects of solvent size and steric hindrance to solvation in the transition state of the various carbanions being formed, but discussion of speculations of this sort must await the accumulation of further data. It would also be desirable to have data on the *exo-cis*-dichloride, but this compound has not yet been described in the literature.

Two alternative processes have been suggested for bimolecular elimination in systems where the groups being eliminated cannot easily attain a *trans*-coplanar conformation. One suggestion has been made that the additional energy of activation required for the less favored process is used partly to twist the molecule more nearly into the requisite geometry and partly to force the mechanism against the still imperfect geometry,[9] but that the process is still concerted, removal of the proton by base being accompanied by formation of the multiple bond and loss of the anion. Unfortunately it seems difficult to define an experimental test for this postulate.

On the other hand, it has been suggested[4a] that a distinctly different mechanism is utilized by those compounds with geometry unfavorable to a *trans* coplanar transition state. This mechanism involves a first step in which the β-proton is transferred to the base to give a carbanion intermediate. The carbanion ultimately loses an anion to form the olefinic or acetylenic product. Energy calculations appear consistent with observed activation energies.[4b] The small amount of deuterium exchange observed in elimination with β-benzene hexachloride (*cis* elimination) was suggested as offering sup-

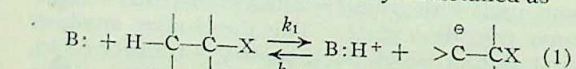
port to the postulated carbanion process.[10] Substantial amounts of deuterium exchange have been observed in treatment of trichloroethylene with alkali,[11] a fact consistent with a carbanion intermediate in elimination where the tendency to abstract a proton from solvent competes favorably with loss of chloride ion.

Another deduction from the dual mechanism theory is that substitution of electron-attracting substituents on the β-carbon atom would minimize the difference in reactivity and energy of activation between the two processes, as it appeared that the carbanion process (where a large negative charge was being developed on the β carbon atom in the transition state) would be more sensitive to the effect of such groups than the concerted process (where the negative charge was being distributed more widely). Such an effect has been observed.[4c,12]

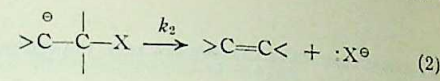
Such an electron-attracting group is a sulfone group, and it might be anticipated that such a group would stabilize the carbanion process markedly. This group (or any other electron-attracting group) might, for example, result in a situation where a stabilized carbanion process might be favored over an alternative concerted elimination process where no activation is present. Indeed, Bordwell and Kern[13] have shown that a *cis* hydrogen activated by the presence of a sulfone group on the same carbon atom will be removed in preference to a *trans* unactivated hydrogen in *trans*-2-*p*-toluenesulfonylcyclohexyl *p*-toluenesulfonate and the corresponding cyclopentyl compounds. In addition, Weinstock, Pearson and Bordwell[14] have shown that the sulfone group has a powerful activating influence in both *cis* and *trans* elimination, although they have not interpreted their data in terms of possible carbanion mechanisms.[15]

We were interested in how the sulfone group might affect elimination rates in boat-form cyclohexane rings and accordingly data were obtained on *exo*-2-*p*-toluenesulfonyl-*endo*-3-chloronorbornane,[16] and they are recorded in Table I. It may be noted that this compound is very reactive, rates being conveniently measurable at 0 and 12° as compared with 100–120° for the dichlorides, and with rates differing by six to eight orders of magnitude if the data on the chlorosulfone are extrapolated to 110°, or by ten to twelve orders of magnitude if the rates on the dichlorides are extrapolated down to 12°. Here we have a *cis* non-coplanar elimination proceeding at a very high rate, and with low activation energy, a result entirely consistent with predictions from the carbanion mechanism theory.

The carbanion mechanism may be detailed as



$$\mathrm{B:} + \mathrm{H{-}C{-}C{-}X} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{B{:}H^+} + \mathrm{{>}C^{\ominus}{-}CX} \quad (1)$$



$$\mathrm{{>}C^{\ominus}{-}C{-}X} \xrightarrow{k_2} \mathrm{{>}C{=}C{<}} + :X^{\ominus} \quad (2)$$

Some confusion apparently may exist as to when it may be experimentally distinguishable from the concerted process, where proton transfer, formation of the multiple bond and loss of halide ion occur simultaneously. It will not be distinguishable by deuterium-exchange studies or by studies of general base catalysis,[15] when $k_2 >> k_{-1}$. It will only be distinguishable when the sensitivities of the methods available for analysis of such results are consistent with the ratio k_{-1}/k_2. We see no reason to believe that it is more moderate[15] or conservative[9] to assume that all reactions in which substantial amounts of deuterium exchange are not observed or in which specific base catalysis is not found are concerted mechanisms, particularly in view of the body of evidence favoring a dual mechanism concept.

Acknowledgments.—The authors gratefully acknowledge support of this work by the Shell Development Company and by a contract between the University of Colorado and the Office of Naval Research. Experimental

Materials Used.—*endo-cis*-2,3-Dichloronorbornane, m.p. 76–77°, and *trans*-2,3-dichloronorbornane, b.p. 43.5–44.5° (2.5 mm.), n^{20}D 1.5027, were prepared substantially as described by Roberts, Johnson and Carboni.[7] Our *trans* isomer was impure, however, and the kinetic work was performed with material that eliminated less than the theoretical amount of chloride ion under appropriate conditions. How this was corrected is described below under rate measurements. After all of the work had been completed, we succeeded in crystallizing the *trans* isomer, m.p. 5.5°. 2-*exo*-*p*-Toluenesulfonyl-3-chloronorbornane, m.p. 115–117°, was prepared by addition of *p*-toluenesulfenyl chloride to norbornene, followed by oxidation to the sulfone.[16]

1-Pentanol.—Commercial *n*-amyl alcohol contained significant amounts of chloride (1–2 mmoles/l.) even after distillation. For this reason *n*-amyl alcohol was treated with 1–2% of sodium and heated at reflux for 15 hours. It was then fractionally distilled and the fraction, b.p. 131–131.5° (630 mm.), was used. It showed no detectable halogen after this treatment.

Sodium 1-Pentoxide Solution.—About 11.5 g. of sodium, which had been cleaned first under toluene and then in 1-pentanol was dissolved in 1 liter of pure 1-pentanol. The solution was stored in a brown rubber-stoppered bottle and remained colorless for several months. Its titer was checked regularly and dropped slowly (less than 1% per month).

Measurements of Reaction Rates.—The rates at above 100° were run in sealed Corning 7280 alkali-resistant glass tubes, substantially as described previously,[3] except that the solvent was 1-pentanol. The thermostated baths appeared to hold constant temperature to ±0.05°, and temperatures recorded were checked against a National Bureau of Standards calibrated thermometer. The extent of reaction was followed by Volhard titration for chloride ion. Titration was accompanied by rapid stirring with a magnetic stirrer. This stirring helped in seeing the end-point clearly in the two-phase system. Calculations of rate were made in the usual graphical fashion,[3] and good lines (constant second-order rate constants) were obtained with the *endo*-*cis*-dichloride. However, the rate constants appeared to fall off rapidly with time with the *trans*-dichloride, and when study of this compound will be described in a paper by S. J. Cristol and C. D. Brindell.

the reaction was run for nine half-lives under pseudo first-order conditions (large excess of base), only 70–75% of the theoretical amount of chloride was produced. This amount did not appear to depend upon the concentration of alkali, so no base-insensitive transformation to a material which does not liberate chloride ion rapidly was involved. We suspect that our *trans* material was contaminated with the *cis-endo* isomer which, of course, is about 1/85 as reactive as the *trans* isomer. To correct for this, we attempted plots of our data feeding into our calculations various factors depending upon the percentage of *trans*-dichloride in the starting material. The data on all of the runs gave excellent straight lines when the value 71% was used to correct the initial concentration of dichloride and, of course, the extent of reaction as well. The rate constants in Table I are thus corrected.

As the solutions were made up at 20° and the reactions were run at 101 and 116°, the rate constants were further corrected for solvent expansion. The observed rate constants were multiplied by 1.09 and 1.11 at 101 and 116°, respectively.[17]

The rates at 12° were carried out in a thermostated water-bath in a room also held at 12°. Appropriate solutions of the chlorosulfone and base in 1-pentanol were equilibrated in the bath, were rapidly mixed in a volumetric flask, which was then filled to the mark with temperature-equilibrated 1-pentanol. The flask was shaken to mix the solution thoroughly and was then immersed in the bath. Samples were withdrawn every few minutes with a pipet having a tip which had been blown out to give rapid delivery, and these were run into an erlenmeyer flask containing 10 ml. of 2 *N* nitric acid. The runs at 0° were conducted in a water-ice bath in a room held at 5°. The pipets used for withdrawing samples were insulated by wrapping them with asbestos string and were stored in a long test-tube at 0°. In other respects the procedure followed was similar to that at the higher temperature.

Mechanisms of Elimination Reactions. XIX. Elimination and Solvolytic Reactivities in Some Bicyclo[2,2,1]heptane and Bicyclo[2,2,2]octane Derivatives[1,2]

BY STANLEY J. CRISTOL AND ROBERT P. ARGANBRIGHT

RECEIVED JANUARY 18, 1957

A striking lack of stereospecificity in elimination reactions involving bonds held in the rigid eclipsed positions available in boat-form cyclohexane molecules has been noted in the reaction of sodium hydroxide with the *cis* and *trans* isomers of 11-*p*-toluenesulfonyl-12-chloro-9,10-dihydro-9,10-ethanoanthracene. Both compounds reacted rapidly with alkali at 0 and 12°, the *cis* compound (*trans* elimination) reacting about three times as fast as the *trans* isomer. These results compared with those reported earlier for 11,12-dichloro-9,10-dihydro-9,10-ethanoanthracene are well accommodated by the assumption that a carbanion is formed in the first step of the elimination reaction. Solvolysis rate constants for several β-chlorothioethers in bicycloheptane and bicyclooctane ring systems were determined in 85% ethanol at 116°. The extremely low reactivities and the minor difference in reactivity between *cis* and *trans* isomers demonstrate the lack of significant neighboring-group acceleration of solvolysis with groups held at rigid eclipsed bond angles.

Previous work[3] has shown that the normal preference for *trans* elimination disappears when groups are held rigidly in fixed positions such that *trans* coplanarity cannot be attained readily in the transition state for elimination. Evidence has been adduced to suggest that in these circumstances an alternative mechanism involving a carbanion is operative. It is the purpose of the present paper to supply further data in support of this postulate.

We have studied the rates of elimination of hydrogen chloride with sodium hydroxide from *cis*- (I) and *trans*-11-*p*-toluenesulfonyl-12-chloro-9,10-dihydro-9,10-ethanoanthracenes (II) to compare the rate constants and quantities of activation with those of the corresponding 11,12-dichlorides previously studied.[4] The rates were measured in a solvent consisting of 50% by volume of ordinary ethanol and 50% of dioxane. The rate data are given in Table I.

It will be noted that these compounds show extremely high reactivity toward elimination; the reactions proceed at quite rapid rates at 0 and 12°. These results may be contrasted with the results on the corresponding dichlorides,[4] which react at comparable rates at temperatures about 150° higher. If the data obtained on the dichlorides are extrapolated to 12°, the comparison of these values with the values given in Table I for the chlorosulfones indicate that substitution of a chlorine atom by a *p*-toluenesulfonyl group increases the rate of elimination by about 10 powers of 10. In addition, it should be noted that these compounds show little stereospecificity in the elimination reaction, *trans* elimination being favored over *cis* by a factor of only 3. It is of interest to note that in the two dichloride systems previously studied, that is, the dichlorodihydroethanoanthracenes[4] and the 2,3-dichloronorbornanes,[1] *cis* elimination was favored slightly over *trans*. In the present system, however, *trans* elimination is slightly favored over *cis*.

The striking lack of stereospecificity in this system, as well as in the systems previously studied, seems to us to be best explained on the basis that carbanion intermediates are involved and that a multiple-stage mechanism for elimination is utilized in these systems where bonds are rigidly held in eclipsed positions and a *trans* coplanar transition state is geometrically improbable. The tremendous increase in reactivity observed when an arenesulfonyl group replaces a chlorine atom in these systems may also be rationalized by the assumption that a carbanion mechanism is involved. We feel that the results given here lend additional support to the arguments given earlier.[1]

It should be noted that a comparison

of the rate data obtained on the dichlorides[1,4] with those data reported for *cis*- and *trans*-1,2-dichlorocyclohexane[5] is also consistent with the assumption that a carbanion intermediate is involved in systems which do not have favorable geometry for the concerted process.

Barton and Cookson[6] have recently discussed the effect of conformation upon neighboring-group participation in solvolytic reactions[7] and have pointed out the necessity for axial–axial relationships in providing neighboring-group assistance in chair-form cyclohexane derivatives. We were interested in a study of solvolysis rates for β-chlorosulfides which have the fixed eclipsed structures of boat-form cyclohexane molecules such as are present in bicycloheptanes and bicycloöctanes. Accordingly, solvolysis rates were studied in 85% ethanol with certain β-chlorothioethers, including *exo*-2-thiocresoxy-*endo*-3-chlorononbornane (III), *exo*-2-thiocresoxy-*endo*-3-chloro-5-norbornene (IV), and *cis*- (V) and *trans*-11-*p*-thiocresoxy-12-chloro-9,10-dihydro-9,10-ethanoanthracene (VI). The rate constants for the compounds studied are given in Table II.

It should be noted that all of the β-chlorosulfides reacted very slowly, even at 116°, the reactivities being roughly equivalent to those of bornyl chloride[8] (*endo* chlorine) or *endo*-norbornyl chloride.[9] No large difference was noted between the *cis* and *trans* isomers studied; the *trans* isomer reacted only four times as fast as the *cis* isomer. The relative inertness of our compounds may also be compared with the reactivity reported for *trans*-2-chlorocyclohexyl phenyl thioether.[10] This compound solvolyzes completely in 30 minutes at 100° in 80% ethanol.

The normal mode of solvolysis of a β-chlorothioether may be presumed[11] to be

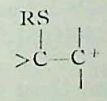
with rate enhancement of about 10^7 over the corresponding simple alkyl halide due to neighboring-group participation of the β sulfur atom.[11] No such rate enhancement is noted in our compounds, and it therefore appears that the formation of the sulfonium intermediate cannot be a part of the rate-determining step, but rather that a simple carbonium ion of type



is being formed. The most reasonable explanation for these results appears to us to be a definite stereochemical requirement for *trans*-coplanarity in neighboring-group assistance of solvolysis and that this requirement cannot be met in the rigid geometry of these bicycloheptanes and bicycloöctanes.

It may be further noted that the norbornene chlorothioether was somewhat less reactive than the norbornane analog. This is consistent with observations made on the corresponding *endo* chlo-

rides[9] and *endo*-*p*-bromobenzenesulfonates.[12] Rate data further indicate that there is little driving force toward solvolysis by participation of the π electrons of the benzene ring in solvolysis of the ethanodihydroanthracenes. Some participation might have been anticipated by analogy with the participation observed in *exo*-dehydronorbornyl systems, although the analogous bicyclo[2.2.2]octenyl systems have not been studied and may indeed show no such participation.[13]

Experimental

Preparation of Compounds.—The preparation of the materials used in these studies will be reported elsewhere. In general the chlorosulfides were prepared by addition of *p*-toluenesulfenyl chloride to the corresponding olefin or of thiocresol to the chloroölefin. The sulfones were prepared by oxidation of the chlorothioether with hydrogen peroxide.

Rate constants for elimination were measured as follows. A weighed amount of the β-chlorosulfone, from 0.1 to 0.8 mmole, was placed in a 100-ml. volumetric flask and 50 ml. of dioxane, measured at the temperature of the run, was added. About 40 ml. of 92.6% (by wt.) ethanol was then added, and the flask was placed in a 12.1° rate bath thermostatically controlled to a ±0.05°. After solution was complete and the contents had come to the temperature of the bath, a measured amount of ethanolic sodium hydroxide (normality calculated at 12.1°) was added followed by enough 92.6% ethanol (kept at 12.1°) to bring the volume up to the mark on the flask. The flask was removed from the bath and was shaken vigorously for several seconds. It was immediately replaced in the bath and, because the rates were fast, the first sample usually was taken almost immediately thereafter.

Since room temperature, in the case of the 12.1° runs, was about 20°, an asbestos-wrapped 10-ml. pipet was used for sampling. The samples were pipetted directly into 5 ml. of 3 *N* nitric acid contained in a 100-ml. erlenmeyer flask, the time being recorded the instant the sample started to flow from the pipet. The same pipet was used for all samples. The tip of the pipet was blown out to allow rapid drainage. The samples were analyzed for chloride ion by the Volhard procedure. Calculations of rate constants were made as described previously.[1,4]

The rate studies at 0° were run similarly except that an ice-water bath was employed in a room held at 2°.

Rate constants for solvolysis were measured as follows: A sample of the β-chlorothioether (about 0.2 mmole) was weighed into a 50-ml. volumetric flask and 50 ml. of 85% (by wt.) ethanol[14] was added at room temperature. After solution of the thioether had occurred, nine 5.5-ml. samples were removed and placed in 15 × 125 mm. Pyrex test-tubes which were then sealed. All tubes in any particular run were then placed in an oil-bath thermostatically maintained at 116.5 ± 0.05°. Tubes were removed at measured time intervals and were placed in a cold chest until the run was finished. The tubes were then opened and warmed to 20° and exactly 5 ml. was pipetted out of each into flasks for titration. Each sample was diluted with 25 ml. of ordinary ethanol, 2 drops of a mixed indicator (0.075% brom cresol green and 0.05% methyl red in ethanol) was added and the sample was titrated with aqueous 0.01 *N* sodium hydroxide. The first-order rate constants fell off with time, presumably due to reaction of ethanol with the hydrochloric acid produced in the solvolysis. The first-order plots were straight lines for the initial period of the reaction, however, and the straight-line portions were used to calculate the rate constants. It has been estimated that these results are accurate to ±30%.

The Relative Stabilities of *cis* and *trans* Isomers. III. The Cyclodecenes

BY NORMAN L. ALLINGER[1,2]

RECEIVED FEBRUARY 18, 1957

The equilibrium constant for the reaction *trans*-cyclodecene ⇄ *cis*-cyclodecene has been determined to be >200 (25°). The dipole moments and other physical properties of the isomers were measured, and the relationships between these various quantities are discussed.

Introduction

It has long been a goal of organic chemists to be able to predict which of the various possible stereoisomeric structures exists in a given compound, either by a consideration of the reactions used to prepare the compound, or by an examination of its physical properties. Thus far no really general methods for accomplishing these purposes have been found. There have been evolved instead numerous rules for determining which of the various stereochemically possible products will result from a given reaction[3] and other rules which may be used to determine structure from physical properties.[4] Among the rules of the latter type, that of von Auwers was the earliest[4a] and it saw considerable service. It became clear at an early date however that exceptions to von Auwers rule existed,[5] nevertheless a great many structures were assigned using this rule some of which subsequently have been shown to be incorrect. When these incorrect assignments were uncovered several workers restated the rule in modified forms in an attempt to obtain a really useful

rule to which, within a precisely defined region of applicability, there would be no exceptions.[4b-f]

In the first paper in this series[4f] the physical properties of the *cis* and *trans* isomers of a great many compounds, including polysubstituted cyclohexanes and cyclopentanes, fused ring systems and olefins were examined, and these properties all seemed to be in agreement with the idea that the isomer of higher density, index of refraction, and boiling point was the less stable.[6] It was not clear at that time whether or not olefins were properly included with the other structures mentioned, since although a double bond is formally a two-membered ring, it is electronically quite different from the larger rings.[7] However, the experimental data available for monoölefinic hydrocarbons appeared without exception to fit the rule. On the other hand, at least one class of compounds, the α,β-unsaturated acids, were known not to be in agreement with the rule. For convenience in discussion, this rule will henceforth be referred to as the *conformational rule*. The existing forces of which this rule is a manifestation are not completely understood. Although the word steric has been used in this connection, it is clear that we are not here dealing with overlapping van der Waals radii, but rather with forces resulting from charge distribution between non-bonded atoms.[8] Whatever the nature of the forces involved, the existence of a conformational rule seems certain; it remains to state the rule correctly and define the region of its applicability.

It was suggested by van Arkel[9] that the boiling points of the *cis* and *trans* isomers of isomeric olefins were in fact determined by their dipole moments, both properties being greater for the same isomer.[10] For an olefin of the type ABC=CBA, where A and B are any substituents, the *cis* isomer would have the greater dipole moment, and consequently the higher boiling point. On the other hand, for an olefin of the type AHC=CHB, where A is any electron-attracting group and B is any electron-repelling group, the *trans* isomer has the greater dipole moment and, according to van Arkel's *dipole rule*, the higher boiling point. The dipole rule then predicts that with monoölefinic hydrocarbons the *cis* isomer will boil higher, but the reverse would be true with, for example, the α,β-unsaturated acid derivatives. These acid derivatives with their large dipole moments clearly obey the dipole rule, and they are in contrast to the predictions of the conformational rule. With the monoölefinic hydrocarbons the dipoles involved are quite small. With these compounds the same order of physical constants is predicted by both of the rules, and it is not certain which effect is in fact controlling the situation.

It seemed desirable at this point to disentangle the two rules by obtaining an isomeric pair of olefinic hydrocarbons in which the dipole rule and the conformational rule gave opposite predictions, so that the relative importance of these rules might be tested in a simple case. The *cis* and *trans* isomers of cyclodecene appeared to offer a suitable test case. Equilibrium studies appeared to indicate that the *cis* isomer had the lower free energy, and it also had the greater values of its physical constants, which facts suggested that perhaps in this case the dipole rule was the more important. However, there appeared to be some uncertainty as to just where the equilibrium point was for the reaction *trans*-cyclodecene $\rightleftarrows$ *cis*-cyclodecene. One of the earliest reported attempts at measurement of this equilibrium constant[11] indicated that $K < 1$ (at 175°), and this value was subsequently changed[12] to $\geqq 5.25$ (95°). Other workers have measured the value of this constant at various elevated temperatures,[13] and have indicated that it is "much greater" than 1. The temperatures at which the physical constants were measured were quite different from those at which the equilibrium constant was measured, the former being near room temperature. Inspection of models shows that the *cis* isomer has the greater entropy. Consequently, if the physical constants were related to the free energies, rather than the heat contents, none of the data mentioned above eliminates the possibility that the *cis* isomer has the more negative free energy at elevated temperatures, but that the free energies are reversed at room temperature because of the contribution of the entropy. There appears to be no reason to expect the physical constants to follow the free energies, either here or elsewhere, and in fact the data available in the literature are consistent only with the physical constants being related to the heat contents.[14] However, proof of the relationship appeared to be desirable in this case.

The dipole moments of the cyclodecenes could be calculated from bond moments. However, since the *trans* compound is obviously under some strain, the possibility that the normal planar sp^2 hybridization of the unsaturated carbons received a contribution from the tetrahedral sp^3 structure could not be dismissed. The latter type of hybridization, if it contributed to the actual structure of the molecule to any appreciable extent, would be expected to yield a very large dipole moment. Consequently the relative magnitudes of the dipole moments could not be unambiguously specified.

Results and Discussion

Pure samples of *cis*- and *trans*-cyclodecene were prepared by conventional methods, and their pu-

(6) Stable in this case refers to heat content rather than to free energy, but the distinction need be made only in certain rare cases.

(7) There is some evidence (M. T. Rogers and J. D. Roberts, This Journal, **68**, 843 (1946); R. H. Eastman, *ibid.*, **76**, 4115 (1954)) that a three-membered ring is somewhere between a saturated and an unsaturated compound electronically, and what is concluded here for olefins may prove of importance also with cyclopropane derivatives.

(10) It was also pointed out by van Arkel that from Kopp's rule the isomer with the higher boiling point would also have the greater density. By definition the same isomer has the smaller molecular volume. It will also in general have the greater refractive index but the smaller molar refractivity.

rity was established by a comparison of their physical properties, including infrared spectra, with the published values. The indications in the literature were that it might be rather difficult to establish equilibrium at room temperature within a reasonable length of time, consequently it was decided to measure the refractive index of the compounds at elevated temperatures. It was found that plots of the refractive indices of the two isomers as functions of temperature from 11–60° were exactly parallel, the values being larger for the *cis* isomer, which indicated that while these quantities might be related to the heat contents they did not appear to be related to the free energies.

A quantitative value of the equilibrium constant was desired at as low a temperature as possible. The published method of isomerization (*p*-toluenesulfonic acid) proved to be too slow to be practical at room temperature; thus pure samples of each of the two isomers were each isomerized to a mixture containing not more than 1% of the other isomer after 24 hours. Since the difficulty seemed to be the mutual insolubility of the acid and the olefin, sulfuric acid was substituted for the solid sulfonic acid. In this case the isomerization proceeded smoothly and cleanly, equilibrium appeared to be reached in less than 120 hours at 25°. The equilibrated mixtures obtained from both isomers under the same conditions were analyzed by the infrared method, and it was found that the mixtures were indistinguishable from the pure *cis* isomer. As little as 1% of the *trans* isomer readily could be measured, and 0.5% could be detected under the conditions used. The amount of *trans* isomer present in the equilibrium mixture was thus less than 0.5%. When the equilibration was carried out in this manner, there was no trace of side reactions such as decalin formation which hampered the earlier investigations. From the equilibration described it can be calculated that for the reaction (at 25°) *trans*-cyclodecene → *cis*-cyclodecene, $-\Delta F \geqq 3.1$ kcal. Consequently, according to the conformational rule the *trans* isomer should have the greater values for its physical properties.[15]

Lastly, the dipole moments of the *cis*- and *trans*-cyclodecenes were determined in heptane solution. The atomic polarizations were neglected in the calculations. If it is assumed that no error is introduced thereby, the dipole moment of the *trans* isomer is indistinguishable from zero, the experimental value being $0.15\ ^{+0.06}_{-0.17} \times 10^{-18}$ e.s.u. The *cis* isomer, on the other hand, with the same qualification as above, was found to have a dipole moment of $0.44 \pm 0.03 \times 10^{-18}$ e.s.u. These values support the assumption that the atomic polarizations may be neglected since these dipoles are "normal," and they also indicate the absence of any detectable amount of unusual hybridization.

(15) Actually ΔH rather than ΔF should be used in this comparison (see ref. 14). Since the free energy change is so large, for ΔH to be opposite in sign from ΔF the entropy of the *cis* isomer would have to be greater than that of the *trans* by more than 11 e.u. This value is improbably large, and the use of ΔF in place of ΔH in this case seems justified. Subsequent to this work it was learned that the heats of hydrogenation of these compounds had been determined in the laboratories of Dr. R. B. Turner, and it was found that the *cis* isomer had the more negative heat content. The author wishes to thank Dr. Turner for making this data available in advance of publication.

Thus the *dipole rule* predicts that the *cis* isomer will have the greater values of its physical constants.

It is clear in the present case that the dipole moments rather than the heat contents are reflected by the physical constants even though the difference in the former is nearly the smallest non-zero value that is to be found in stereoisomeric organic compounds, and the difference in the latter is as large as the difference found between most pairs of stereoisomers. Thus it appears that the conformational rule is applicable to isomers which do not differ in dipole moment, while for isomers which do so differ, the dipole rule is to be applied.

All unstrained saturated hydrocarbons necessarily have zero dipole moments,[16] and among these hydrocarbons the conformational rule should invariably apply. There are, to the author's knowledge, no exceptions among these compounds. The conformational rule should also apply to monofunctional compounds (*e.g.*, the 2-methylcyclohexanols) since the two isomers do not differ in dipole moment. With difunctional compounds the situation is less simple. The *cis*- and *trans*-1,2- and 1,3-disubstituted cyclohexanes (ee and ea conformations) have, to a first approximation, the same angles between substituents and should not differ in dipole moment, hence the conformational rule should apply. If the substituents are 1,4- and if either both are electron withdrawing or both are electron repelling, the *cis* isomer will have a greater dipole moment. The conformational rule then leads to the correct prediction here, but probably fortuitously. A 1,4-disubstituted cyclohexane with one electron-withdrawing group and one electron-attracting group will be another test case as the dipole and conformational rules lead to opposite predictions, and in this case the dipoles are physically separated. There appear to be no dipole moments reported for such a pair of isomers, and it is planned to make such measurements in the future.

It now appears desirable to state the conformational rule in a more precise way than was previously possible: *For stereoisomers in cyclic systems which do not differ in dipole moment, the isomer which has the smaller molecular volume is the isomer which has the higher heat content.*[17]

Acknowledgment.—The author wishes to thank Professor Paul D. Bartlett for making it possible for him to spend the year in his laboratory at Harvard University.

trans-**Cyclodecene.**—Sebacoin was prepared from di-

(16) See the discussion by L. E. Sutton in E. A. Braude and F. C. Nachod, "Determination of Organic Structures by Physical Methods," Academic Press, Inc., New York, N. Y., 1955, p. 386.

(17) Several modifications have been incorporated in this statement of the rule relative to earlier versions,[4] and they require comment. First, the requirement of the same dipole moment seems clearly indicated by the present work. Second, the expression "smaller molecular volume" conveniently summarizes the nature of the densities, refractive indices, boiling points, molecular refractivities, and other less common properties (see ref. 4f for references to the experimental data). Lastly, the heat content is actually the quantity reflected in the physical properties. When the expression "relative stability" is used, there is some ambiguity as to whether heat content or free energy is indicated. It should be realized that for stereoisomers, differences in the latter are usually, but not necessarily, good approximations for differences in the former.

methyl sebacate[18] and was reduced with zinc and hydrochloric acid to cyclodecanone.[19] The ketone had n^{25}D 1.4802, reported[13b] n^{20}D 1.4800. The oxime of the ketone was prepared in 95% yield, m.p. 78.5–79.5°, reported[20] m.p. 80°. Reduction of the oxime with sodium and ethanol[20] gave cyclodecylamine in 63% yield, b.p. 101–103° (17 mm.), reported[13b] b.p. 84–86° (4 mm.). Cyclodecyl dimethylamine was obtained by methylation in 86% yield and was in turn converted to the trimethylammonium iodide (94%).[13b] The iodide was then converted to the hydroxide, which was decomposed at 100–130° (20 mm.).[11] The crude distillate was purified and redistilled at a bath temperature of 100–130° (20 mm.) to yield pure *trans*-cyclodecene, n^{25}D 1.4795, yield 71%. The reported constants are[11] n^{20}D 1.4822, b.p. 68–70° (10 mm.). The infrared spectrum of the compound proved to be identical with those reported.[11,13a]

***cis*-Cyclodecene.**—Sebacoin was oxidized to 1,2-cyclodecanedione with bismuth oxide[21] in 89% yield, m.p. 39.7–41.4°, reported[11] m.p. 40–41°. The diketone was converted to the acetylene by mercuric oxide oxidation of the dihydrazone.[11] The yield of pure cyclodecyne was 16%. The infrared spectrum of the compound was identical with that reported. Hydrogenation of the acetylene to the pure *cis*-olefin proceeded cleanly, the hydrogen uptake being quantitative. The catalyst used for the hydrogenation was described earlier.[22] The yield of *cis*-cyclodecene was 75%, distilled at a bath temperature of 100–130° (20 mm.), n^{25}D 1.4835. The reported[11] constants are n^{20}D 1.4854 and b.p. 194–195° (740 mm.). The infrared spectrum was identical with those published.[11,13a]

TABLE I

REFRACTIVE INDICES OF THE CYCLODECENES (n_D)

t, °C.	*cis*	*trans*	t, °C.	*cis*	*trans*
11.0	1.4892	1.4852	40.0	1.4769	1.4730
20.0	1.4856	1.4818	50.0	1.4728	1.4688
25.0	1.4835	1.4795	60.0	1.4686	1.4646
30.0	1.4811	1.4773			

The refractometer was calibrated before use. The values of the refractive indices found are in good agreement with those reported by Blomquist, Burge and Suesy[11] (*cis* n^{20}D 1.4854, *trans* n^{20}D 1.4822), and that reported by Cope, McLean and Nelson[13b] (*trans* n^{25}D 1.4795), but these values differ significantly from the values reported by Prelog, Schenker and Günthard.[13a] Since this same deviation exists between the relative indices obtained by the latter group and the values obtained by others for other compounds and since it is consistent in both magnitude and direction, an instrumental error seems indicated.

Equilibration of the Cyclodecenes.—Three hundred milligrams of *trans*-cyclodecene and 20 mg. of concentrated sulfuric acid were allowed to stand at 25.0° for 120 hours with occasional shaking. The hydrocarbon layer was taken up in pure pentane, and the pentane layer was washed well with water. After removal of the solvent, the olefin was distilled at 20 mm. with a bath temperature of 100°. The same equilibration was then carried out starting with the *cis* isomer. The equilibrium mixtures were analyzed by the base line density infrared method,[12] using the pure *cis* and *trans* isomers as standards. It was found that the same mixture was obtained starting with either isomer, and it contained 97 ± 3% *cis* and not more than 0.5% *trans*. The equilibration experiments and analyses were then repeated as a check, and the results were identical.

Dipole Moments of the *cis*- and *trans*-Cyclodecenes.—The apparatus used for the dielectric constant measurements employed the heterodyne beat principle with a fixed frequency crystal oscillator at 100 kc. It has been described previously.[23] The dielectric constant cell held 60 ml. of solution and was thermostated in an oil-bath at 25.00 ± 0.02°. The general experimental procedure followed was that outlined by Smyth.[24] All weights were corrected to vacuum.

The molar polarization of the solute at infinite dilution was obtained following the method of Halverstadt and Kumler,[25] the pertinent relationship being

$$P_{2\infty} = [(\epsilon_1 - 1)/(\epsilon_1 + 2)][(1/d_1)][(M_2 - M_1\beta/d_1)] + [3M_1\alpha/(\epsilon_1 + 2)^2 d_1]$$

where $\epsilon_{12} = \epsilon_1 + \alpha N_2$, $d_{12} = d_1 + \beta N_2$, ϵ_1 = dielectric constant of the solvent; d_1, N_1 and M_1 are, respectively, its density, mole fraction in solution and molecular weight while the quantities with subscripts 2 and 12 have the same significance for the solute and solution, respectively. The data are summarized in Table II.

TABLE II

DIELECTRIC CONSTANTS OF CYCLODECENE SOLUTIONS IN *n*-HEPTANE

cis			*trans*		
N_2	d	ϵ	N_2	d	ϵ
0.020228	0.68406	1.0986	0.020273	0.68394	1.9100
.020228	.68406	1.9081	.011876	.68224	1.9065
.011116	.68207	1.9041	.005392	.68080	1.9054
.005820	.68092	1.9021	.000000	.67963	1.9025
.003482	.68041	1.9007			
.000000	.67963	1.8991			
α = 0.4596, β = 0.21844, $P_{2\infty}$ = 49.35 cc., ϵ_1 = 1.8992, d_1 = 0.67964			α = 0.328, β = 0.21330, $P_{2\infty}$ = 45.89 cc., ϵ_1 = 1.9028, d_1 = 0.67965		

The values of α and β were obtained in each case by the method of least squares. The calculation of the dipole moments from the molar polarizabilities made use of the Debye equation

$$\mu = 0.012181 \times 10^{-18}[(P_{2\infty} - R_D)T]^{1/2}$$

The molar refractivities were calculated from the refractive indices obtained in the present work (at 20°) and the densities reported by Blomquist and co-workers.[11] The values of R thus calculated are: *cis* 45.22, *trans* 45.43, which are in reasonable agreement with the theoretical value of 45.71.[26] The experimental rather than theoretical values for the molar refractivity were employed in the calculations, although use of the latter instead does not significantly affect the results.

The *trans* isomer was found to have a dipole moment of 0.15×10^{-18} e.s.u. The error in this value results almost entirely from the error in α, and it is estimated to be such that $\mu_{trans} = 0.15^{+0.06}_{-0.17} \times 10^{-18}$ e.s.u. The dipole moment of the *trans* isomer is hence indistinguishable from zero. For the *cis* isomer in a similar manner it is found that $\mu_{cis} = 0.44 \pm 0.03 \times 10^{-18}$ e.s.u.

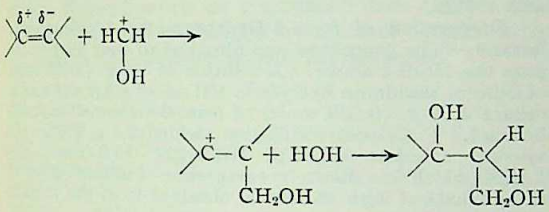
Stereochemistry of the Prins Reaction with Cyclohexene

BY EDWARD E. SMISSMAN AND ROBERT A. MODE

RECEIVED NOVEMBER 26, 1956

The reaction of formaldehyde with cyclohexene in acid media has been shown to give *trans*-2-hydroxymethyl-1-hydroxycyclohexane as the only 1,3-diol. No *cis*-diol was obtained.

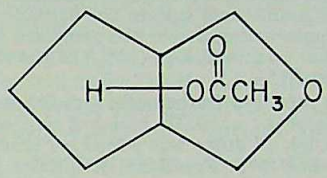
The mechanism of the Prins reaction has been reviewed and reported by Franzen and Krauch[1] to involve the initial protonation of formaldehyde followed by attachment of the hydroxymethyl carbonium ion to the double bond and finally solvolysis of the resulting carbonium ion. We have



investigated the stereochemistry of this reaction using cyclohexene and have found that only *trans*-diol is formed. Blomquist and Wolinsky[2] have studied this same reaction and have obtained the same results. We prepared the *cis*- and *trans*-2-hydroxymethyl-1-hydroxycyclohexane by reduction of 2-carbethoxycyclohexanone. Catalytic reduction gave predominantly *cis*-2-carbethoxycyclohexanol.[3] The *trans*-2-carboxycyclohexanol was obtained by epimerization of the *cis* compound in basic solution. The *cis*- and *trans*-2-carboxycyclohexanol esters were reduced to the corresponding 1,3-diols with lithium aluminum hydride. The *cis*-diol was shown to be a solid while the *trans*-diol and the product obtained from the Prins reaction were viscous liquids. Infrared spectra of *trans*-diol and the Prins reaction product were superimposable while the *cis*-diol spectra were found to differ markedly above the 8μ region.

The configuration has been shown to be *trans*. The exact mechanism of the reaction cannot be postulated until the conformational aspects have been studied. If the mechanism reported in the paper of Franzen and Krauch[1] was correct, a mixture of *cis*- and *trans*-diol should be obtained. If the initial attack of the hydroxymethylcarbonium ion is axial, then the resulting *trans*-diol must go to the flip conformation to produce the acetonide which we isolated. The conformational study would require a system incapable of undergoing a change in conformation once it is formed.

Other products are obtained during the Prins reaction, and these have been discussed by Olsen and Padberg[5] and more recently by Blomquist and Wolinsky.[2] One of the most important of these is hexahydrophthalanyl acetate, reported by Blomquist and Wolinsky to have the structure



This investigation was supported in part by a research Grant A-1190 from the National Institute of Arthritis and Metabolic Diseases, USPHS.

Experimental

Preparation of *trans*-2-Hydroxymethyl-1-hydroxycyclohexane by the Prins Reaction.[4]—Two hundred grams (2.22 moles) of trioxane, 1200 ml. of glacial acetic acid and 100 ml. of concentrated sulfuric acid were placed in a 2-l. three-necked flask. The mixture was heated (100–110°) until the trioxane depolymerized. The solution was allowed to cool to room temperature and 480 g. (5.84 moles) of freshly distilled cyclohexene was added dropwise over a period of 2 hr., the temperature being maintained between 45 and 65°. After completion of addition, the mixture was heated for 1.5 hr. at 65° and then stirred for 24 hr. at room temperature. One liter of water was then added to the mixture and the solution was extracted with three 750-ml. portions of ether. The ether was washed with water, saturated sodium bicarbonate solution until neutral and then with water. After concentration the crude product was fractionally distilled. The following higher boiling fractions containing the desired product were obtained: 1, b.p. 78–87° (0.80 mm.), 164 g.; 2, b.p. 88–93° (0.80 mm.), 179 g. Fraction 2 consisted, for the most part, of the diacetate of 2-hydroxymethyl-1-hydroxycyclohexane. Fraction 1 was found to contain only about 50% of the desired diacetate of the 1,3-glycol, the remainder consisting of the hexahydrophthalanyl acetate postulated by Olsen and Padberg.[5]

Fraction 2 (179 g.) was saponified with a solution of 94 g. of potassium hydroxide dissolved in 300 ml. of 6:1 aqueous alcohol. The solution was concentrated *in vacuo* and then extracted with ether. Fractional distillation gave a quantitative yield of a very viscous, water-clear, odorless glycol, b.p. 101–103° (0.96 mm.), n^{25}D 1.4840, bis-phenylurethan, m.p. 159–160°.

Saponification of fraction one (163.4 g.) yielded only 42 g. (49%) of the desired glycol. The remainder consisted of hexahydrophthalanol whose structure was postulated by Olsen and Padberg.[5]

The over-all yield of *trans*-2-hydroxymethyl-1-hydroxycyclohexane (configuration proved by infrared comparison with stereospecifically prepared *trans*-glycol) was found to be 150 g. (19.7%). Acid hydrolysis of the formaldehyde acetal of 2-hydroxymethyl-1-hydroxycyclohexane also yields the *trans*-glycol. This acetal is found in lower boiling fractions and is stable to base.

Preparation of 2-Carbethoxycyclohexanol.—Seventy-three and eight-tenths grams (0.433 mole) of 2-carbethoxycyclohexanone,[6] 70 ml. of absolute ethanol and 1.5 g. of Adams catalyst were placed in a hydrogenation apparatus.[7] The mixture was hydrogenated for 48 hr. at room temperature and five atmospheres pressure. The theoretical amount of

hydrogen was consumed and on fractional distillation, 65 g. (87%), of *cis*-2-carbethoxycyclohexanol, b.p. 125–217° (27 mm.), $n^{25}D$ 1.4585 (lit.[3] 117–118° (17 mm.)).

Anal. Calcd. for $C_9H_{16}O_3$: C, 62.76; H, 9.36. Found: C, 62.94; H, 9.47.

Preparation of *cis*-2-Carboxycyclohexanol.—A mixture of 14.5 g. (0.08 mole) of 2-carbethoxycyclohexanol (95% *cis*) and 45 ml. of 25% aq. sodium hydroxide was stirred for 12 hr. The sodium salt of *cis*-2-carboxycyclohexanol acid separated and was filtered. It was dissolved in a small amount of water and the solution made acid to congo red with 10% hydrochloric acid. The aqueous solution was saturated with ammonium sulfate and extracted with ether. The ether-soluble material was recrystallized from a small amount of ether to give 5.4 g. (44%) of the *cis*-acid, m.p. 79–80° (lit.[3] 80–81°).

Preparation of *cis*-2-Carbomethoxycyclohexanol.—To a cooled solution of 5.1 g. (0.035 mole) of *cis*-2-carboxycyclohexanol in 25 ml. of ether was added an ether solution of diazomethane at 0–5°. Fractional distillation gave a quantitative yield of the desired ester, b.p. 87.5–88.5° (3 mm.), $n^{25}D$ 1.4647 (lit.[3] b.p. 105° (14 mm.), $n^{25}D$ 1.4645).

Preparation of *cis*-2-Hydroxymethyl-1-hydroxycyclohexane.—To a solution of 1.44 g. (0.038 mole) of lithium aluminum hydride in 100 ml. of anhydrous ether, we added 5.4 g. (0.034 mole) of *cis*-2-carbomethoxycyclohexanol in an equal volume of ether at such a rate as to maintain slow refluxing. After addition was complete, the mixture was refluxed and stirred for an additional 1.5 hr. The excess lithium aluminum hydride was decomposed with moist ether followed by water and the metal alkoxides with cold dilute sulfuric acid. The aqueous solution was saturated with ammonium sulfate and extracted with ether. Distillation of the resulting glycol yielded a very viscous, colorless oil, b.p. 124° (2 mm.). On standing several hr. the glycol crystallized, m.p. 48–49° (lit.[8] 49–50°).

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.58; H, 10.84. Found: C, 64.65; H, 10.48.

The di-*p*-nitrobenzoate of *cis*-2-hydroxymethyl-1-hydroxycyclohexane was prepared by the usual procedure for these derivatives, m.p. 133.5–134 (lit.[9] 134°). The mono-*p*-nitrobenzoate, previously unreported, also was isolated, m.p. 95–96°.

Anal. Calcd. for $C_{14}H_{17}O_5N$: C, 60.28; H, 6.14; N, 5.02. Found: C, 59.60; H, 6.03; N, 5.00.

Preparation of *trans*-2-Carboxycyclohexanol.—The mother liquors from the preparation of *cis*-2-carboxycyclohexanol were concentrated *in vacuo* and refluxed with 7.5 *N* potassium hydroxide. The mixture was cooled, acidified to congo red with sulfuric acid and saturated with ammonium sulfate. The aqueous solution was extracted several times with ether. The *trans*-acid was recrystallized from ethyl acetate, m.p. 109–111° (lit.[3] m.p. 111°).

In a similar epimerization 12.1 g. (0.072 mole) of sodium *cis*-cyclohexanol-2-carboxylate was transformed into the *trans*-acid by refluxing with base. The yield was 5.6 g. (54%) of pure *trans*-acid.

Preparation of *trans*-2-Carbomethoxycyclohexanol.—The procedure was identical to that used for the *cis*-ester. Fractional distillation yielded a quantitative amount of the *trans*-methyl ester, b.p. 99.8–101.8° (2 mm.), m.p. 34–35°, $n^{25}D$ 1.4632.

Preparation of *trans*-2-Hydroxymethyl-1-hydroxycyclohexane.—The procedure was identical to that used to prepare the *cis*-diol above. A solution of 1.3 g. (0.032 mole) of lithium aluminum hydride in 100 ml. of ether was used to reduce 4.54 g. (0.029 mole) of *trans*-2-carbomethoxycyclohexanol. Fractional distillation yielded 2.4 g. (63%) of a viscous, colorless oil, b.p. 103.5–104° (0.9 mm.), $n^{25}D$ 1.4829, which was shown by comparison of infrared spectrum to be identical with the glycol obtained from the Prins reaction.

The acetonide of *trans*-2-hydroxymethyl-1-hydroxycyclohexane was prepared, b.p. 106–107° (30 mm.), 214–216° (740 mm.), $n^{25}D$ 1.4602.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 70.60; H, 10.75.

The bis-phenylurethan of *trans*-2-hydroxymethyl-1-hydroxycyclohexanol melted at 159–160.5° (lit.[5] m.p. 160–161).

Epoxyethers. XI. O→O Acyl Migrations with α-Hydroxyacylals

BY CALVIN L. STEVENS AND BERNARD T. GILLIS[1,2]

RECEIVED NOVEMBER 28, 1956

1,2-Epoxy-1-methoxy-2-methylpropane (X) was isolated in good yield from the reaction of α-haloisobutyraldehydes with dry sodium methoxide. This epoxyether X reacted with organic acids to form relatively stable α-hydroxyacylals XI (pseudoesters) which readily underwent O → O acyl migration with the loss of alcohol to give esters of α-hydroxyisobutyraldehyde (XIII). At 150°, the 3,5-dinitrobenzoate pseudoester XI eliminated 3,5-dinitrobenzoic acid to form the dioxane derivative IX.

The reaction of an organic acid with an epoxyether has been shown previously to give an α-ketoester. In one example, the intermediate α-hydroxyacylal could be isolated and was shown to undergo irreversible O→O acyl migration to form the α-ketoester and alcohol.[3] Acylals derived from aldehyde epoxyethers were found to be relatively more stable than those from ketone epoxyethers, one being distilled under reduced pressure without decomposition.[4] Since the O→O acyl migration is accompanied by formation of a carbonyl group in α-hydroxyacylals, these compounds provide unique and simple examples for the study of such migrations. The present work demonstrates that the more stable acylals from aldehyde epoxyethers can also be made to undergo acyl migration.

The aldehyde epoxyether chosen for this study was that from isobutyraldehyde. The starting α-chloroaldehyde I was prepared in 60% yield by direct chlorination of isobutyraldehyde using a modification of the method of Brown and Ash.[4,5]

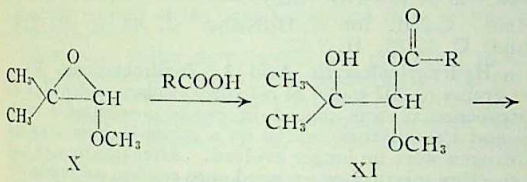
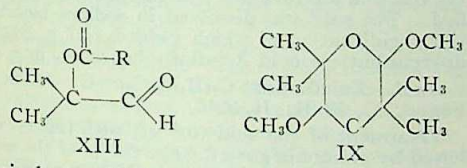
Direct bromination in the presence of calcium carbonate gave 35% of α-bromoisobutyraldehyde.[6,7] The α-haloisobutyraldehydes trimerized either in the presence of a trace of acid or during long standing. The monomeric haloaldehydes were regenerated from their trimers during distillation.

α-Chloroisobutyraldehyde and α-bromoisobutyraldehyde *gave the same* 2,4-dinitrophenylhydrazone when treated with the standard alcoholic 2,4-dinitrophenylhydrazine reagent. The α-chloroisobutyraldehyde derivative previously had been reported[8] to melt at 106°, that of α-bromoisobutyraldehyde at 116°.[9] In the present work, the derivative from both haloaldehydes, m.p. 116°, was found beyond doubt to be α-ethoxyisobutyraldehyde 2,4-dinitrophenylhydrazone. A negative Beilstein test, ultraviolet absorption spectra and carbon–hydrogen analyses supported this conclusion. Recent work of Ramirez[10] has shown that solvolysis of the α-halogen by alcohol occurs in the formation of 2,4-dinitrophenylhydrazones.



X XI



XIII IX

α-Chloroisobutyraldehyde (I) yielded 82% of α-hydroxyisobutyraldehyde dimethylacetal (II) when allowed to react with sodium methoxide in excess methanol for 1.5 hr. at 50°. The structure of II was proved by preparation of its solid 3,5-dinitrobenzoate derivative III, hydrolysis of the acetal to the aldehyde IV, followed by oxidation to the acid V. This acid was converted to an amide VI which was prepared independently from acetone cyanohydrin.

1,2-Epoxy-1-methoxy-2-methylpropane (X) was obtained in 37% yield from the reaction of α-chloroisobutyraldehyde and dry sodium methoxide in ether. The substitution of diethyl carbitol as solvent increased the yield to 53%, undoubtedly due to increased ease of isolation from the latter solvent.

The epoxyether X was identified by methanolysis to α-hydroxyisobutyraldehyde dimethylacetal in 57% yield. The infrared spectrum of the latter was superimposable on that of II obtained directly from α-chloroisobutyraldehyde. The 3,5-dinitrobenzoate derivatives of the two acetals showed no depression in melting point upon mixing.

When the epoxyether X was allowed to react with 3,5-dinitrobenzoic acid an α-hydroxyacylal XI was formed in 81% yield. The assignment of structure XI to the product of the reaction was based upon the fact that extraction of an ethereal solution with sodium carbonate solution permitted isolation of the acylal from the ether in 90% yield, proving that the acylal was not a complex of acid and epoxyether. An alternate structure, the methyl alcohol hemiacetal of α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate, was eliminated since XI could be oxidized with concentrated nitric acid to give a 98% yield of 3,5-dinitrobenzoic and a 48% yield of α-hydroxyisobutyric acids; authentic α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate gave 60% of α-hydroxyisobutyric acid 3,5-dinitrobenzoate under identical conditions. The fact that the Tollens test failed with XI and that methanol did not react with the aldehyde XIII to give XI provided further evidence against the hemiacetal structure. Spectral data showed the presence of hydroxyl and ester groups and together with the analytical data confirmed structure XI.

A 3,5-dinitrobenzoate acylal corresponding to XI but made from a ketone epoxyether has been shown to undergo O→O acyl migration smoothly at the melting point with the formation of an α-ketoester and alcohol.[3] This acyl migration also took place in an inert solvent at low temperatures.[3] Acylal XI behaved in a totally different manner. When heated above the melting point a change occurred and the resulting mixture partially solidified. The solid was not the aldehyde ester XIII but rather 3,5-dinitrobenzoic acid. When the pyrolysis was conducted under vacuum a second crystalline product could be isolated and shown to be the dioxane IX.

Parham[11] has shown recently that α-hydroxyacetals will undergo acetal interchange with the formation of dioxanes. Using this method IX was synthesized from α-hydroxyisobutyraldehyde dimethylacetal (II) and the crystalline isomer isolated shown to be identical in all respects with IX from the pyrolysis.

The O→O acyl migration of XI could be made to proceed smoothly at room temperature in ether solution with the aid of triethylamine catalyst. The structure of the resulting α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate (XIII) was proved by oxidation to the corresponding acid and by synthesis from the α-hydroxyacetal II.

The epoxyether X reacted readily with acetic acid at 0° to give the acylal XI in which R is methyl in 58% yield. This liquid acylal could be distilled under reduced pressure without decomposition. However, when the acylal was heated in the presence of triethylamine catalyst, O→O acetyl migration proceeded smoothly with the evolution of methanol and the formation of α-acetoxyisobutyraldehyde in 79% yield.

Experimental

α-Chloroisobutyraldehyde (I).—In a 500-ml. flask equipped with a dropping funnel, stirrer and reflux condenser protected with a drying tube was placed 72.1 g. (1.0 mole) of isobutyraldehyde. To the aldehyde 135.0 g. (1.0 mole) of freshly distilled sulfuryl chloride was added slowly with agitation to maintain a temperature of 25–40°. After the addition was complete, the reaction was heated for 2 hr.

and stirred for 4 hr., then flash distilled at 40 mm. pressure at a temperature of 80°. Final distillation through a 15-cm. Vigreux column gave 64 g. (60%) of α-chloroisobutyraldehyde,[8] b.p. 86–89°, $n^{25}D$ 1.4081, d^{25} 1.0199. The product contained 33.2% chlorine (calcd. 33.3%).

A 2,4-dinitrophenylhydrazone derivative of the α-chloroisobutyraldehyde was prepared by the method of Shriner and Fuson,[12] m.p. 116°, and corresponded to α-ethoxyisobutyraldehyde 2,4-dinitrophenylhydrazone, λ_{max} 357 mμ (95% alcohol).

Anal. Calcd. for $C_{12}H_{16}N_4O_5$: C, 48.64; H, 5.44. Found: C, 48.07; H, 5.49.

α-Chloroisobutyraldehyde (18 g., 0.168 mole) was added dropwise with stirring to an excess of concentrated nitric acid. After the evolution of nitrogen dioxide ceased, the remainder of the nitrogen dioxide was aerated from the mixture which then was extracted continuously with ether for 5 days. The ether was removed and the residue was refluxed with excess thionyl chloride for 3 hr. Distillation yielded 16 g. (68%) of α-chloroisobutyryl chloride,[13] b.p. 95–113°. Refractionation of the acid chloride gave a b.p. 111–112.5°, $n^{25}D$ 1.4313, d^{25} 1.1802.

The acid chloride could be converted in 77% yield to the known α-chloroisobutyramide,[14] m.p. 118–119°, and in 79% yield to the known α-chloroisobutyr-*p*-toluidide,[15] m.p. 68–69°.

The α-chloroisobutyraldehyde was trimerized by a trace of acid and the resultant solid trimer[16] melted at 106–107°. The monomeric α-chloroisobutyraldehyde could be regenerated from the trimer by heat and distillation.

α-Bromoisobutyraldehyde.—In a 1-l. flask equipped with condenser, drying tube, stirrer and dropping funnel was placed 150 g. (2.1 moles) of isobutyraldehyde, 200 ml. of carbon disulfide and 250 g. (2.5 moles) of calcium carbonate. Added slowly with agitation was 330 g. (2.06 moles) of bromine. Upon completion of the addition, the reaction mixture was stirred for 4 hr. and the excess bromine destroyed with sodium thiosulfate. The salts were removed by filtration and washed with carbon disulfide and the combined solution dried over anhydrous sodium sulfate. After filtration, the solution was distilled at atmospheric pressure through a 15-cm. Vigreux column to yield 106 g. (35%) of α-bromoisobutyraldehyde, b.p. 108–112°, $n^{25}D$ 1.4567. Redistillation gave b.p. 111–112°, d^{25} 1.4044, $n^{25}D$ 1.4500. The bromine content was 52.6% (calcd. 52.9).

The α-bromoisobutyraldehyde was trimerized in the same manner as the α-chloroisobutyraldehyde to yield a white solid,[17] m.p. 129–130°. The monomeric α-bromoisobutyraldehyde could be generated from the trimer by distillation.

A 2,4-dinitrophenylhydrazone derivative of the α-bromoisobutyraldehyde was prepared by the method of Shriner and Fuson[12] and melted at 116°. A mixture melting point determination with the derivative obtained from α-chloroisobutyraldehyde was undepressed.

α-Hydroxyisobutyraldehyde Dimethylacetal (II).—To 200 ml. of anhydrous methanol was added 6.5 g. (0.28 g. atom) of freshly cut sodium metal. After the sodium was completely dissolved, the sodium methoxide solution was cooled to 0° and 30 g. (0.282 mole) of α-chloroisobutyraldehyde was introduced over a period of 5 minutes. The reaction mixture was heated at 50° with stirring for 1.5 hr. The precipitated salt was removed by centrifugation and washed once with ether. The solutions were combined and distilled through a 30-cm. tubular column at atmospheric pressure to yield 31 g. (82%) of α-hydroxyisobutyraldehyde dimethylacetal, b.p. 148–149°, d^{25} 0.9694, $n^{25}D$ 1.4123.

Anal. Calcd. for $C_6H_{14}O_3$: C, 53.70; H, 10.51. Found: C, 53.42; H, 10.55.

α-Hydroxyisobutyraldehyde Dimethylacetal 3,5-Dinitrobenzoate (III).—To 8.36 g. (0.036 mole) of 3,5-dinitrobenzoyl chloride in excess anhydrous pyridine was added 4.88 g. (0.036 mole) of α-hydroxyisobutyraldehyde dimethylacetal. The reactants were heated and then poured onto cracked ice. A solid resulted which was filtered, dissolved in ether, extracted with sodium bicarbonate and saturated sodium chloride solution and then poured through anhydrous sodium sulfate. The ether was removed and 7.2 g. (61%) of α-hydroxyisobutyraldehyde dimethylacetal 3,5-dinitrobenzoate, m.p. 70–71°, was obtained. Recrystallization from a methanol–water mixture raised the melting point to 71–72°.

Anal. Calcd. for $C_{13}H_{16}N_2O_8$: C, 47.56; H, 4.91. Found: C, 47.81; H, 5.20.

α-Hydroxyisobutyraldehyde 3,5-Dinitrobenzoate (IV).—The acetal III (0.86 g., 0.0026 mole) and 14 ml. of concentrated hydrochloric acid were mixed and warmed. To this mixture was added 5 ml. of water and the reaction was heated 30 minutes on a steam-bath. The reaction mixture was then poured onto cracked ice from which 0.39 g. (53%) of α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate, m.p. 140–142°, was isolated. An analytical sample melted at 143–144°.

Anal. Calcd. for $C_{11}H_{10}N_2O_7$: C, 46.81; H, 3.57. Found: C, 46.57; H, 3.58.

A 2,4-dinitrophenylhydrazone derivative of the aldehyde was prepared according to the directions of Shriner and Fuson,[12] m.p. 174–175° (dec).

Anal. Calcd. for $C_{17}H_{14}N_6O_{10}$: C, 44.16; H, 3.06. Found: C, 43.72; H, 3.42.

α-Hydroxyisobutyric Acid 3,5-Dinitrobenzoate (V).—Two grams (0.007 mole) of α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate was placed in excess concentrated nitric acid and the mixture heated on a steam-bath until oxides of nitrogen were no longer evolved. After this time (3 hr.) the reaction mixture was poured onto cracked ice and solidified. The solid was dissolved in sodium bicarbonate solution, acidification of which yielded 1.27 g. (60%) of α-hydroxyisobutyric acid 3,5-dinitrobenzoate, m.p. 149–150°.

Anal. Calcd. for $C_{11}H_{10}N_2O_8$: C, 44.30; H, 3.38. Found: C, 43.94; H, 3.45.

Treatment of the acid (0.5 g.) with thionyl chloride followed by ammonia gave 0.40 g. (80%) of the α-hydroxyisobutyramide 3,5-dinitrobenzoate (VI), m.p. 177–178°.

Anal. Calcd. for $C_{11}H_{11}N_3O_7$: C, 44.44; H, 3.73. Found: C, 44.60; H, 3.97.

Acetone Cyanohydrin 3,5-Dinitrobenzoate.—Acetone cyanohydrin (5 g., 0.06 mole), 26.9 g. (0.117 mole) of 3,5-dinitrobenzoyl chloride and 10 ml. of anhydrous pyridine were mixed and heated on a steam-bath for 2 hr. From the reaction 14.88 g. (89%) of acetone cyanohydrin 3,5-dinitrobenzoate (VII), m.p. 125–126°, was isolated.

Anal. Calcd. for $C_{11}H_9N_3O_6$: C, 47.32; H, 3.25. Found: C, 46.86; H, 3.35.

Hydrolysis of 1.0 g. (0.00358 mole) of the above nitrile was accomplished in sulfuric acid solution to give 0.56 g. (53%) of α-hydroxyisobutyramide 3,5-dinitrobenzoate, m.p. 168–172°. Recrystallization from ethanol resulted in a solid, m.p. 178–179°, whose infrared absorption spectrum was superimposable with the amide obtained from the parent acid. A mixture melting point of the two amides was undepressed.

2,2,5,5-Tetramethyl-3,6-dimethoxy-*p*-dioxane (IX).—α-Hydroxyisobutyraldehyde dimethylacetal (12 g., 0.0894 mole) and a drop of sulfuric acid were heated to 100°. From the reaction 3.3 ml. of methanol, $n^{25}D$ 1.3270, was collected. The remaining material in the flask solidified at room temperature and amounted to 8.54 g. of 2,2,5,5-tetramethyl-3,6-dimethoxy-*p*-dioxane, m.p. 58–61°. The infrared spectrum of this compound had no hydroxyl or carbonyl absorption. A small sample sublimed at room temperature and 1 mm. pressure to give an analytical sample, m.p. 61–62°.

Anal. Calcd. for $C_{10}H_{20}O_4$: C, 58.79; H, 9.87. Found: C, 59.01; H, 9.54.

1,2-Epoxy-1-methoxy-2-methylpropane (X).—Two procedures were used. Procedure A was essentially the same as reported[4] for the reaction of α-chlorobutyraldehyde and sodium methoxide. From 25 g. of α-chloroisobutyraldehyde there was obtained 8.78 g. (37%) of 1,2-epoxy-1-methoxy-1-methylpropane, b.p. 93–94°, d^{25} 0.9036, $n^{25}D$ 1.3889.

Procedure B.—Dry sodium methoxide was prepared from

11.5 g. (0.5 g. atom) of sodium. Diethyl carbitol was added to the dry finely powdered methoxide and the resulting slurry was cooled to 0°. To this slurry was added 39.5 g. (0.37 mole) of α-chloroisobutyraldehyde, and the reaction mixture was heated for 1.5 hr. at 50° with agitation. The product was distilled directly from the reaction mixture at 10 mm. pressure and 50° into a receiver cooled in a Dry Ice–acetone mixture. Final distillation through a 30-cm. tubular column at atmospheric pressure gave 19.97 g. (53%) of the epoxyether, b.p. 92–93°, $n^{25}D$ 1.3885.

When 28.5 g. (0.188 mole) of α-bromoisobutyraldehyde was treated with sodium methoxide following procedure B, 8.15 g. (42.5%) of the epoxyether was obtained, b.p. 91–96°, $n^{25}D$ 1.3884.

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.79; H, 9.87; OCH_3, 30.3. Found: C, 59.05; H, 10.04; OCH_3, 30.2.

To 3.65 g. (0.0357 mole) of the epoxyether in 20 ml. of anhydrous ether and 3.42 g. (0.107 mole) of anhydrous methanol at −30° was added a drop of hydrochloric acid. The reaction was then warmed slightly on a steam-bath. After cooling the flask to room temperature, the hydrochloric acid was neutralized with excess solid sodium carbonate. The reaction mixture was filtered and distilled. The α-hydroxyisobutyraldehyde dimethylacetal obtained amounted to 2.72 g. (57%), b.p. 63–64° (25 mm.), $n^{25}D$ 1.4122. The infrared spectrum of this material was superimposable on that of the acetal obtained from α-chloroisobutyraldehyde.

When 1.0 g. of the above acetal was permitted to react with 3,5-dinitrobenzoyl chloride in pyridine, 1.16 g. (48%) of the 3,5-dinitrobenzoate derivative was isolated, m.p. 70–71°. A mixture melting point determination with the authentic material obtained from α-chloroisobutyraldehyde was not depressed.

1-Methoxy-2-methylpropane-1,2-diol 1-(3,5-Dinitrobenzoate) (XI).—To 5.3 g. (0.052 mole) of epoxyether X in anhydrous ether was added 10.9 g. (0.052 mole) of 3,5-dinitrobenzoic acid in anhydrous ether. The reaction mixture was allowed to stand overnight. The ethereal solution was dried over anhydrous sodium sulfate and filtered. The ether was partially removed, the solution cooled to a sirup, a small amount of petroleum ether (30–60°) was added and upon scratching the product solidified to yield 13.18 g. (81%) of 1-methoxy-2-methylpropane-1,2-diol 1-(3,5-dinitrobenzoate), m.p. 84–85°.

Anal. Calcd. for $C_{12}H_{14}N_2O_8$: C, 45.86; H, 4.49; OCH_3, 9.87. Found: C, 45.46; H, 4.32; OCH_3, 9.99.

When 50 mg. of 1-methoxy-2-methylpropane-1,2-diol 1-(3,5-dinitrobenzoate) was placed in 50 ml. of ether and extracted with three 15-ml. portions of cold 5% sodium carbonate, no solid was obtained on acidification of the carbonate layer. Upon evaporation of the ether layer, addition of petroleum ether (30–60°) and cooling, there was obtained 45 mg. of the unchanged acylal, m.p. 81–83°. A mixture melting point with material melting 83–84° was not depressed.

Treatment of 7.74 g. (0.0246 mole) of the α-hydroxyacylal with excess nitric acid for 3 hr. on the steam-bath until oxides of nitrogen were no longer evolved gave two acids. The reaction mixture was poured onto cracked ice and filtered to give 5.10 g. (98%) of 3,5-dinitrobenzoic acid, m.p. 203–204°. The acidity of the remaining solution was reduced to *p*H 5, and the solution was continuously extracted with ether for 3 days. The ether was removed in part, the solution dried with anydrous sodium sulfate and product crystallized from a benzene–ether mixture to yield 1.22 g. (47.5%) of α-hydroxyisobutyric acid, m.p. 79°. A mixture melting point determination with the authentic hydroxy acid was undepressed. The infrared spectra of the two samples were superimposable.

Pyrolysis of 1-Methoxy-2-methylpropane-1,2-diol 1-(3,5-Dinitrobenzoate).—In a molecular still, 4.5 g. (0.014 mole) of the solid α-hydroxyacylal was placed under a pressure of 5 mm. and heated. The acylal melted cleanly and when the temperature reached 135°, vigorous bubbling occurred and the melt resolidified. After 0.5 hr. the solid residue dissolved in a bicarbonate solution and upon reacidification yielded 2.58 g. (85%) of 3,5-dinitrobenzoic acid, m.p. 203–204°. A mixture melting point determination with authentic acid showed no depression. The distillate from the pyrolysis amounted to 1.05 g. (73%) of semi-solid 2,2,5,5-tetramethyl-3,6-dimethoxy-*p*-dioxane, which probably contained both *cis* and *trans* isomers. Recrystallization from petroleum ether yielded an analytical sample, m.p. 61–62°. The infrared absorption of this compound and the compound obtained by pyrolysis of the α-hydroxyisobutyraldehyde dimethylacetal were identical.

Anal. Calcd. for $C_{10}H_{20}O_4$: C, 58.79; H, 9.87. Found: C, 58.60; H, 9.68.

Rearrangement of 1-Methoxy-2-methylpropane-1,2-diol 1-(3,5-Dinitrobenzoate).—To 5 g. (0.016 mole) of 1-methoxy-2-methylpropane-1,2-diol 1-(3,5-dinitrobenzoate) dissolved in ether was added a catalytic amount of triethylamine. After the solution remained at room temperature overnight, white crystals had formed. The solid was filtered and amounted to 4.08 g. (90%) of α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate, m.p. 143–144°. A mixture melting point determination with authentic material from hydrolysis of α-hydroxyisobutyraldehyde dimethylacetal 3,5-dinitrobenzoate was not depressed.

Into a 10-ml. erlenmeyer flask was placed 0.5 g. (0.0016 mole) of the solid acylal in anhydrous benzene, and the solution was heated for 4 hr. Upon evaporating off the benzene an oil formed which was cooled, scratched and solidified. Ligroin and acetone were added and the solution was cooled to yield a white solid, 0.13 g. (29%), of the α-hydroxyisobutyraldehyde 3,5-dinitrobenzoate, m.p. 141–143°. A mixture melting point with the material above was not depressed, m.p. 142–143°.

1-Methoxy-2-methylpropane-1,2-diol 1-Acetate (XI).—Ten grams (0.0978 mole) of epoxyether was dissolved in 70 ml. of anhydrous ether, cooled to 0°, and 5.87 g. (0.0978 mole) of pure acetic acid in 20 ml. of anhydrous ether was added. The reaction mixture was stoppered, placed in a desiccator, and permitted to stand in the refrigerator overnight. The mixture was then extracted with three 20-ml. portions of cold saturated sodium bicarbonate and dried over anhydrous sodium sulfate. After filtration and removal of the ether under vacuum, the liquid acylal was distilled. The yield was 9.27 g. (58.4%) of 1-methoxy-2-methylpropane-1,2-diol 1-acetate, b.p. 84–85° (13 mm.), d^{25} 1.0454, $n^{25}D$ 1.4187.

Anal. Calcd. for $C_7H_{14}O_4$: C, 51.83; H, 8.70; OCH_3, 19.13. Found: C, 51.59; H, 8.97; OCH_3, 19.16.

Rearrangement of 1-Methoxy-2-methylpropane-1,2-diol 1-Acetate.—The liquid α-hydroxyacylal (5 g., 0.0308 mole) and 0.5 ml. of triethylamine were heated to 90° for 3 hr. The temperature was then raised to 105° and methanol and the triethylamine were collected until approximately the theoretical amount of methanol had been removed. The residue was then distilled at reduced pressure to yield 3.17 g. (79%) of α-acetoxyisobutyraldehyde, b.p. 79–81° (50 mm.), d^{25} 1.0155, $n^{25}D$ 1.4093.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.74. Found: C, 54.86; H, 8.09.

A 2,4-dinitrophenylhydrazone derivative melted at 113–114°. *Anal.* Calcd. for $C_{12}H_{14}N_4O_6$: C, 46.44; H, 4.54. Found: C, 46.20; H, 4.82.

The Reaction of Acetals with Malonic Acid and its Derivatives. A Contribution to the Knowledge of the Knoevenagel–Doebner Reaction

BY J. KLEIN AND ERNST D. BERGMANN

RECEIVED NOVEMBER 2, 1956

The acetals of aromatic aldehydes, cinnamic aldehydes and—with lower yields—also of aliphatic aldehydes react with malonic acid in the presence of pyridine and piperidine in the manner of a Knoevenagel reaction. The reaction does not proceed *via* the free aldehydes. Ethyl hydrogen malonate reacts with these acetals analogously in the absence of any catalyst, giving the corresponding ethyl hydrogen arylidene- and cinnamylidene-malonates. A reaction mechanism is proposed, invoking the formation of a hydrogen-bonded complex between the two components of the reaction mixture.

In a study to be published elsewhere, it was found that the acetals of 2-phenyl-1,2,3,6-tetrahydro- and 2-phenyl-hexahydrobenzaldehyde react with malonic acid in the presence of pyridine and piperidine in the manner of a Knoevenagel reaction, giving the corresponding hydrogenated 2-phenylcinnamic acids, with liberation of carbon dioxide. A systematic study of the reaction between dialkyl acetals of aldehydes and malonic acid led to the following conclusions: the diethylacetals of aromatic and of cinnamic aldehydes condense with malonic acid in quantitative yields. The aromatic aldehyde acetals thus give cinnamic acids. This is particularly noteworthy in the case of *p*-dimethylaminobenzaldehyde diethylacetal; this aldehyde is refractory in the Perkin reaction[1] but gives[2] by Doebner's method a yield of 85%. Bulky *o*-substituents (not, *e.g.*, *o*-methoxy) decrease the yield under the same operating conditions (to 50–60%); prolongation of the reaction time gives satisfactory yields also in these cases. It appears that these substituents decrease the rate at which condensation takes place. The acetals of aliphatic and hydroaromatic aldehydes react more slowly than those of aromatic ones, giving α,β-unsaturated monocarboxylic acids. The yields were low, but at least in a number of these cases the acetals have been recovered, so that not the yield but rather the conversion rates appear to be affected adversely.

The reaction between the acetals of cinnamic aldehydes and malonic acid leads to mixtures of the corresponding malonic and monocarboxylic acids; it has been shown that the former are decarboxylated only slowly, even in boiling pyridine.[3] Thus it must be assumed that the proximity of the aryl groups accelerates the decarboxylation. This assumption is supported by the observation that ethyl hydrogen (*p*-methylbenzylidene)-malonate (see below) is decarboxylated within a few minutes, when heated in boiling piperidine.

The mechanism of these reactions is not without interest. Under the experimental conditions employed, the acetals appear to condense directly and not *via* the aldehydes.[4,5] This point is emphasized by analogous experiments carried out with ethyl hydrogen malonate, which has been used before[6,7] in the Knoevenagel reaction with aromatic aldehydes, giving substituted ethyl cinnamates in the presence of pyridine and piperidine. Heated with the acetals of *p*-tolualdehyde and cinnamaldehyde in benzene without any addition of a catalyst, good yields (60 and 89% respectively) of ethyl hydrogen (*p*-methylbenzylidene)- and cinnamylidene-malonates were obtained. Under the same conditions, *free* *p*-tolualdehyde did not give appreciable amounts (6%) of ethyl hydrogen (*p*-methylbenzylidene)-malonate; also when an azeotropic trap was used to remove the water formed during the reaction, about the same yield (4%) of ethyl hydrogen (*p*-methylbenzylidene)-malonate was obtained.

Whilst in the reaction with the acetal of *p*-tolualdehyde only one of the possible stereoisomers was isolated, there is strong indication that with the acetal of cinnamaldehyde a mixture of two stereomeric compounds is formed, one of which has been isolated in pure form. The unresolved remaining mixture had the theoretically expected molecular weight and practically the same absorption spectrum as the pure isomer.

For an understanding of the reaction mechanism, it is of importance to note that diethyl malonate under the same conditions, *i.e.*, without catalyst, does not condense at all with *p*-tolualdehyde: at least one free carboxyl group is necessary for the reaction. Addition of piperidine caused the condensation to proceed with a yield of 2%, and alternative addition of *p*-toluenesulfonic acid led to about 5% of diethyl (*p*-methylbenzylidene)-malonate. In the latter case, incidentally, ethyl alcohol is liberated more quickly, but this is not followed by condensation. We believe, therefore, that the primary reaction is the formation of a complex between the acetal and the acid, based on a hydrogen bond

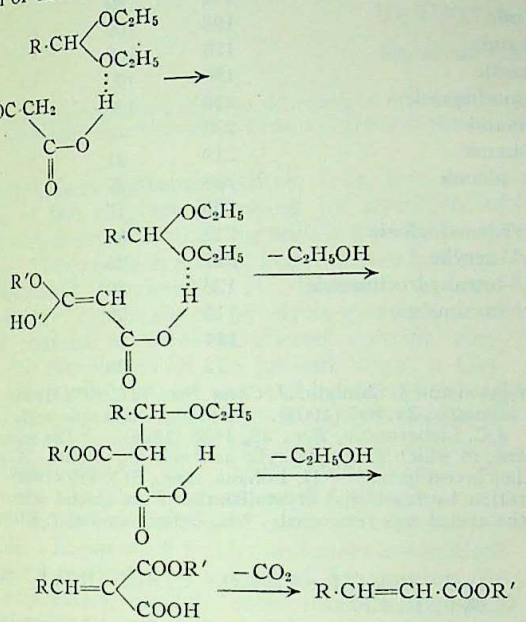
Thus the methylene group of the acid component is brought into the immediate vicinity of the central atom of the acetal molecule which then reacts



As in the case of the Knoevenagel reaction in the classical sense, the decarboxylation step requires the presence of pyridine,[8] whilst the elimination of ethanol from the ethoxydicarboxylic acid or its monoester appears to be spontaneous.

It is interesting to note that the cyclic acetal formed from benzaldehyde and ethylene glycol (2-phenyl-1,3-dioxolane) is capable of the same reaction with malonic acid as the diethylacetal, giving cinnamic acid. However, under comparable conditions, the yield is very much lower for the cyclic acetal. It seems likely that the oxygen atoms in the cyclic structure are less prone to form hydrogen bonds than those in an open acetal.

Whether this hypothesis really represents the facts can only be decided by kinetic measurements which will be reported in a later publication. The possibility that this condensation proceeds *via* the free cation $ArCH{\cdot}OC_2H_5^+$ which may be formed under the influence of the acid present in the reaction mixture is made improbable by the observation that when *p*-tolualdehyde diethylacetal was heated with diethyl malonate in the presence of equimolar amounts of *p*-nitrobenzoic or chloroacetic acids (these acids having approximately the same *pK* as hydrogen ethyl malonate), only 1–4% of the condensation product was obtained.

Experimental

Preparation of Diethylacetals. Method I.—The aldehyde (1 mole), ethyl orthoformate (1.1 mole) and anhydrous ethanol (three times the weight of the orthoformate) were kept for 12 hr. at room temperature, after a few drops of a saturated solution of hydrogen chloride in alcohol had been added. The mixture was stirred with an excess of solid sodium carbonate for 15 minutes, diluted with an equal volume of ether, filtered and distilled.

Method II.—Instead of hydrogen chloride, ammonium nitrate[9] (1 g.) was used as catalyst and the mixture refluxed for 30 minutes, cooled, treated with solid sodium carbonate and worked up as above. The properties of the diethylacetals are recorded in Table I.

Acetaldehyde dibutylacetal was prepared according to Weizmann, Bergmann and Sulzbacher,[10] b.p. 184°, and 2-phenyl-1,3-dioxolane according to Hibbert and Timm,[11] b.p. 134° (40 mm.).

Reaction of the Acetals with Malonic Acid.—The mixture of the acetal (0.1 mole), malonic acid (0.2 mole), pyridine (42 ml.) and piperidine (2 ml.) was heated at 100° for 3 hr. and at 140° for 30 minutes; it was then cooled and poured into a mixture of ice and concentrated hydrochloric acid. Crystalline products were filtered, oily ones isolated by extraction with ether. These ether extracts were treated with 5% sodium carbonate solution and the acidic products liberated with dilute acid and extracted again with ether. The results are summarized in Table II.

Reaction of *p*-Tolualdehyde Diethylacetal with Ethyl Hydrogen Malonate.—Ethyl hydrogen malonate was prepared according to Breslow, Baumgarten and Hauser.[12,13] (a) From a solution of 9.7 g. of the acetal in 65 ml. of benzene, 15 ml. of the solvent was distilled off, in order to remove

Klein, unpublished results. [p] 55% of the acetal was recovered.

traces of water, and 7.3 g. of ethyl hydrogen malonate was added. The mixture was refluxed for 10 hr. and the volatile products were removed, ultimately at 150° in a vacuum of 20 mm. The residue solidified and was recrystallized from ligroin, whereupon it melted at 95–115° (yield 6 g.). Recrystallization from benzene raised the m.p. to 124–126° and finally 127°. Analysis indicated that the product was ethyl hydrogen (*p*-methylbenzylidene)-malonate.

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.7; H, 6.0. Found: C, 67.1; H, 6.1.

When the same reaction was carried out using 8 g. of *diethyl malonate*, the starting materials were recovered unchanged, after 6 hr. at reflux temperature.

(b) When the same reaction was carried out in the presence of 3 drops of piperidine and the benzene solution was extracted with 5% sodium carbonate solution, acidification gave 7 g. of a product of m.p. 118–120°, which after two recrystallizations from benzene rose to 127°. The benzene solution contained 2.8 g. of an oil which, according to the boiling point and the ability to form a dinitrophenylhydrazone under acidic conditions, was unchanged acetal.

When the reaction was repeated with 8 g. of *diethyl malonate*, 0.4 g. of diethyl *p*-methylbenzylidene-malonate was obtained.

(c) The reaction was repeated, but 50 mg. of *p*-toluenesulfonic acid was added as catalyst. Alcohol was liberated very quickly. After 24 hr., the reaction mixture was washed with water, dried and distilled. A fraction amounting to 7.8 g. boiled between 90 and 110° (20 mm.) and 4.3 g. between 155 and 185° (1.5 mm.). The latter fraction solidified quickly. It was recrystallized from ligroin (1.5 g., m.p. 100–118°) and benzene, m.p. 124–125°.

When this reaction was repeated, using 8 g. of *diethyl malonate*, there was obtained after 6 hr. of refluxing 1 g. of diethyl (*p*-methylbenzylidene)-malonate which gave, after hydrolysis, *p*-methylbenzylidenemalonic acid, m.p. 214°, after recrystallization from butyl acetate.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.1; H, 4.9. Found: C, 63.9; H, 4.7.

(d) When 4 g. of *p*-tolualdehyde, 4.5 g. of ethyl hydrogen malonate and 30 ml. of benzene were refluxed for 10 hr., the work-up gave 2.8 g. of *p*-tolualdehyde, identified as dinitrophenylhydrazone and semicarbazone, and 0.5 g. of crude ethyl hydrogen (*p*-methylbenzylidene)-malonate, m.p. 112–120°.

(e) When 2.2 g. of ethyl hydrogen (*p*-methylbenzylidene)-malonate was refluxed for 30 minutes in 10 ml. of piperidine, 1.3 g. of ethyl *p*-methylcinnamate, b.p. 142° (1 mm.), was obtained. It was identified by analysis and ultraviolet spectrum.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.8; H, 7.4. Found: C, 76.1; H, 7.4; ultraviolet spectrum (in ethanol), 223 mμ (4.23), 285 mμ (4.27).

Reaction of Cinnamaldehyde Diethylacetal and Ethyl Hydrogen Malonate.—From 10.3 g. of the acetal, 7.3 g. of ethyl hydrogen malonate, 50 ml. of benzene and 3 drops of piperidine, which were refluxed together for 10 hr., there was obtained by the usual work-up 10.5 g. of an acidic, yellow product of m.p. 75–110°. Successive recrystallization from benzene and carbon tetrachloride gave pure ethyl hydrogen cinnamylidene-malonate of sharp m.p. 119–120°.

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.3; H, 5.7. Found: C, 68.7; H, 5.6; ultraviolet spectrum, 315 mμ (log ε 4.51).

The mother liquors of the recrystallization left a solid product of m.p. 69–72°, which has a molecular weight corresponding to the above compound (calcd., 246; found, 243) and practically the same absorption spectrum; however, the extinction coefficient was somewhat lower: 315 mμ (log ε 4.34).

When the reaction was repeated in the presence of 50 mg. of *p*-toluenesulfonic acid as catalyst, the yield of the crude acid (m.p. 75–110°) was only 5 g.

Cyclic Ethers Made by Pyrolysis of Carbonate Esters

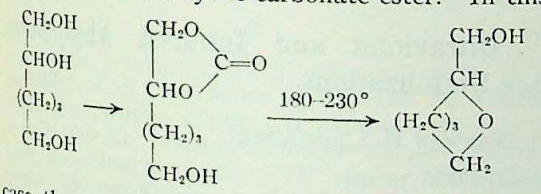
BY DEXTER B. PATTISON

RECEIVED JANUARY 17, 1957

Cyclic ethers containing three to six atoms in the ring are readily prepared in good yield by pyrolysis of the corresponding carbonate esters, if an activating hydroxyl group is present.

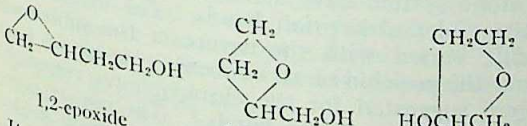
Cyclic ethers containing three, four, five or six atoms in the ring are prepared by pyrolysis of cyclic carbonate esters having one or two hydroxyl groups. The reaction is more general than has been demonstrated previously. H. Bruson[1] reported that glyceryl carbonate on pyrolysis gives glycidol, which contains a three-membered epoxide ring. Near the completion of the present work, a German patent application[2] was published describing the preparation of 3-ethyl and 3-methyloxetane-3-methanol by pyrolysis of the carbonate esters of trimethylolpropane and trimethylolethane, respectively. In the German work, phosgene was used to make the carbonate ester of trimethylolpropane. In our work a safer and more convenient laboratory method was employed for making the carbonate esters, namely, ester interchange with diethyl carbonate or ethylene carbonate.

A typical example of the formation of a six-membered oxide ring is the preparation of tetrahydropyran-2-methanol in 62% yield from 1,2,6-hexanetriol *via* the cyclic carbonate ester. In this



case the 1,5-epoxide was formed, and there was none of the 1,2- or the 1,6-epoxide. The structure was proved by the infrared spectrum which was identical with that of an authentic sample of tetrahydropyran-2-methanol.

A typical example of the formation of a five-membered ring is the synthesis of 3-hydroxytetrahydrofuran in 88% yield from 1,2,4-butanetriol *via* the cyclic carbonate ester. In this case the three possible structures of the product are shown below.



It was shown that the product was not a 1,2-epoxide because the material did not react at 100° with *n*-butylamine; and under these conditions glycidol, a 1,2-epoxide, is converted quantitatively to high boiling products, mainly 3-butylamino-1,2-propanediol. The compound had the same boiling point, refractive index and infrared spectrum as an authentic sample of 3-hydroxytetrahydrofuran[3] prepared by dehydration of 1,2,4-butanetriol using sulfuric acid as catalyst.

Four-membered oxide ring compounds which have been synthesized by this method are 3-ethyl-oxetanemethanol, 3-methyl-3-oxetanemethanol and 3,3-oxetanedimethanol.[4] They were made in yields of 87, 77 and 34%, respectively, from trimethylolpropane, trimethylolethane and pentaerythritol.

Cyclic carbonates containing no hydroxyl groups are much more stable than carbonate ester containing a hydroxyl group. For example a mixture of 2,2-diethylpropanediol and its cyclic carbonate ester can be distilled at 220° under slightly reduced pressure without decomposition, whereas the cyclic carbonate of trimethylolpropane decomposes rapidly at 180–200° to carbon dioxide and 3-ethyl-3-oxetanemethanol.

TABLE I

PREPARATION OF EPOXIDES BY PYROLYSIS OF CARBONATE ESTERS

Starting triol or tetrol	Alkyl carbonate	Product % Yield[a]	Product % Conversion[a]
1,2,6-Hexanetriol	Ethylene	62	78
1,2,4-Butanetriol	Diethyl	88	82
Trimethylolpropane	Ethylene	72	69
Trimethylolpropane	Diethyl	87	92

Trimethylolethane	Diethyl	77	97
Pentaerythritol	Diethyl	34	100

[a] $\%\ \text{Yield} = \dfrac{\text{mol. wt. polyol}}{\dfrac{\text{g. product} \times \text{mol. wt. product}}{\text{g. polyol charged} - \text{g. polyol recovered}}} \times 100$

$\%\ \text{Conversion} = \dfrac{\text{g. polyol charged} - \text{g. polyol recovered}}{\text{g. polyol charged}} \times 100$

Experimental

Typical preparations employing ethylene carbonate or diethyl carbonate are described below. In Table I yield data are given, and in Table II physical properties and analytical data are recorded.

Tetrahydropyran-2-methanol from 1,2,6-Hexanetriol.—A mixture of 670 g. of 1,2,6-hexanetriol (5.0 moles) and 493 g. of ethylene carbonate (5.5 moles) was kept at 140–150°, and ethylene glycol (336 g.) was removed by distillation at 26–10 mm. pressure. The pot temperature was raised gradually to 250° and the pressure fell, due to carbon dioxide evolution.

Under full motor pump vacuum 510 g. of product was obtained. Part of this boiled at 100–130° under 30–130 mm. pressure, but near the end, when carbon dioxide evolution had ceased, the boiling point was 150–175° and the pressure was 2–10 mm. Redistillation through an efficient column gave 281 g. of tetrahydropyran-2-methanol, boiling at 57° at 4 mm. or 78° at 13 mm. and 150 g. of 1,2,6-hexanetriol, boiling at 174–180° at 6 mm.

					50.5		8.8		906

3-Ethyl-3-oxetanemethanol from Trimethylolpropane.—A mixture of 268 g. of trimethylolpropane (2.0 moles), 236 g. of diethyl carbonate (2.0 moles) and 0.10 g. of potassium hydroxide dissolved in 5 ml. of absolute alcohol was refluxed until pot temperature was below 105° (15 minutes), and the mixture was distilled keeping the head temperature 76–78°. Distillation was continued until the pot temperature was 145°, and then the pressure was reduced gradually to 50 mm., maintaining the pot temperature at 140–150°. The weight of distillate was 179 g. (theory 184 g. alcohol). Upon heating above 180°, carbon dioxide evolution was rapid and most of the material distilled at 190–210° pot temperature, 90–140° head temperature and 50–90 mm. pressure. Near the end the pressure became 2–10 mm. and the head temperature rose. Redistillation through an efficient column gave: 13.4 g., b.p. 84–86° at 3.5 mm.; 136.6 g., b.p. 84–84.5 at 2.8 mm.; 24.4 g., b.p. 84.5–85.5 at 2.8 mm.; 26.1 g., residue.

The main fraction was analytically pure 3-ethyl-3-oxetanemethanol, and from the residue analytically pure trimethylolpropane was obtained by distillation.

Endocyclic α,β-Unsaturated Ketones. VI.[1] Ultraviolet and Infrared Absorption Spectra and Resonance Stabilizations

BY RICHARD D. CAMPBELL[2] AND NORMAN H. CROMWELL[3]

RECEIVED MARCH 1, 1957

New data are presented for the ultraviolet absorption spectra of thirteen ketones. These compounds are members of three series, *viz.*, 1,1-dimethyl-2-keto-1,2-dihydronaphthalene (1,1-dimethyl-2(1*H*)-naphthalenone) (II), 4,4-dimethyl-1-keto-1,4-dihydronaphthalene (4,4-dimethyl-1-(4*H*)-naphthalenone) (I), and perinaphthenone-7 (1-(1*H*)-benzonaphthenone) (III). With previously reported data for eight related compounds, the spectra are discussed with respect to resonance stabilizations, effect of nature and position of substituents, and type of conjugation. New infrared spectral data are presented for twenty-one ketones in the three series. These results are discussed with respect to the same factors.

Ultraviolet Absorption Spectra Studies

Introduction.—Studies of ultraviolet absorption spectra of α,β-unsaturated ketones have mainly dealt with open chain systems, with some treatment of endocyclic series. The effect of conjugation of the unsaturated ketone system with phenyl groups has been studied, and chromophores assigned to ultraviolet absorption bands.[4,5] Absorption in the 2300–2500 Å. region was ascribed to the benzoyl or acrylophenone chromophore, and intense absorption from 2800 to 3500 Å. to the cinnamoyl chromophore. The effect of linear and crossed conjugation, and of endo- and exocyclic double bonds on the spectra of α,β-unsaturated ketones has been discussed.[6]

It was observed[4,7,8] that various substituents on the α- or β-carbon atom of the α,β-unsaturated ketone system have a bathochromic effect on the ultraviolet absorption bands. The extent of the shift varied with the nature of the substituent, and the position of attachment. Resonance forms were suggested for the chromophores responsible for the characteristic bands.[4] The importance of chelation in the β-hydroxy[7] and β-amino ketones was discussed.[4] Since such chelation or ionic interaction is impossible in the endocyclic series, it seemed of considerable interest to study these endocyclic compounds.

The compounds used in these studies are all of

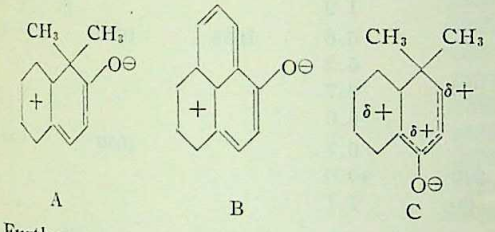
known structure. Their sources[9-17] are indicated in Table I. Since a detailed comparison of spectra needed to be made in order to study the effects of substituents on the spectra of the parent ketones, care was taken in imposing uniform conditions on the spectral determinations, with due regard to temperature, light exposure and solvent effects. Spectra used from the literature were checked for these conditions.

Discussion of Results.—In the three series of compounds studied, the parent endocyclic α,β-unsaturated ketones are 4,4-dimethyl-1-keto-1,4-dihydronaphthalene (I), 1,1-dimethyl-2-keto-1,2-dihydronaphthalene (II) and perinaphthenone-7 (III). In the order named, these compounds showed strong absorption bands at successively higher intensity and longer wave length. The same result was observed in the analogous open chain compounds,[4] ethylideneacetophenone, benzalacetone and chalcone. The aromatic ring on the β-carbon atom of the α,β-unsaturated carbonyl system carries the positive charge in the longest formally polarized (cinnamoyl) structures indicated by forms A and B, for ketones II and III.



A B C

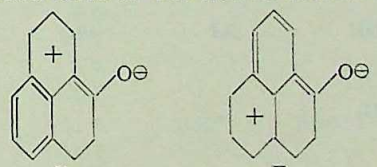
Further resonance stabilization of form B is possible. Canonical forms for III can be written with the positive charge on carbon atoms 1, 3, 4, 6, 7, 9 or 13. This accounts for the fact that the long wave length bands of III appear 500–800 Å. nearer the visible compared with the corresponding band (3000 Å.) of ketone II.

Although the extinction coefficients for the long wave length bands of II and III are nearly equal, the integrated intensity for this band of III is greater. This may be ascribed to the more extensive electronic system of III involved in the transition. Intensity of light absorption is related to the probability of the occurrence of the electronic transition, polarity of the excited state, and length of the conjugated system.[18]

The intense absorption bands below 2500 Å. for parent ketone I and its dihydro derivative IV may be attributed to the benzoyl polarization.[4,5] The vinyl ketone system of I also is responsible for absorption in this region. Absorption in the region 2300–2400 Å. is characteristic of vinyl ketones.[6] The weak bands in the region 2800–3000 Å. for I and IV also are attributed to the benzoyl polarization.[4,5] That this band for I is more intense than for IV is the expected result because I possesses a longer conjugated system.[18] This longer conjugated system is indicated by form C above. The simultaneous interaction of the double bond and the aromatic ring with the carbonyl group cannot be described by a single valence-bond structure. It is not apparent whether such simultaneous resonance interaction is impossible or the classical structures are inadequate for these cross-conjugated systems.

The intense band (3000 Å.) due to the long conjugated system of II is wiped out in the dihydro compound V in which the conjugated system is broken. The carbonyl group in V is insulated from the benzene ring. Only a weak isolated carbonyl band[19] remains in the 2600–2900 Å. region for V. The tetralin system also absorbs weakly in this region.[20]

The extensive resonance stabilization of III is decreased in the dihydro derivative VII. This is evident from the decreased intensity and hypsochromic shift (380–450 Å.) of the absorption band in the 3000–4000 A. region. The positive charge of the polarized form of VII can be carried by either



D E

aromatic ring, as forms D and E indicate. The two forms D are expected to be more stable due to the retention of the Kekule ring. In the three forms E the Kekule structure is absent. However, the long wave length band of VII is nearer the visible and more intense than the benzoyl band of IV or the principal band of the naphthalene nucleus.[20] Hence this band of VII must involve an important contribution from forms E, as well as forms D.

Further evidence for the nature of the resonance stabilizations possible in these three series of ketones (I, II and III) is revealed in the spectra of their α-bromo derivatives VIII, XII and XV, respectively. Introduction of the α-bromo substituent onto ketone II causes a bathochromic shift of 160 Å. for the long wave length band. The α-bromo substituent was reported[8] to cause a bathochromic shift of 80–120 Å. for α,β-unsaturated ketones. The shift indicates that the bromine atom lends more resonance stabilization to the excited state than to the ground state. In addition to forms indicated by A, forms F and G might be stabilizing the excited state by supporting part of the positive charge. One may consider two or more molecular orbitals simultaneously encompassing the systems described by A, F and G,

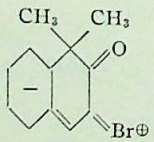
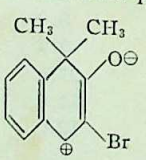
[a] Numbers are literature references which appear throughout the article. All samples were freshly purified according to the literature directions. [b] The ultraviolet–visible spectra were determined using a Cary recording spectrophotometer, Model 11 MS, according to the manufacturer's directions. The sample solutions were freshly prepared using 2,2,4-trimethylpentane (Eastman Kodak spectra grade) in suitable concentration (10^{-3} to 10^{-5} *M*). [c] The infrared spectra were determined between 700 and 4000 cm.$^{-1}$ using a Perkin–Elmer Model 21 double-beam infrared spectrophotometer. The Nujol mulls (or pure liquid) were made up to give good resolution. The determinations using carbon tetrachloride solutions were carried out in 1.0 mm. or 0.1 mm. matched cells. The concentration of these solutions was 12 mg./ml. [d] The values for Δλ and Δν were calculated by subtracting the value for the parent ketone from that of the derivative for the corresponding band, and in corresponding medium where possible. [e] Values in parentheses are shoulders. [f] Solvent was absolute methanol. [g] Pure liquid. See footnote *c*. [h] Beckman DU spectrophotometer. [i] Data from ref. 9a. [j] Data from ref. 17. [k] Data from ref. 10. [l] Data from A. Hassner, Ph.D. Thesis, University of Nebr., 1956. [m] Satd. soln.

without conflict with the Pauli exclusion principle.



F



G

The bromine substituent contributes in some such indirect manner to the resonance stabilization of the excited state. It has been pointed out[8] that valence-bond structures such as A, F and G cannot be written to show the resonance contribution of the bromine atom to the polarized carbonyl system. This problem is present in any cross conjugated system.

Introduction of the α-bromo substituent onto ketone I was reported[8] to give a bathochromic shift of 140 Å., using ethanol as solvent. The shift observed by us using isoöctane as solvent was 200 or 260 Å., depending on assignment of the split peak for VIII (2500, 2560 Å.). Only one peak was reported by Nussbaum, *et al.*,[8] for VIII at 2560 Å. in ethanol; the bands for I in ethanol and isoöctane are 2420 and 2300 Å., respectively. The solvent effect is as expected.[20] This solvent effect is greater with the parent ketone I than with the α-bromo derivative VIII. A generalization made by Nussbaum, *et al.*,[8] applies to these compounds: the α-bromo substituent causes a greater shift in the spectrum of phenyl vinyl ketones (*viz.*, I) than of β-styryl ketones (*viz.*, II), see Table I.

Introduction of the bromine atom onto the α-position of ketone III results in a bathochromic shift of 10–20 Å. of the long wave length bands (3300–4000 Å.). This indicates that the bromine atom hardly makes any more resonance contribution to the stability of the excited state than of the ground state. As indicated before, the positive charge of the polarized form B already is supported by extensive delocalization both in the ground state and in the excited state.

An additional triplet band (2300–2800 Å.) appears in the spectrum of XV. This triplet is characteristic of the α-substituted perinaphthenones to be mentioned later. Absorption in this region is characteristic of benzoyl polarizations stabilized by additional resonance interactions.[4,5,20] Canonical forms H, J and K, repre-

sent such polarizations in XV. Although the two polarized molecular orbitals implied by J cannot interact by first-order conjugation, electrostatic interaction is expected to contribute some stabilization to the polar form. One might expect that the three forms K are of very nearly the same energy, *i.e.*, degenerate states. Under the electrostatic influence of polarization H (implied in J), the degeneracy of K gives rise to the triplet (Stark effect)[21] in the 2300–2800 Å. region.

The ultraviolet spectra of the derivatives of III with N-cyclohexylamino, morpholino and hydroxyl groups in the α-position (XX, XVI and XVIII, respectively) are nearly identical.[10] These substituents result in a considerable decrease in the intensity of absorption in the 3000–4000 Å. region, and a hypsochromic shift of 90–290 Å. for these absorption maxima. This may indicate resonance interaction and stabilization in the ground state to a greater extent than in the excited state.

Two bands appear in the spectrum of the α-substituted derivatives of III, and not in the spectrum of III. One of these, in the 2300–2800 Å. region, is the triplet discussed above, and attributed to chromophores described by forms H, J and K. The triplet was not resolved in the spectrum of XX. The other new band is a broad, low intensity absorption extending into the visible region (4200–5000 Å.). This low intensity band has been reported for similar ketones.[9b,4] The shoulder (3920 Å.) in the spectrum of XV might be considered to correspond to this band characteristic of α-substituted α,β-unsaturated ketones.

The absorption maxima for the α-substituted derivatives are lower than the corresponding maxima for the parent ketone III, in the longer wave length region. However, inspection of the spectral curves shows that the integrated intensity in the region 2500–5000 Å. is greater for the α-substituted ketones. Thus the longer, intensely absorbing chromophores of the parent ketone are broken into smaller chromophores (see H, J and K) by the α-substituent. The resonance effect of the substituents is seen as an increase in the absorption over the 2500–5000 Å. range, and not in individual bands.

Introduction of the hydroxy or morpholino groups into the β-position of ketone III results in a hypsochromic shift (110–280 Å.) of the bands in the 3300–4000 Å. region. This may indicate that the substituents contribute more resonance stabilization to the ground state than to the excited state. The shift is greater for the hydroxyl group. The β-substituents introduce no bands which did not appear in III, and some fine structure is lost.[20] The increase in intensity of absorption in the 3300–4000 Å. region may be attributed to the extension of the resonating system and the greater electrical moment involved.[4,18]

The imino and epoxy derivatives have been discussed elsewhere.[10,17] The three membered ring has a small effect on the resonance in this series which is unlike the effect of either the α- or β-substituents.

(21) H. S. Taylor and S. Glasstone, "A Treatise on Physical Chemistry," Vol. I, 3rd ed., John Wiley and Sons, Inc., New York, N. Y., 1942, p. 281.

Introduction of the morpholino, methoxy or hydroxy groups into the α-position of ketone I results in bathochromic shifts of 180, 200 and 240 Å., respectively, for the strong band (2300–2800 Å.), indicating resonance stabilization of the excited state with respect to the ground state.

The absorption band of I in the 2700–3100 Å. region is shifted 20–60 Å. to longer wave length (except in X) and increased in intensity by the α-substituents. The resonance stabilization of the excited state may be due to ionic forms described[4] for similar compounds. Since this is a cross-conjugated system, it is difficult to describe a polarization in which both the carbonyl oxygen and α-substituent simultaneously carry a charge, but some such interaction seems to occur.[4]

Since the electronic system of II is more closely related to benzalacetone, chalcone and ketone III than to I, the effects of substituents on the spectrum of II should follow this relationship. The β-morpholino and β-hydroxy groups cause bathochromic shifts (530 and 350 Å., respectively) of the cinnamoyl band of II. This is consistent with the effect observed in other series.[4,7,22,23] That the effect of the amino group is greater is consistent with its greater electromeric effect.[19] In those cases in which hydrogen bonding is possible[4,22,23] the effect of hydroxyl is greater. Intramolecular hydrogen bonding is not possible in XIV. One might predict that the unknown α-hydroxy derivative of II would have a cinnamoyl band shifted about 300 Å. to longer wave length from the corresponding band of II, and with little more than one-half of the intensity.[4,23] One might also expect a broad, low intensity band extending into the visible region.[9b,4]

The spectral studies in the three series, I, II and III result in the following conclusions:

1. The effects of substituents on α,β-unsaturated ketones vary widely not only with the nature of the substituent, but also with the position of the substituent in the molecule and the steric and electronic nature of the ketone system.
2. In the perinaphthenone-7 (III) system, extensive resonance interaction is indicated both in the ground state and excited state.
3. In the cross-conjugated system (I), the substituent effects are small.
4. In the linear conjugated system (II), the substituent effects are larger.

Infrared Absorption Spectra Studies

Introduction.—The infrared absorption by ketones due to the carbonyl stretching vibration has been intensively studied. Factors influencing the polarity of the carbonyl group, and thus the absorption frequency, have been discussed.[24] Most of the studies of such factors have dealt with the immediate environment of the carbonyl group, with some study of the farther-reaching resonance effects. Conjugation effects of aryl and olefinic groups in open chain compounds have been

(22) B. Eistert, F. Weygand and E. Csendes, *Ber.*, **84**, 763 (1951).

studied.[24,25] Some substituent effects have been investigated,[25,26] but not with endocyclic α,β-unsaturated ketones. Hydrogen bonding effects have been observed.[24,27] Such effects might operate in α-substituted endocyclic α,β-unsaturated ketones but would be geometrically impossible in the β-derivatives.[4]

For some of the compounds involved in this study, infrared data have been determined using Nujol mulls. It has been pointed out[24,25] that intermolecular forces in condensed phases have an important influence on the infrared carbonyl absorption frequency. These forces can be minimized by using dilute solutions in carbon tetrachloride.

The discussion above, concerning the ultraviolet spectra of these compounds, dealt with some evidence for the effect of the various substituents on the ground state of the endocyclic α,β-unsaturated carbonyl system. It seemed of interest to obtain the more direct evidence of infrared spectra for these effects, and to study these spectra in relation to each other and to previous infrared data.[24]

Discussion of Results.—The physical state of the sample is important.[24] In dilute carbon tetrachloride solution the carbonyl band generally was found to be 10–20 cm.$^{-1}$ toward higher wave numbers than the carbonyl band observed in the condensed phase (*viz.*, liquid or Nujol mull). In some cases the difference was less, particularly in the perinaphthenone-7 (III) series. In the condensed phase, intermolecular effects might be expected to increase the polarity of the carbonyl group. Thus the solution data give a more reliable picture of the isolated molecule.[25] In the discussion which follows, references will be made almost exclusively to the solution data.

The carbonyl absorption frequency gives evidence of the polarity (single bond character) of the carbonyl group. The normal undisturbed carbonyl frequency is 1705–1725 cm.$^{-1}$ in aliphatic ketones.[24] Conjugation with an aryl group reduces the wave number to 1680–1700 cm.$^{-1}$. Phenyl vinyl ketones and β-styryl ketones absorb in the same range[25] (*viz.*, 1680 and 1690 cm.$^{-1}$, resp.).

Endocyclic ketones I and II absorb at 1665 and 1662 cm.$^{-1}$, respectively. This indicates that resonance interaction causes the carbonyl groups to be slightly more polar than in the corresponding open chain compounds.[25] The cyclic conjugated systems in I and II are held rigidly in position for maximum resonance interaction and polarization.[28]

Perinaphthenone-7 (III) shows even more extensive resonance interaction between the carbonyl group and the rest of the aromatic system. The carbonyl absorption frequency (1646 cm.$^{-1}$) indicates considerable polarity of the carbonyl group. Evidence for this extensive resonance interaction in the ground state of III and its derivatives was also noted in the ultraviolet spectra.

The dihydro derivatives in the three series exhibit carbonyl bands in the range expected. Ketone V has an aliphatic carbonyl group, and absorbs at 1712 cm.$^{-1}$. Ketones IV and VII are aryl ketones, and absorb at 1685 and 1690 cm.$^{-1}$, respectively. The α-bromine atom in VI shifts the absorption band 12 cm.$^{-1}$ to higher wave number, as expected.[24]

In all three series of unsaturated ketones, introduction of a bromine atom into the α-position caused a shift to higher wave numbers. This indicates that the strong inductive and coulombic field effects of bromine increase the double bond character of the carbonyl group. Several workers[24] have observed that the shift caused by an equatorial α-bromine was 20 cm.$^{-1}$ in saturated ketones, where only the inductive and coulombic field effects can operate. In the II, I and III series, the shift is progressively less (16, 8, and 4 cm.$^{-1}$, respectively). This indicates that the resonance and electrostatic dipolar interaction[29] of the bromine atom with the carbonyl group is progressively greater for the three series in the order named, and partly cancels the inductive and coulombic field effects, see Fig. 1. The resonance stabilization of the excited state for these compounds has been discussed above, in relation to the ultraviolet spectra.

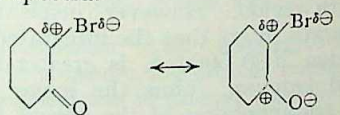

Fig. 1.—Coulombic field effect: equatorial bromine tends to suppress this indicated resonance in saturated cyclic ketones; see R. N. Jones, *et al.*, THIS JOURNAL, **74**, 2830 (1952).

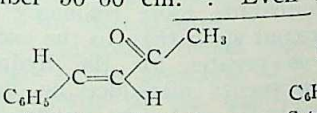
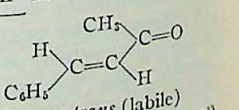
The effect of the β-morpholino or β-hydroxyl group on the carbonyl band of open chain α,β-unsaturated ketones is varied. Where hydrogen bonding (resonance chelation)[24] is possible, the β-amino group[27] reduced the carbonyl band wave number 50–60 cm.$^{-1}$. Even in the absence of



S-*cis-trans* (labile) (C=O$_{CCl_4}$ band, 1699 cm.$^{-1}$)



S-*trans-trans* (labile) (C=O$_{CCl_4}$ band, 1678 cm.$^{-1}$)

The endocyclic ketone II might be expected to have its C=O band (1662 cm.$^{-1}$) nearer to that of the S-*trans-trans* form of benzalacetone than to that of the S-*cis-trans* comformation. Fuson, *et al.*, ref. 25, have reported C=O bands at 1700–1685 cm.$^{-1}$ and C=C bands at 1670–1662 cm.$^{-1}$ for various β-styryl ketones. We suggest that these lower frequency bands might best be assigned to the carbonyl group of the S-*trans-trans* forms of these compounds; see E. A. Braude and C. J. Timmons, *J. Chem. Soc.*, 3771 (1955). House, THIS JOURNAL, **78**, 4394 (1956); **79**, 1490 (1957), reported C=O bands for 2-benzalcyclohexanone-1 (an S-*cis-trans* structure) and 3-phenyl-2-cyclohexenone-1 (an S-*trans-trans* structure) at 1685 and 1660 cm.$^{-1}$, respectively.

(25) N. Fuson, M. L. Josien and E. M. Shelton, THIS JOURNAL, **76**, 2528 (1954).

(26) A. H. Soloway and S. L. Friess, *ibid.*, **73**, 5000 (1951).

(27) N. H. Cromwell, *et al.*, *ibid.*, **71**, 3337 (1949).

(28) In this Laboratory Prof. H. E. Baumgarten has recently measured the infrared spectrum of highly purified benzalacetone. Using Nujol mulls, bands were found at, 1688(V.S.); 1665(W); 1615–1605 (V.S.); 1585(S); 6 mg./ml. CCl_4 in 1.0 mm. matched cells, 1699 (79% abs.); 1678 (94% abs.); 1617 (92% abs.). We believe that a C=O band assignment should be made to both the 1688–1699 and 1665–1678 cm.$^{-1}$ bands. The strong 1617–1605 cm.$^{-1}$ bands are probably composite C=C and conjugated phenyl bands. The two C=O bands are apparently associated with two possible rotational isomers of *trans*-benzalacetone; see footnote *b*, Table I, N. H. Cromwell and R. J. Mohrbacher, THIS JOURNAL, **76**, 6251 (1953).

(29) See, for example, J. Jaffé, The indicated (↔) electrostatic interaction should aid resonance.

chelation, the shift is approximately 30 cm.$^{-1}$ to lower wave number.[27] In the endocyclic compounds the chelation and dipolar[10] interaction effects are expected to be absent. In series II, the β-morpholino group effect seems anomalous, *i.e.*, it causes a shift of 8 cm.$^{-1}$ to higher wave number. It has been observed[27] that the resonance effect of the β-amino group is less in β-styryl ketones than in phenyl vinyl ketones. It would seem that in XIII the resonance effect of the morpholino group is less than its electron-withdrawing inductive effect.[30] The inductive effect of an α-bromine atom causes a shift in the same direction (see above). The β-hydroxyl group of XIV causes a shift of 1 cm.$^{-1}$ to higher wave length; again the expected[24] shift is to lower wave length. Here resonance and inductive factors are nearly balanced.

In the perinaphthenone-7 (III) series, the β-morpholino and β-hydroxyl groups cause shifts of the carbonyl band of 6 and 10 cm.$^{-1}$ to lower wave number. The shifts indicate that the carbonyl group has developed more single bond character through resonance interaction with the substituents, but the effect is smaller than in open chain compounds.[27] In XVII and XIX, intramolecular hydrogen bonding and dipolar[10] effects are not possible Also, the parent ketone system of III is extensively resonance stabilized, so the resonance effect of the substituents is less important.

Introduction of substituents into the α-position of parent ketone III results in shifts of the carbonyl band to lower wave numbers, indicating a more polar carbonyl group. The shifts for the α-morpholino, α-hydroxy and α-cyclohexylamino groups are −6, −16 and −24 cm.$^{-1}$, respectively. In the latter two (*viz.*, XVIII and XX), a five-atom chelate ring is possible. Intramolecular hydrogen bonding seems to increase the polarity of the carbonyl group in these compounds. The problem of direct resonance interaction between the carbonyl group and α-substituents has been discussed (see ultraviolet spectra discussion).

In series I, the effects of α-substitution on the polarity of the carbonyl group vary according to the nature of the substituent. It has been noted above and elsewhere,[24,27] that the inductive (electron withdrawing) effect of α-substituents decreases the polarity of the carbonyl group (shift to higher wave number), whereas the resonance effect and intramolecular hydrogen bonding give the opposite result. On the basis of electronegativity, and inductive effects,[31] the expected order of decreasing electron withdrawing (inductive) effect for the substituents is: bromo, hydroxy, methoxy and morpholino. The shifts caused by the α-substituents are: bromo, 8 cm.$^{-1}$; methoxy, 5 cm.$^{-1}$; morpholino, −3 cm.$^{-1}$; and hydroxy, −16 cm.$^{-1}$. For the bromo and methoxy substituents, the inductive effect is more important than the resonance effect. In the morpholino derivative IX the resonance effect is more important. Here the resonance effect may be aided in some manner by dipole interaction.[4] The hydroxyl group in XI seems to engage in intramolecular hydrogen bonding, thus increasing the polarity of the carbonyl group. In XI the resonance and hydrogen bonding effects of the substituent are considerably more important than the inductive effect on the polarity of the carbonyl group.

For the epoxy and imino derivatives of III, (XXI and XXII, respectively), the infrared spectra of Nujol mulls were reported[10,17] and discussed[17] in terms of the steric requirements of the three-ring for resonance interaction. It was suggested by N. Fuson[25] that data obtained in carbon tetrachloride solution would be necessary, to isolate the effect of the three-ring on the carbonyl frequency. Now these data are reported, and the previous conclusions[17] are essentially confirmed.

Stereochemistry of Allylic Rearrangements. IX. The Solvolysis of *trans*-α,γ-Dimethylallyl Acid Phthalate in Aqueous Acetone[1]

BY HARLAN L. GOERING AND RICHARD W. GREINER[2]

RECEIVED JANUARY 14, 1957

The polarimetric (k_α) and titrimetric (k_t) rate constants for the solvolysis of *trans*-α,γ-dimethylallyl acid phthalate (I) in aqueous acetone have been determined. At concentrations up to 0.1 M both k_α and k_t are steady during the reaction and $k_\alpha > k_t$ under all conditions at which the two were compared. The greater rate of loss of optical activity than of formation of solvolysis products is due to partial racemization of the reactant, by an isomeric intramolecular (SNi′) allylic rearrangement, prior to solvolysis. The data are consistent with a picture involving the reversible formation of a symmetrical ion-pair intermediate which is irreversibly converted to solvolysis products.

In earlier papers in this series[3,4] it was pointed out that an intermediate (an "internal ion-pair" intermediate according to Winstein's classification[5]) is involved in the ionization–dissociation step of carbonium-ion reactions in allylic systems. This intermediate can return to the original allylic compound or its allylic isomer by internal return—presumably this represents the mechanism of the SNi′[6] rearrangement of allylic compounds[3]—or dissociate to the allylic cation and the accompanying anion. In non-reactive solvents, *e.g.*, non-hydroxylic solvents, the dissociated carbonium ion and anion recombine; however, in hydroxylic solvents this recombination is completely diverted by solvolysis.[3,4] Thus, in hydroxylic solvents the SNi′ rearrangement is cleanly isolated from an intermolecular isomeric rearrangement.

Optically active symmetrical allylic systems, *i.e.*, systems with similar α- and γ-alkyl substituents, are especially well suited for studying the SNi′ rearrangement (internal return) which accompanies solvolysis. In such systems the SNi′ rearrangement results only in the interconversion of enantiomers and thus does not disturb the first-order rate of product formation but results in a larger rate of loss of optical activity (polarimetric rate) than of product formation (titrimetric rate). The first-order rate constant for the conversion of one enantiomer to the other by the SNi′ rearrangement is $(1/2)(k_\alpha - k_t)$ and thus can be determined readily from the polarimetric (k_α) and titrimetric (k_t) rate constants.[3,4]

As described in earlier papers in this series, internal return is involved in the solvolysis of the isomeric 5-methyl-2-cyclohexenyl chlorides in ethanol and acetic acid[4] and the corresponding acid phthalates[3a] and *p*-nitrobenzoates[3b] in aqueous acetone. In the present work we have examined the solvolysis of α,γ-dimethylallyl acid phthalate in aqueous acetone to determine the importance of internal return in this acyclic symmetrical allylic system relative to that in the 5-methyl-2-cyclohexenyl system.

Results

The α,γ-dimethylallyl acid phthalate used in the present work was apparently the pure *trans* isomer. That the material was homogeneous was indicated by a rather sharp reproducible melting point (89–90.5°) which was unchanged by recrystallization. The infrared spectrum of α,γ-dimethylallyl alcohol obtained by reduction of the pure acid phthalate with lithium aluminum hydride had a strong absorption band at 10.4 μ and no bands above 14 μ, which is characteristic of *trans*-1,2-disubstituted ethylenes.[7] The neutral equivalents of the samples of racemic and optically active acid phthalate used in the kinetic experiments were within 0.3% of the theoretical value.

The first-order polarimetric (k_α) and titrimetric (k_t) rate constants for the solvolysis of *trans*-α,γ-dimethylallyl acid phthalate (I) in 70, 80 and 90% aqueous acetone are given in Table I. The data are arranged so that the polarimetric rate constants are for the same conditions as the preceding titrimetric rate constants.

The polarimetric constants were determined from the rate of loss of optical activity of solutions of (+)-I. In all cases solvolysis resulted in complete loss of optical activity, and the polarimetric constants were steady over the range that the reaction was followed (88 to 94% completion). The observed first-order rate constants were reproducible and most of the values for $k\alpha$ given in Table I are average values of two independent kinetic experiments. A typical kinetic experiment is included in the Experimental section.

The titrimetric constants (k_t) were determined from the rate of increase in acidity of solutions of racemic I. In all cases the observed initial titer, *i.e.*, the titer of freshly prepared solutions prior to heating, agreed well with the calculated value. The observed infinity titers, however, were found to be approximately 2% less than the calculated values (twice the initial titer). Evidently this discrepancy is due to conversion of about 1% of the phthalic acid to phthalic anhydride under the conditions of the solvolysis experiments. In a control experiment the titer of a 0.05 M solution of phthalic acid in 90% acetone at 100° was determined periodically. The titer of this solution decreased slowly and after a period of time, corresponding to infinity time for the solvolysis, the percentage difference between the initial and final titers was the same as between the observed and calculated infinity titers.

TABLE I

POLARIMETRIC AND TITRIMETRIC RATE CONSTANTS FOR THE SOLVOLYSIS OF *trans*-α,γ-DIMETHYLALLYL ACID PHTHALATE IN AQUEOUS ACETONE

Acid phthalate, $10^2 M$	Method[b]	k,[c,d] 10^3 hr.$^{-1}$	$k\alpha/k_t$[e]
	90% (vol.[a]) acetone, 99.81°		
7.50	T	110 ± 6[f]	
10.0	T	117 ± 4	2.52 ± 0.16
10.0	P	295 ± 8[f]	
5.00	T	108 ± 4	2.69 ± 0.14
5.00	P	291 ± 4	
2.50	T	102 ± 2	2.83 ± 0.17
2.50	P	289 ± 11[f]	
5.00[g]	T	11.9 ± 0.6	2.50 ± 0.14
5.00[g]	P	29.8 ± 0.1	
5.00[h]	T	3.97 ± 0.16	2.43 ± 0.13
5.00[h]	P	9.66 ± 0.11	
	80% (vol.[a]) acetone, 79.58°		
5.00	T	52.9 ± 0.9	1.89 ± 0.05
5.00	P	100 ± 1	
	70% (vol.[a]) acetone, 79.58°		
5.00	T	142 ± 2	1.68 ± 0.03
5.00	P	238 ± 2	

[a] Based on volumes of pure components at 25° before mixing. [b] T = titrimetric and P = polarimetric. [c] These are values for k_α (polarimetric determinations) and k_t (titrimetric determinations). [d] These values are the average (and mean deviation) of two or more independent kinetic experiments, except as noted. [e] Indicated uncertainty determined from limiting values for k_α and k_t. [f] These values are the average (and mean deviation) of from seven to thirteen determinations within a kinetic experiment. [g] Temperature, 79.58°. [h] Temperature, 70.12°.

Because the conversion of phthalic acid to phthalic anhydride is slow, the calculated rather than the observed infinity titers were used to calculate the first-order titrimetric constants. The constants obtained in this way did not show any significant trends in reactions followed to 75–85% completion. With one exception the values for k_t in Table I are average values of two or more independent kinetic experiments. A typical kinetic experiment is included in the Experimental section.

In order to establish that the solvolysis of I in aqueous acetone involves alkyl–oxygen cleavage, the rate of solvolysis of the saturated analog, 2-pentyl acid phthalate, in 90% acetone at 100° was determined. The rate constant for this compound under these conditions is $7.4 \pm 0.4 \times 10^{-4}$ hr.$^{-1}$ or 1/45 of that for I. Since there is no apparent reason why an allylic ester should undergo acyl–oxygen cleavage more readily than the saturated analog, the observed factor of 145 appears to be compelling evidence that the solvolysis of I involves exclusive alkyl–oxygen cleavage.

As shown in the final column of Table I the polarimetric rate exceeds the titrimetric rate under all conditions where the two were compared. The polarimetric rate constants increase slightly as the initial concentration of acid phthalate is increased, and the titrimetric constants show a somewhat larger increase with increase in concentration. This increase in rate presumably is due to a slight increase in the ionizing power of the medium as the acid phthalate concentration is increased. Both $k\alpha$ and k_t show marked increases as the ionizing power of the solvent is increased; *cf.* rates in 70% and 90% aqueous acetone. The titrimetric rate is slightly more sensitive than the polarimetric rate to increase in ionizing power of the solvent. Thus $k\alpha/k_t$ decreases as the ionizing power increases. This behavior is similar to that observed previously for the solvolysis of *cis*-5-methyl-2-cyclohexenyl acid phthalate in aqueous acetone.[3a]

Excellent linear plots are obtained when log $k\alpha$ or log k_t is plotted against the Y values[8] of the solvents. The slopes of these plots, m,[8] are 0.542 for k_t and 0.454 for k_α. These values are similar to those calculated[8] for the solvolysis of *cis*-5-methyl-2-cyclohexenyl acid phthalate in aqueous acetone[3a] (m = 0.472 for k_t and 0.429 for $k\alpha$). Thus both k_α and k_t show about the same sensitivity to changes in the ionizing power of the solvent in the two systems.

The activation parameters for loss of optical activity ($k\alpha$), solvolysis (k_t) and racemization or SNi′ rearrangement ($k_\alpha - k_t$) in 90% acetone are given in Table II. These data were determined from least-square plots of log k *vs.* $1/T$.

TABLE II

ACTIVATION PARAMETERS FOR THE SOLVOLYSIS OF 0.05 M α,γ-DIMETHYLALLYL ACID PHTHALATE IN "90%" AQUEOUS ACETONE[a]

	E_a[b] kcal./mole	log A	$\Delta H^{\pm}$,[b,c] kcal./mole	$\Delta S^{\pm}$,[b,c] e.u.
$k\alpha$	29.1 ± 0.2	12.974	28.4 ± 0.2	−1.61 ± 0.51
k_t	28.3 ± 0.6	12.077	27.6 ± 0.6	−5.71 ± 1.79
$(k\alpha - k_t)$	29.8 ± 0.8	13.156	29.0 ± 0.8	−0.77 ± 2.0

[a] These values were calculated from the rate constants at 70, 80 and 100° given in Table I. [b] The indicated uncertainties were calculated from the limiting values of the rate constants at 70 and 100°. [c] These values were calculated for 100°.

The present system is a little more reactive than the 5-methyl-2-cyclohexenyl system. In 90% aqueous acetone at 100°, $k\alpha$, k_t and $k\alpha - k_t$ are larger for I than for the isomeric 5-methyl-2-cyclohexenyl acid phthalates by factors of about 5, 3 and 7, respectively.

Discussion

The solvolysis of α,γ-dimethylallyl acid phthalate (I) is similar to that of the isomeric 5-methyl-2-cyclohexenyl acid phthalates[3a] in that $k_\alpha > k_t$ in each case. It appears that the present data are consistent with the mechanism suggested previously[3,4] for the solvolysis and rearrangement of allylic compounds. According to this picture, which is illustrated below for the present system—the indicated rotations for the enantiomers of I have been chosen arbitrarily—an "internal ion-pair"[5] intermediate (II) is common to solvolysis and intramolecular (SNi′) rearrangement. The first-order rate constant for loss of optical activity is $k\alpha$. That for formation of phthalic acid, *i.e.*, the titrimetric rate constant (k_t) is $k_\alpha\, k_2/(2k_1 + k_2)$, and that for the conversion of one enantiomer to the other is $1/2\,(k_\alpha - k_t)$.

In the present system the intramolecular rearrangement results in the interconversion of enantiomers providing that the planar allylic moiety in II has the indicated configuration. The steady polarimetric and titrimetric rates suggest that I reacts *via* the conformation corresponding to the indicated configuration for II, *i.e.*, the configuration with the α- and γ-methyl groups *cis*. If II had the other configuration (*i.e.*, with the methyl groups *trans*) the SNi′ rearrangement would result in the conversion of optically active *trans*-acid phthalate to optically active *cis*-acid phthalate. This would likely disturb the polarimetric and possibly also the titrimetric rate. Scale models also indicate that the configuration indicated for the α,γ-dimethylallylcarbonium ion in II is the more stable one.[9]

It has been shown recently that in the intramolecular rearrangement of α-phenyl-γ-methylallyl[10a] and α-phenylallyl *p*-nitrobenzoate[10b] the carbonyl oxygen atom in the reactant becomes the alkyl oxygen atom in the product. This suggests that there is some covalent bonding between the allylic carbon atoms and the oxygen atoms in the symmetrical intermediate II. However, from the way in which k_α responds to changes in the ionizing power of the solvent, it appears that there must be considerable charge separation in the intermediate.

Experimental

Materials.—*trans*-α,γ-Dimethylallyl alcohol, b.p. 116–121°, n^{20}D 1.4280 (lit.[11] b.p. 116–121°, n^{20}D 1.4280) was prepared according to the previously described method.[11,12] The alcohol was converted[12] to *dl*-*trans*-α,γ-dimethylallyl acid phthalate, m.p. 89–90.5° (lit.[12] 90–90.5°); neut. equiv. found 233.9, calcd. 234.2. The acid phthalate was resolved according to the method of Kenyon, *et al.*[12] The (+)-*trans*-α,γ-dimethylallyl acid phthalate obtained in this way had a melting point of 78–83.6° and $[\alpha]^{25}$D 35.4° (*l* = 4, *c* 1.1, ethanol) (lit.[12] m.p. 82–84°, $[\alpha]$D 38.3° for optically pure material).

Reduction of α,γ-Dimethylallyl Acid Phthalate with Lithium Aluminum Hydride.—The ester was reduced according to the method of Doering and Zeiss.[13] α,γ-Dimethylallyl alcohol, b.p. 116–121°, was isolated in 66% yield. The infrared spectrum of this material was found to have a strong band at 10.4 μ.

Kinetic Experiments.—The kinetic runs were carried out as described previously.[3a] Typical kinetic experiments are summarized in Tables III and IV.

Synthesis of 2,2-Dialkylcyclopropane Nitriles[1]

BY EDWARD R. NELSON, M. MAIENTHAL, L. A. LANE AND A. A. BENDERLY

RECEIVED JANUARY 2, 1957

The ditosylate of 2,2-dimethyl-1,3-propanediol reacted with potassium cyanide in ethylene glycol to give 2,2-dimethylcyclopropane nitrile in 63% yield. In a similar manner, the ditosylate of 2,2-diethyl-1,3-propanediol was converted to 2,2-diethylcyclopropane nitrile. The ditosylates of 1,3-propanediol and 2-methyl-1,3-propanediol failed to yield cyclopropane derivatives when treated under comparable conditions.

In a recent publication, Brown and van Gulick[2] described the synthesis of 2,2-dimethyl-4-methoxybutyronitrile by the treatment of 2,2-dimethyl-3-methoxypropyl tosylate with potassium cyanide in refluxing ethylene glycol. An attempt to adapt this procedure to the preparation of β,β-dimethylglutaronitrile from the ditosylate of 2,2-dimethyl-1,3-propanediol unexpectedly resulted in a cyclopropane nitrile. On hydrolysis, this nitrile gave 2,2-dimethylcyclopropane carboxylic acid, as shown by comparisons of the infrared spectrum of the corresponding amide with that of the amide of an authentic sample prepared by the method of Kishner.[3] Thus the original cyclopropane nitrile was identified as 2,2-dimethylcyclopropane nitrile.

The physical properties of the acid and amide described above corresponded closely to those reported by Kishner,[3] and also by Blanc,[4] for the same compounds prepared by different methods.

A survey of the methods of synthesizing cyclopropane compounds was compiled by Feldman[5] in 1940. Subsequently Schlatter[6,7] concluded that the most satisfactory method of obtaining cyclopropane nitrile involved the halogenation of 1,3-propanediol followed by reaction with sodium cyanide. This procedure resulted in only a 25% yield of the nitrile. Thus, the reaction of the ditosylate of 2,2-dimethyl-1,3-propanediol with potassium cyanide to give a cyclopropane ring structure appeared to be of interest because of the high yield of 2,2-dimethylcyclopropane nitrile (63%) and the ease of preparation of the ditosylate.

Reactions of potassium cyanide with the ditosylates of three other 1,3-glycols were then attempted in an effort to determine the general applicability of this method of ring closure. In the first experiments, treatment of the ditosylate of 2,2-diethyl-1,3-propanediol with potassium cyanide resulted in a 66% yield of 2,2-diethylcyclopropane nitrile. The infrared spectra of the acid and amide of this compound were similar to those obtained from the dimethylcyclopropanes. Presumably, other 2,2-dialkylcyclopropane nitriles could be prepared in a similar fashion.

The ditosylates of 2-methyl-1,3-propanediol and 1,3-propanediol, however, failed to yield cyclopropane derivatives under comparable conditions. This result probably is due to the absence of geminal alkyl groups and related steric effects in these two compounds. Such effects have been studied by Ingold[8] for the reaction of α-bromo-β-alkylglutaric acid with alkali.

None of the cyclopropane compounds prepared in this investigation had infrared bands in the region 1000 to 1020 cm^{-1} which is reported by Bellamy[9] to be a characteristic absorption band for cyclopropane compounds. However, all five compounds had bands of medium intensity nearby: 2,2-dimethylcyclopropane nitrile at 1034 $cm.^{-1}$, 2,2-dimethylcyclopropane carboxylic acid at 1037 $cm.^{-1}$, 2,2-dimethylcyclopropanecarboxamide at 1036 $cm.^{-1}$, 2,2-diethylcyclopropane nitrile at 1024 $cm.^{-1}$ and 2,2-diethylcyclopropane carboxamide at 1024 $cm.^{-1}$. In all likelihood the characteristic region for cyclopropane absorption should be broadened to 1000–1040 $cm.^{-1}$. This is supported by work of Cromwell and Mohrbacher[10] who reported bands in the region 1025–1036 $cm.^{-1}$.

Experimental

Ditosylate of 2,2-Dimethyl-1,3-propanediol.—A solution containing 286 g. (1.5 moles) of *p*-toluenesulfonyl chloride in 500 ml. of pyridine was held below 0°, and 52 g. (0.5 mole) of 2,2-dimethyl-1,3-propanediol in 100 ml. of pyridine was added. The mixture was stirred at 0° for 2 additional hours and then allowed to stand overnight at room temperature. The reaction mixture was poured into 1 liter of water and ice and the solid collected by filtering. The product was washed with water, dilute sulfuric acid, dilute sodium carbonate and again with water. There was obtained 194 g. of the ditosylate (94% yield) which, after two recrystallizations from a mixture of acetone and water, melted at 121–123°; reported 116–120° by Brown and van Gulick.[2]

Anal. Calcd. for $C_{19}H_{24}S_2O_6$: C, 55.3; H, 5.9; S, 15.5. Found: C, 55.4; H, 5.9; S, 14.9.

2,2-Dimethylcyclopropane Nitrile.—A mixture of 206 g. (0.5 mole) of the ditosylate of 2,2-dimethyl-1,3-propanediol and 97.6 g. (1.5 moles) of potassium cyanide in one liter of ethylene glycol was heated. The solids dissolved on warming and the reaction mixture turned dark when its temperature reached 70 to 90°. The distillation product, produced at 175°, consisted of a mixture of two liquids. Distillation of this mixture continued until a vapor temperature of 198° was reached. One-hundred-fifty ml. of a colorless two-phase system was obtained in about 2 hr. The top phase was separated and the lower phase, ethylene glycol, was extracted three times with 100 ml. of *n*-pentane which was combined with the top phase. The pentane was then removed by distillation and the final product, obtained in 63% yield, was a clear liquid with a very sharp boiling point, 154.5–155.5°, $n^{23}D$ 1.4261, and $d^{24.6}_{20}$ 0.8536. It slowly re-

duced a 2% potassium permanganate solution, indicating the presence of some unsaturated material.

Anal. Calcd. for C_6H_9N: C, 75.7; H, 9.5; N, 14.7. Found: C, 75.5; H, 9.7; N, 14.6.

2,2-Dimethylcyclopropane Carboxylic Acid.—The nitrile was hydrolyzed by refluxing with aqueous potassium hydroxide for 48 hr. The colorless acid was collected, b.p. 83–84° (5 mm.), 198–201° (1 atm.), $n^{20}D$ 1.4405 (78% yield); reported for 2,2-dimethylcyclopropane carboxylic acid, b.p. 100° (10 mm.), b.p. 198° (751 mm.),[4] n_D 1.4385.[3] This acid slowly reduced a 2% potassium permanganate solution, indicating the presence of some unsaturated material.

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.1; H, 8.8. Found: C, 63.3, 62.8; H, 8.9, 9.0.

2,2-Dimethylcyclopropane Carboxamide.—The acid was converted into the amide *via* the acid chloride, by action of liquid ammonia upon the latter compound. The amide, after recrystallization from ethyl acetate, gave white needles, m.p. 177–177.5°; reported[4] m.p. 177°, yield 44%.

This amide did not reduce a dilute solution of potassium permanganate in acetone.

Anal. Calcd. for $C_6H_{11}NO$: C, 63.7; H, 9.8. Found: C, 63.7; H, 9.8.

A sample of this amide was hydrolyzed back to the acid using aqueous potassium hydroxide; this acid, $n^{20}D$ 1.4398, did not decolorize dilute potassium permanganate.

2,2-Dimethyl-1-isobutenylcyclopropane.—This synthesis was performed by a modification of methods described by Kishner[3] and Smith and Rogier.[11] To a mixture of 127.4 g. (0.92 mole) of phorone in 250 ml. of absolute ethanol, cooled in an ice-bath, there was added 93.3 g. (1.84 moles) of hydrazine hydrate in small amounts with stirring. After the reaction mixture had cooled, it was heated on a water-bath for an hour. The excess hydrate and ethanol were removed under 15 mm. pressure and a temperature of 80°.

The crude pyrazoline obtained from the above reaction was mixed with 6.2 g. of 5% platinum on asbestos and 14.0 g. of powdered potassium hydroxide, after which it was heated in an oil-bath. At a bath temperature of 175°, 2,2-dimethyl-1-isobutenylcyclopropane began to distil from the reaction mixture with evolution of nitrogen. The temperature of the bath was raised to 200° over a period of 2 hr. by which time the distillation had ceased. Upon redistillation, 69 g. (55% over-all yield) was obtained, b.p. 130–132°.

2,2-Dimethylcyclopropane Carboxylic Acid and its Amide.—A mixture of 25 g. (0.2 mole) of the above hydrocarbon and 63.2 g. (0.4 mole) of potassium permanganate in one liter of water was stirred at room temperature for 4 hr. The manganese dioxide was removed by filtration and the filtrate was made acid to litmus with dilute sulfuric acid. The acid was extracted with ether, and distillation of the ether solution gave 3.7 g. (8.1% yield) of 2,2-dimethylcyclopropane carboxylic acid, b.p. 95–98° (12 mm.). The infrared spectrum showed this material to be somewhat impure.

The amide of this sample was prepared by treating the acid with thionyl chloride and aqueous ammonium hydroxide according to the method of Shriner and Fuson.[12] The amide melted at 177° with sublimation. The spectrum of this amide was the same as that of the amide prepared from the acid originally obtained from the reaction of the 2,2-dimethyl-1,3-propanediol ditosylate and potassium cyanide.

Ditosylate of 2,2-Diethyl-1,3-propanediol.—To 66.1 g. (0.5 mole) of 2,2-diethyl-1,3-propanediol there was added 286 g. (1.5 moles) of *p*-toluenesulfonyl chloride in 600 ml. of pyridine. This synthesis was carried out in the same fashion as that used previously for 2,2-dimethyl-1,3-propanediol. The product was crystallized from acetone yielding 152.1 g. (69% yield), m.p. 109–110°.

Anal. Calcd. for $C_{21}H_{28}O_6S_2$: C, 57.2; H, 6.4. Found: C, 57.2; H, 6.5.

2,2-Diethylcyclopropane Nitrile.—This reaction was conducted in a fashion similar to that described previously for the ditosylate of 2,2-dimethyl-1,3-propanediol. A solution of 152 g. (0.34 mole) of the above ditosylate, 65.1 g. (1.0 mole) of potassium cyanide and a liter of ethylene glycol was heated. A codistillation took place at a vapor temperature of 188° giving a two-phase distillate. The lower phase was extracted with *n*-pentane, and the pentane extract was combined with the upper phase. The combined solution was washed with water, dried with calcium sulfate and distilled. It yielded 28.4 g. (66% yield) of 2,2-diethylcyclopropane nitrile, $n^{20}D$ 1.4422, b.p. 76–77° (8 mm.). The infrared spectrum was similar to that obtained with 2,2-dimethylcyclopropane nitrile.

Anal. Calcd. for $C_8H_{13}N$: C, 78.0; H, 10.6. Found: C, 77.8; H, 10.8.

2,2-Diethylcyclopropane Carboxylic Acid and Amide.—Thirty-five and five-tenths grams of 2,2-diethylcyclopropane nitrile was hydrolyzed by refluxing in an alcoholic solution of potassium hydroxide for 4.5 days. The resulting mixture was filtered and yielded 25 g. of the crude amide (61% yield), m.p. 133–135°. Recrystallization from a mixture of ethyl alcohol and water raised the melting point to 136–137° with sublimation. The amide did not react with dilute potassium permanganate solution in acetone.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.7. Found: C, 67.9; H, 10.6.

The filtrate from the above-described filtration of the amide was extracted with ether and acidified. The acid was extracted with ether. The ether extract was distilled, yielding 7.5 g. (18.2% yield) of 2,2-diethylcyclopropane carboxylic acid, b.p. 109–112° (6 mm.), $n^{25.5}D$ 1.4488.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.6; H, 9.9. Found: C, 67.6; H, 9.8.

Ditosylate of 1,3-Propanediol.—This synthesis also was conducted in a fashion similar to that described previously for the ditosylate of 2,2-dimethyl-1,3-propanediol. Thirty-eight g. (0.5 mole) of propanediol-1,3 was added to 286 g. (1.5 moles) of *p*-toluenesulfonyl chloride in 600 ml. of pyridine, and the product was recrystallized from acetone and water yielding 106 g. (55% yield), m.p. 94°; reported[13] 94°.

Reaction of Potassium Cyanide with the Ditosylate of 1,3-Propanediol.—This reaction was carried out in the same fashion as that described for the ditosylate of 2,2-dimethyl-1,3-propanediol. A solution of 152.1 g. (0.39 mole) of the ditosylate of propanediol-1,3, 77.4 g. (1.19 moles) of potassium cyanide and 750 g. of ethylene glycol was heated and distillation began at 199°. The distillation was stopped when 100 ml. of distillate was collected and found to contain only ethylene glycol.

2-Methylpropanediol-1,3.—To a slurry of 50.4 g. (1.33 moles) of lithium aluminum hydride in 1.5 liters of anhydrous ether, there was added, over a period of 2 hr., 231.9 g. (1.33 moles) of ethyl methylmalonate, b.p. 82–84° (13 mm.), which had been prepared by a method described in "Organic Syntheses."[14] After the addition was completed, the mixture was refluxed for an additional hour. Upon cooling, 25 ml. of 1-propanol was added followed by 250 ml. of saturated sodium chloride solution. After the salts were removed by filtration and the ether by evaporation, the solution was distilled through a two-foot-long vacuum Vigreux column, yielding 41.7 g. (46.3% yield) of 2-methylpropanediol-1,3, b.p. 106–109° (16 mm.), $n^{25}D$ 1.4433; reported[15] b.p. 107–109° (12 mm.); reported[16] n^4D 1.4499.

Ditosylate of 2-Methylpropanediol-1,3.—This synthesis was conducted in a fashion similar to that described for the ditosylate of 2,2-dimethyl-1,3-propanediol. To 45.06 g. (0.5 mole) of 2-methylpropanediol there was added 286 g. (1.5 moles) of *p*-toluenesulfonyl chloride in 600 ml. of pyridine. When the reaction mixture was poured into ice-water, there was obtained an oil which was difficult to crystallize. Recrystallization from methanol four times, and from ether and pentane twice, did not produce a material of sharp or constant melting point. Yield after six recrystallizations: 83.66 g. (42% yield) of white crystals, m.p. 78–83°. The infrared spectrum showed this material to be similar to the other ditosylates and free of hydroxyl groups.

Anal. Calcd. for $C_{18}H_{22}S_2O_6$: C, 54.3; H, 5.6. Found: C, 54.6; H, 5.8.

Reaction of Potassium Cyanide with the Ditosylate of 2-Methylpropanediol.—This reaction was also carried out in the same fashion as that described for the ditosylate of 2,2-dimethyl-1,3-propanediol. A solution of 83.6 g. (0.22 mole) of the ditosylate of 2-methylpropanediol and 43.0 g. (0.66 mole) of potassium cyanide in 600 ml. of ethylene glycol was heated. There was no distillate below the boiling point of ethylene glycol. Extraction of the 175 ml. of distillate with *n*-pentane, and evaporation of the pentane, yielded no product.

Acknowledgments.—The authors are indebted to these members of the National Bureau of Standards: J. Stewart for infrared spectroscopy and the suggestion that the region characteristic of cyclopropane absorption be broadened and R. Paulson and Miss Lorna Tregoning for the analyses.

The Reaction of *t*-Butylethylene and 1-Hexene with Bromine in Methanol[1a]

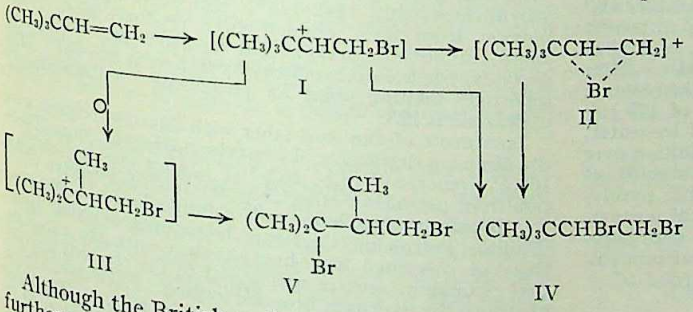
BY W. H. PUTERBAUGH[1b] AND MELVIN S. NEWMAN

RECEIVED JANUARY 23, 1957

The addition of bromine in methanol to *t*-butylethylene produces 1,2-dibromo-3,3-dimethylbutane (IV) and 2-bromo-1-methoxy-3,3-dimethylbutane (VI) in roughly equal amounts. The addition of bromine in methanol to 1-hexene produces about 31% of 1,2-dibromohexane and 59% of a mixture of 1-bromo-2-methoxyhexane and 2-bromo-1-methoxyhexane in the ratio four-to-one, respectively. The mechanism of these reactions is discussed.

The work herein described was undertaken to obtain qualitative evidence about the mechanism of addition of bromine to *t*-butylethylene in particular and to olefins in general. The interest in this work was aroused by the report that the rate of bromination of *t*-butylethylene was only slightly less than that of *n*-butylethylene[2] (0.70 to 1.05).

The rate-determining step undoubtedly involves the formation of a positively-charged bromine-containing intermediate since the rates are first order with respect to olefin and bromine.[2] If the first-formed intermediate is the carbonium ion I, the further reaction of I with the reaction medium might involve attachment of bromine directly to the internal carbon of I. Alternatively, compound I might rearrange to the cyclic bromonium ion II or to skeletally rearranged III. Both I and II would yield the dibromide IV, whereas III would yield the 1,3-dibromide V.



Although the British authors recognized that the further reaction of I would be expected to be slow[3] because of the neopentyl character of the intermediate, they did not go into any further discussion of how I forms final product nor did they prove the structure of the dibromide formed.

In our analysis of this problem we believed that if Compound I were formed directly, it would rearrange rapidly to II which would then be expected to react further at the terminal less hindered carbon to yield IV.[4] The noteworthy feature of this over-all reaction path is that *both bromine atoms enter the final molecule by attack at the terminal carbon*.[5,6]

In order to test this hypothesis, we have studied the reaction of *t*-butylethylene and of *n*-butylethylene with solutions of bromine in methanol, a reagent which adds bromo and methoxy groups to an olefin.[7]

The addition of a solution of bromine in methanol to *t*-butylethylene yielded about 45% of 1,2-dibromo-3,3-dimethylbutane (IV) and 44% of 2-bromo-1-methoxy-3,3-dimethylbutane (VI). The structure of IV was proved by debromination with zinc to yield *t*-butylethylene. The structure of VI was proved by dehydrobromination with sodium amide in liquid ammonia to an unsaturated ether VII, which on treatment with 2,4-dinitrophenylhydrazine reagent afforded the 2,4-dinitrophenylhydrazone of *t*-butylacetaldehyde in high yield. This result supports the hypothesis that both addenda enter the molecule by attack at the terminal carbon, although the first-formed species may be either I or II.

Although the accuracy of our experimental work does not exclude the possibility that small amounts of skeletally rearranged substances were formed, certainly the quantities were very small, if any. This finding is of interest in light of the fact that addition of hydro-

(2) P. W. Robertson, J. K. Heyes and B. E. Swedlund, *J. Chem. Soc.*, 1014 (1952). In this paper steric factors are ruled out on what seems to us inadequate grounds.

(3) However, if the formation of the bromine-containing intermediate I is the rate-determining step, the rate of further reaction of I would not affect the over-all rate.

(4) The stereochemistry of addition of bromine to *cis*- and *trans*-olefins demands an intermediate of type II. However, with *t*-butylethylene it is conceivable that an intermediate of type I could form first and then go into a type II intermediate.

gen chloride to *t*-butylethylene gives from 60 to 65% of rearranged chloride, 2-chloro-2,3-dimethylbutane.[8] Furthermore, when neopentyl-type carbonium ions are formed from neopentyl halides and alcohols by bond cleavage, rearrangement almost always occurs to a large extent.

$$(CH_3)_3CCH{=}CH_2 \xrightarrow[CH_3OH]{Br_2} (CH_3)_3CCHBrCH_2OCH_3$$

$$(CH_3)_3CCHBrCH_2OCH_3 \xrightarrow[NaNH_2]{VI} (CH_3)_3CCH{=}CHOCH_3 \xrightarrow{VII} (CH_3)_3CCH_2CHO$$

For comparison we added bromine in methanol to 1-hexene and obtained about 31% of dibromide and 59% of methoxybromide.[9] The latter was shown to consist of about 4–5 parts of 1-bromo-2-methoxyhexane to 1 part of 2-bromo-1-methoxyhexane by dehydrobromination to a mixture of enol ethers VIII and IX. The composition of this mixture was estimated by crude separation of the 2,4-dinitrophenylhydrazones obtained therefrom and by hydrolysis to a mixture of 2-hexanone and hexanal which was analyzed by oxidation and titration of the hexanoic acid produced, as described in the Experimental part. Further work in this field is being carried out.

$$n\text{-}C_4H_9CH{=}CH_2 \xrightarrow[CH_3OH]{Br_2} \xrightarrow{NaNH_2} C_4H_9C(OCH_3){=}CH_2 + C_4H_9CH{=}CHOCH_3$$

$$C_4H_9C(OCH_3){=}CH_2 \xrightarrow{VIII} C_4H_9COCH_3 \qquad C_4H_9CH{=}CHOCH_3 \xrightarrow{IX} C_4H_9CH_2CHO$$

Experimental[10]

***t*-Butylethylene.**—To a stirred mixture of 12.6 g. (0.33 mole) of lithium aluminum hydride and 350 ml. of ether was added dropwise over 3.25 hr., 100 g. (1.00 mole) of pinacolone[11] in 125 ml. of ether. After stirring and refluxing for 45 minutes the mixture was cooled to room temperature and 163 g. (1.60 moles) of acetic anhydride added dropwise over 1.5 hr. The mixture was refluxed for 4 hr. and 84 g. (1.40 moles) of glacial acetic acid then added rapidly. After stirring overnight (12 hr.) at room temperature the reaction mixture was decomposed by adding a solution of 120 ml. of concentrated hydrochloric acid in 240 ml. of ice-water. The crude acetate was pyrolyzed by dropwise addition over 3 hr. to a pyrolysis tube heated to 510° under a constant stream of nitrogen as described previously.[12] The pyrolysate was taken up in toluene, washed with several portions of saturated sodium bicarbonate solution, once with saturated sodium chloride solution and dried over calcium sulfate. Distillation at atmospheric pressure afforded 57 g. (68%) of *t*-butylethylene, b.p. 40–42°.

Bromomethoxylation of *t*-Butylethylene.—To a stirred ice-cooled solution of 31 g. of *t*-butylethylene in 1 l. of absolute methanol protected from light was added dropwise over 3.5 hr. a solution of 60 g. of bromine in 300 ml. of methanol. After stirring for an additional 0.5 hr., the mixture was poured into 2 l. of ice-water containing 20.2 g. of sodium bicarbonate. The mixture was extracted with petroleum ether, b.p. 35–40° (Skellysolve F). Rectification of the washed and dried reaction products through a small packed column afforded 32 g. (44%) of methoxybromide IV, b.p. 81–82° at 30 mm., and 41 g. (45%) of dibromide III, b.p. 100–101° at 30 mm.

The methoxybromide fraction was redistilled to obtain an analytical sample of 1-methoxy-2-bromo-3,3-dimethylbutane (IV), b.p. 81° at 30 mm., $n^{20}D$ 1.4588, d^{27} 1.214.

Anal. Calcd. for $C_7H_{15}OBr$: C, 43.1; H, 7.8; Br, 41.0. Found: C, 43.0; H, 7.6; Br, 41.1.

The dibromide fraction also was redistilled to obtain an analytical sample of III,[13] b.p. 85° at 12 mm., $n^{20}D$ 1.5055, d^{27} 1.620.

Anal. Calcd. for $C_6H_{12}Br_2$: C, 29.5; H, 5.0; Br, 65.5. Found: C, 29.7; H, 5.1; Br, 65.3.

Debromination of III.—A solution of 40 g. of III in 40 ml. of alcohol was added dropwise with stirring to a mixture of 33 g. of zinc dust and 80 ml. of alcohol. After the exothermic reaction moderated, the mixture was heated and stirred for 90 minutes. There was isolated 6.6 g. (48%) of pure *t*-butylethylene, identical in physical properties and infrared spectrum to authentic *t*-butylethylene. No other olefin was found in appreciable amount.

Dehydrobromination of *t*-Butylethylene Methoxybromide (IV).—To a stirred suspension of sodium amide prepared from 5.2 g. (0.226 mole) of sodium and 450 ml. of liquid ammonia was added over 0.5 hr. 40 g. (0.205 mole) of IV in 100 ml. of ether. The mixture was stirred for 1.5 hr. in liquid ammonia until the ammonia evaporated, then refluxed for 0.5 hr. in ether. To the cooled mixture was added 100 ml. of ether followed by 75 ml. of water. The washed and dried reaction products on rectification yielded 12.7 g. (54%) of the enol ether, b.p. 100–106° at 750 mm., and 11.4 g. (28%) of recovered IV, b.p. 75–80° at 30 mm. The enol ether was redistilled to yield 11.5 g. (49%) of 1-methoxy-3,3-dimethyl-1-butene (VII), b.p. 103–106°.

After stirring with saturated sodium bisulfite solution, the enol ether was redistilled to give the analytical sample, b.p. 106° at 750 mm., $n^{20}D$ 1.4092.

Anal. Calcd. for $C_7H_{14}O$: C, 73.6; H, 12.4. Found: C, 73.7; H, 12.6.

Proof of Structure of VII.—To the reagent prepared from 1.7 g. of 2,4-dinitrophenylhydrazine, 3.5 ml. of concentrated hydrochloric acid and 35 ml. of 95% ethanol was added 1.0 g. of VII obtained as described above. An immediate precipitate formed which on cooling was filtered to yield 2.21 g. (92%) of *t*-butylacetaldehyde 2,4-dinitrophenylhydrazone, m.p. 142–146°. One recrystallization of a portion from 95% ethanol gave product, m.p. 147.5–148.0°, in 90% recovery. The reported[14] m.p. for *t*-butylacetaldehyde 2,4-dinitrophenylhydrazone is 146–147°. The reported[15] melting point for pinacolone 2,4-dinitrophenylhydrazone is 125°.

Treatment of the enol ether with dimedon reagent gave the dimedon derivative of *t*-butylacetaldehyde, m.p. 163.0–163.5° (reported[15] m.p. 162–163°), after one recrystallization from petroleum ether (b.p. 90–100°, Skellysolve C).

Bromo-methoxylation of *n*-Butylethylene.—Hexene-1 (Phillips Petroleum Co.) was bromo-methoxylated essentially as described for *t*-butylethylene with the exception that potassium acetate was added to the reaction mixture to absorb the hydrogen bromide formed. From the addition during 2 hr. of 119 g. (0.72 mole) of bromine in 450 ml. of methanol to 60 g. (0.714 mole) of hexene-1 and 74 g. (0.72 mole) of potassium acetate dissolved in 1300 ml. of methanol, there was obtained on distillation at 15 mm., 73 g. of methoxybromide, b.p. 75–78°; 20 g. of intermediate fraction, b.p. 78–88°, and 44 g. of dibromide, b.p. 88–90°. Assuming the intermediate fraction to consist of equal amounts of methoxybromide and dibromide, the yield of methoxybromide was 59% and of dibromide 31%.

Redistillation of the methoxybromide fraction gave an analytical sample, b.p. 68° at 10 mm., $n^{23}D$ 1.4495.

(8) G. G. Ecke, N. C. Cook and F. C. Whitmore, THIS JOURNAL, **72**, 1511 (1950).

(9) This proportion was obtained when potassium acetate was present. When no potassium acetate was present, a lower proportion of methoxybromide was obtained, but qualitatively the rate of bromine addition (decolorization) seemed about the same.

Anal. Calcd. for $C_7H_{15}OBr$: C, 43.1; H, 7.8; Br, 41.0. Found: C, 43.0; H, 7.9; Br, 41.2.

Dehydrobromination of *n*-Butylethylene Methoxybromide.—Treatment of 50 g. (0.256 mole) of the methoxybromide obtained from *n*-butylethylene with sodium amide prepared from 6.9 g. (0.3 mole) of sodium essentially as described above for *t*-butylethylene methoxybromide gave on distillation, 11.2 g. (38%) of enol ether, b.p. 120–126° (760 mm.), and 14.1 g. (28%) of recovered methoxybromide, b.p. 75–80° (20 mm.). There was also obtained 4.9 g. (23%) of hexyne-1, b.p. 60–64°. The enol ether fraction was redistilled to obtain an analytical sample, b.p. 122° at 750 mm.

Anal. Calcd. for $C_7H_{14}O$: C, 73.6; H, 12.4. Found: C, 73.5; H, 12.4.

Structure of Enol Ether Obtained from *n*-Butylethylene Methoxybromide.—To the 2,4-dinitrophenylhydrazine reagent prepared from 1.7 g. of 2,4-dinitrophenylhydrazine, 3.5 ml. of concentrated hydrochloric acid and 40 ml. of 95% ethanol was added 1 g. of the enol ether fraction, b.p. 120–126°, obtained as described above. The precipitate was filtered to yield 2.1 g. (89%) of a mixture of methyl *n*-butyl ketone and *n*-hexaldehyde 2,4-dinitrophenylhydrazones, m.p. 80–102°. Recrystallization of a 1.33-g. portion from 60 ml. of 95% ethanol gave as first crop, 0.88 g. (66%) of short orange crystals, m.p. 103.5–107°. The mixed m.p. with authentic methyl *n*-butyl ketone 2,4-dinitrophenylhydrazone (m.p. 107.5–108.5°) was 106–108°. Partial evaporation and freezing of the filtrate yielded 0.4 g. of yellow-orange crystals, m.p. 82–95°. From the latter it was possible to separate by hand a few long yellow needles, m.p. 105.5–107.5°, mixed m.p. with authentic *n*-hexaldehyde 2,4-dinitrophenylhydrazone (m.p. 105.5–107.5°) 106.0–107.5°. However, attempts to further separate the second crop quantitatively by recrystallization and chromatography were unsuccessful.

The amount of terminal enol ether in the enol ether mixture, which was shown above to be less than 34%, was estimated by conversion to a mixture of aldehyde and ketone, oxidation of the mixture with silver oxide and titration of the acid formed from oxidation of the aldehyde, as described below.

A mixture of 8.5 g. of enol ether, 2 ml. of concentrated hydrochloric acid, 6 ml. of water and 10 ml. of ethanol was refluxed 5 minutes. The mixture was diluted with water, taken up in ether, dried and distilled to yield 5 g. (67%), b.p. 124–125°, of a mixture of methyl *n*-butyl ketone and *n*-hexaldehyde. To a silver oxide reagent prepared from 3.40 g. of silver nitrate in 10 ml. of water and 2.40 g. of sodium hydroxide in 10 ml. of water was added 2.50 g. of the ketone–aldehyde mixture. After stirring for 30 minutes, the mixture was filtered with suction and extracted with ether. The aqueous layer was then carefully acidified, salted out and extracted with four 20-ml. portions of ether. The ether extracts were washed with saturated sodium chloride solution and dried. Removal of the solvent left an acidic residue, which on titration with standard base was shown to contain 4.7 mmoles (19%) of acid calculated as caproic acid. The acid isolated from this titration was refluxed with excess aniline for 2 hr. One recrystallization of the crude anilide from 95% ethanol gave *n*-caproanilide, m.p. 95.0–95.5° (reported[16] m.p. 96°). A duplicate run gave an acid yield of 15%. A check on the method with a mixture of 0.02 mole of methyl ethyl ketone and 0.005 mole of *n*-heptaldehyde gave on titration 0.0049 mole (98% of theory) of acid formed.

The enol ether formed from dehydrobromination of the methoxybromide obtained from *n*-butylethylene was thus shown by these methods to consist of approximately 80–85% of 2-methoxyhexene-1 and 15–20% of 1-methoxyhexene-1.

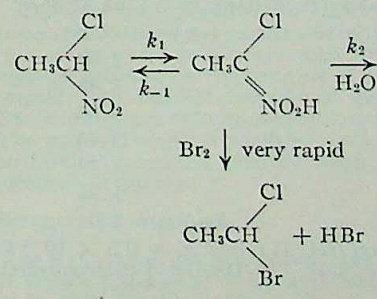
aci-Nitroalkanes. IV. The Mechanism of the Hydrolysis of 1-Chloronitroethane

BY M. FREDERICK HAWTHORNE AND R. DONALD STRAHM

RECEIVED FEBRUARY 11, 1957

In water at 35.0° and in independent first-order rate determinations, 1-chloronitroethane has been found to release chloride ion approximately one-third as rapidly as it absorbs bromine. 1-Deutero-1-chloronitroethane when examined in an identical manner showed approximately a twofold diminution in both measured rate constants. These facts prove that the hydrolytic release of chloride ion from 1-chloronitroethane is preceded by a tautomerization to the reactive *aci*-isomer and that return of the *aci*-isomer to reactant is kinetically important relative to the hydrolysis of the *aci*-isomer. The products of hydrolysis of 1-chloronitroethane have been found to be equivalent amounts of hydrogen chloride, acetic acid and a colorless gas which is probably nitrous oxide. Conductometric examination of the rate of hydrolysis of 1-chloronitroethane affords an instance in which the approach of a reaction system to a steady state situation may be observed.

It was recently reported by Pearson and Dillon[1] that 1-chloronitroethane hydrolyzed in aqueous solution at 34.9° to yield chloride ion at a rate equal to approximately one-half the rate at which the same nitroalkane ionized (absorbed bromine) under the same conditions. In view of the recent finding that the displacement of chloride ion from 1-chloronitroethane by nitrite ion is preceded by the tautomerization of the nitro compound to its *aci*-nitroisomer, it was proposed[2] that the hydrolysis of 1-chloronitroethane and the kinetic observations of Pearson and Dillon[1] could be explained on a similar basis if the rate of return of *aci*-1-chloronitroethane to its hydrolytically stable isomer were comparable to the rate of displacement of chloride ion from the reactive *aci*-isomeride by solvent water ($k_{-1} \sim k_2$).



Therefore

$$\frac{d[Cl^{\ominus}]}{dt} = \frac{k_1 k_2}{k_{-1} + k_2}[CH_3ClNO_2] \text{ and}$$

$$\frac{-d[Br_2]}{dt} = k_1[CH_3ClNO_2] \quad (1)$$

Since both the rate of chloride ion release and the rate of bromination depend, according to this rationalization, upon the magnitude of the ionization rate constant, k_1, both reactions should show a kinetic primary isotope effect of equal magnitude when deuterium is substituted for protium on the carbon atom alpha to the nitro group.[2] This prediction has been confirmed within possible experimental error and the products of hydrolysis determined.

Results

1-Chloronitroethane was purified carefully by regeneration from its anion followed by fractional distillation[2] and 1-deutero-1-chloronitroethane was prepared by regeneration in deuterium oxide and fractionally distilled.[2]

The initial rates of ionization of these two materials in water at 35.0° were determined under zero-order conditions by the conductometric bromination method of Pearson and Dillon.[1] Table I summarizes the ionization rate constants of both the protium (k_{iH}) and deuterium (k_{iD}) compounds.

TABLE I

THE RATES OF IONIZATION OF 1-CHLORO- AND 1-DEUTERO-1-CHLORONITROETHANE IN WATER AT 35.0°

Init. concentrations, mole/l. $(Br_2) \times 10^2$	(CH_3CHNO_2Cl)	k_i,[a] min.$^{-1} \times 10^5$
1.53	0.0509	11.7
1.45	.102	12.7
2.06	.974	12.0
0.66	.040[b]	6.00
.71	.0772[b]	6.37
.10	.0795[b]	6.00
		$k_{iH}/k_{iD} \sim 2.0$

[a] Pearson and Dillon (ref. 1) report $k_i = 1 \times 10^{-4}$ min.$^{-1}$ at 34.9° for protium compound. [b] 1-Deutero-1-chloronitroethane.

Table II reports the initial first-order rate constants obtained for the hydrolytic release of chloride ion from both 1-chloronitroethane (k_{sH}) and its 1-deutero analog (k_{sD}) in water at 35.0°. These first-order rate constants were obtained by direct titration of released chloride ion and the rate runs were carried to approximately 25% completion in every case.

TABLE II

THE RATE OF CHLORIDE ION RELEASE BY 1-CHLORO- AND 1-DEUTERO-1-CHLORONITROETHANE IN WATER AT 35.0°

$[CH_3CHNO_2Cl]$, mole/l. $\times 10^2$	k_s,[a] min.$^{-1} \times 10^5$
0.97	3.50
1.99	3.49
3.48	3.56
3.56	3.45
0.88[b]	1.70
2.76[b]	1.75
	$k_{sH}/k_{sD} \sim 2.0$

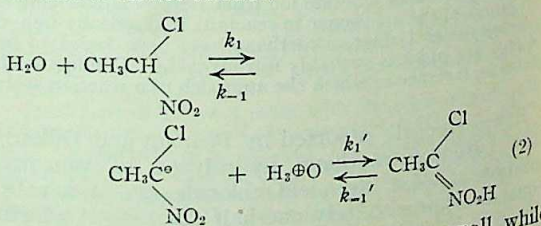
[a] Pearson and Dillon (ref. 1) report $k_s = 0.5 \times 10^{-4}$ for protium compound at 34.9°. [b] 1-Deutero-1-chloronitroethane.

The products of the hydrolysis of 1-chloronitroethane were accounted for in a quantitative fashion when the hydrolysis reaction was carried out in a sealed tube at 100°. These products consisted of one mole of hydrogen chloride and one mole of acetic acid per mole of 1-chloronitroethane consumed. The acetic acid was identified by conversion to its *p*-nitrobenzyl ester and by its characteristic potentiometric titration curve. Hydrogen chloride was determined by chloride ion analysis and by potentiometric titration of hydrogen ion. In addition to these products a considerable but undetermined amount of a colorless gas was produced which presumably was nitrous oxide. Nitrite ion was not present.

Discussion

Since the substitution of the 1-protium by deuterium produces an approximate twofold diminution in both rates of ionization and hydrolysis of 1-chloronitroethane at 35.0°, it may be concluded that the over-all hydrolysis reaction involves the breaking of a carbon–hydrogen bond prior to the expulsion of chloride ion. The near constant ratio of k_i to k_s which is equal to approximately 3.4 and which is obtained regardless of the isotopic nature of the reactant 1-chloronitroethane points up the fact that only a definite fraction of the molecules of 1-chloronitroethane which tautomerize to the *aci*-isomer react in such a manner as to produce chloride ion. All of these results are best rationalized in terms of the formulation (1) in which $k_{-1} \sim 2.4k_2$.

An additional piece of evidence also was obtained which indicates the correctness of this rationale. It was observed that freshly prepared aqueous solutions of 1-chloronitroethane initially gave only a very low rate of increase in conductance with time. However, this rate of increase of conductance increased as time progressed and finally became a linear function of time. Similarly, aqueous solutions of 1-chloronitroethane which had been employed in conductometric bromination rate determinations gave similar conductance *vs.* time curves following the consumption of the initially added bromine. These observations fit the proposed reaction scheme since the equilibria 2 are involved in the transformation of 1-chloronitroethane to its *aci*-isomer.



In these equilibria[3] k_1 and k_{-1} are small while k'_1 and k'_{-1} are large and k'_1/k'_{-1} may be of the order of 10^3. Thus, a solution which contains only very little *aci*-1-chloronitroethane will show a small initial conductance. However, as ionization (k_1 process) proceeds, the products of this ionization will be an equilibrium mixture of the solvolytically inert 1-chloronitroethane anion and the reactive *aci*-1-chloronitroethane. As a result of this situation, the first 1-chloronitroethane which ionizes will produce the electrolytes hydrogen ion and 1-chloronitroethane anion, but as these products accu-

(3) See D. Turnbull and S. H. Maron, THIS JOURNAL, 65, 212 (1943), for a discussion of similar equilibria.

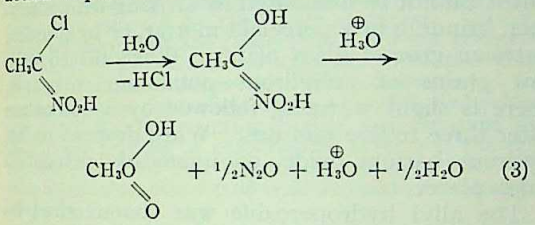
mulate the concentration of *aci*-1-chloronitroethane will increase and the rate of appearance of the products of the hydrolysis of this material will also increase. Since these products are hydrogen ion, chloride ion and dissociated acetic acid, an enhancement in the rate of increase of conductance will occur until the concentrations of 1-chloronitroethane anion and *aci*-1-chloronitroethane reach the steady state concentrations of the reaction system. The length of time required to reach the steady state condition was roughly inversely proportional to the initial concentration of substrate. Figure 1 illustrates this point.

The products of the hydrolysis of 1-chloronitroethane may be explained on the basis of the reaction sequence 3 in which the proposed reaction



takes the course of the nucleophilic displacement of chloride ion by water followed by a Nef reaction[4] of the resulting *aci*-1-hydroxynitroethane.

Experimental

Materials.—The 1-chloronitroethane was a portion of material which had been purified previously for another study.[2] The 1-deutero-1-chloronitroethane was similarly a portion of previously prepared material.[2]

The solvent water employed in the conductometric experiments gave an infinite resistance reading in the apparatus employed and had been prepared by the passage of distilled water through a commercial Deeminizer ion exchange column.

Rates of Bromination.—The rates of bromination were determined using low concentrations of bromine (1×10^{-4} to 2×10^{-3} *M*) and much greater concentrations of 1-chloronitroethane or 1-deutero-1-chloronitroethane in conductivity water at 35.00 + 0.01°. Resistance readings were obtained in a low resistance conductivity cell using a Leeds and Northrup conductivity apparatus and a General Electric Type ST-2A oscilloscope as a null point indicator.

An accurately measured small volume of a standard aqueous bromine solution was added to a known volume of a 1-chloronitroethane solution prepared from a weighed amount of nitroalkane at zero time. Both solutions were thermostated previous to the time of mixing. Resistance readings were taken at various time intervals and conductance plotted *vs.* time. Linear plots were obtained up to the time at which all of the added bromine was consumed. Beyond this point the conductance remained constant for a few moments and then began to rise at a progressively greater rate until a new linear conductance *vs.* time curve was established. The curves of Fig. 1 are similar to those obtained under these conditions. The time, *t*, required for the consumption of the known added bromine $[Br_2]_0$, was used along with the initial nitroalkane concentration, $[RNO_2]_0$, to calculate the first-order ionization rate constant, k_1.

$$k_1 t = [Br_2]_0/[RNO_2]_0$$

The deuterated substrate was treated in an identical fashion as were the experiments which were carried out in the absence of bromine.

(4) See M. F. Hawthorne, THIS JOURNAL, **79**, 2510 (1957), for a recent discussion of the mechanism of this reaction.

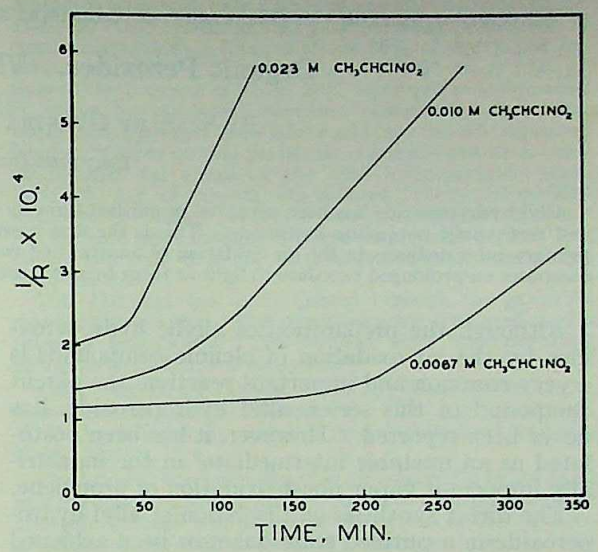


Fig. 1.—Conductivity *vs.* time curves for the hydrolysis of 1-chloronitroethane in water at 35.0°.

Rates of Hydrolysis.—Solutions of 1-chloronitroethane or 1-deutero-1-chloronitroethane were prepared in distilled water and thermostated at 35.00 ± 0.01°. Periodically, aliquots were withdrawn and chloride ion was titrated potentiometrically with 0.01 *N* standard silver nitrate solution using a Beckman model G *p*H meter with silver and calomel electrodes. The titration data were treated graphically and a correction was applied for the solubility of silver chloride. The reactions were carried to approximately 25% completion in every case and the first-order hydrolysis rate constants were obtained graphically from a plot of log [chloronitroethane] *vs.* time.

Product Analysis.—1-Chloronitroethane (1.180 g.) and 6 ml. of water were sealed in a glass tube and heated in a steam-bath for two weeks. The tube was then cooled to −80° and opened. A considerable quantity of colorless gas was released when the tube was opened. The contents were carefully washed into a 50-ml. volumetric flask and diluted to the mark with the distilled water.

A 10-ml. aliquot of the solution was titrated for chloride ion by the Mohr method after neutralizing with sodium hydroxide. The solution was found to be 0.215 *M* in chloride ion (99.7% of theoretical for complete hydrolysis). The concentration of hydrogen ion was found to be 0.427 *M* by the titration of another 10-ml. aliquot to a phenolphthalein end-point with standard sodium hydroxide.

A second acid titration was carried out on a 10-ml. aliquot using a Beckman *p*H meter. A break occurred at *p*H 3.1 indicating the solution to be 0.214 *M* in a strong acid. Another very sharp break occurred just beyond *p*H 7 giving a total hydrogen ion concentration of 0.427 *M*. A qualitative test for nitrite ion was negative.

The weak acid present in the reaction mixture was shown to be acetic acid by the partial neutralization of a 20-ml. portion of the reaction mixture with 10% sodium hydroxide solution followed by the addition of 0.5 g. of *p*-nitrobenzyl bromide and sufficient ethanol to give solution at reflux. The solution was refluxed several hours and cooled with ice. The material which crystallized melted at 72.5°[5] and gave an infrared spectrum identical with that of authentic *p*-nitrobenzyl acetate.

HUNTSVILLE, ALABAMA

(5) R. L. Shriner and R. C. Fuson, "The Systematic Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1947, report the melting point of *p*-nitrobenzyl acetate to be 78°.

Organic Peroxides. VI. Allyl Hydroperoxide[1]

BY STANLEY DYKSTRA AND HARRY S. MOSHER

RECEIVED OCTOBER 31, 1956

Allyl hydroperoxide has been prepared in purified form by the reaction of allyl methanesulfonate with hydrogen peroxide and methanolic potassium hydroxide. This is the first member of the series of allylic type hydroperoxides which are the primary intermediates in the air oxidation of unsaturated compounds. Allyl hydroperoxide detonates on heating and decomposes on prolonged exposure to light at room temperature but is relatively stable in the cold and dark.

Although the preparation of allylic hydroperoxides by the air oxidation of olefinic compounds is a very common and important reaction, the parent compound of this series, allyl hydroperoxide, has never been reported. However, it has been postulated as an unstable intermediate[2] in the industrially important vapor phase oxidation of propylene.

The direct synthesis and isolation of allyl hydroperoxide in a purified state has now been achieved by the action of hydrogen peroxide on allyl methane sulfonate by the method of Williams and Mosher.[3] Although the usual procedure[3] gave solutions indicating allyl hydroperoxide yields of 30–40% as measured by titration, considerable difficulty was experienced in isolation and purification because of its unstable nature. It underwent slow decomposition at 40–60° with the formation of an explosive polymeric residue. It detonated when heated rapidly in a capillary tube. The distilled but impure product, which was known to contain at least water and hydrogen peroxide, was very sensitive to light. Exposure to artificial room illumination for only ten minutes resulted in extensive destruction in some of the impure samples of allyl hydroperoxide as evidenced by the appearance of a carbonyl band at 5.95 μ in the infrared spectrum. Because of the decomposition of these crude preparations in the presence of light and heat, the preparation and purification of allyl hydroperoxide was conducted entirely in Pyrex low actinic glassware in the presence of artificial illumination from a photographic red light; initial purification was accomplished by evaporative distillation below 20°; final purification was by gas–liquid partition chromotography.[4] Samples so purified did not show this rapid decomposition on exposure to light.

The sensitivity to light must be dependent upon impurities and cannot be the result of enhanced absorption and photodissociation since the ultraviolet absorption spectrum of allyl hydroperoxide (log ϵ 0 at 312 mμ) shows only a slight bathochromic shift from that of *n*-butyl hydroperoxide (log ϵ 0 at 302 mμ) which is stable to ordinary light. Thus the amount of light which will pass through a Pyrex flask and be absorbed by allyl hydroperoxide must be extremely small.

Allyl hydroperoxide is extremely irritating to the mucous membrane of the nose. Even the slightest contact with the skin causes a prolonged burning sensation and blisters which persist for approximately one week. It detonates when heated, but it cannot be detonated by striking with a hammer, grinding in a porcelain mortar, or by grinding between ground glass plates. When placed on a few grains of anhydrous potassium carbonate, there is slight warming followed by a detonation after three to five minutes. When dropped on anhydrous barium oxide, an immediate detonation takes place.

The allyl hydroperoxide was characterized by carbon hydrogen analysis, active oxygen determination, infrared and ultraviolet spectra, positive reaction to bromine in carbon tetrachloride, solubility in cold dilute sodium hydroxide solution and reduction to propanol.

The starting material, allyl methanesulfonate, could not be made by the procedure of Sekera and Marvel.[5] The method which Hahn and Walter[6] developed for the preparation of allyl phenylsulfonate was also unsatisfactory, although it did result in a 20% yield of allyl methanesulfonate. The treatment of methanesulfonyl chloride and allyl alcohol in ether solution with powdered potassium hydroxide also gave very low yields. These findings correspond to those reported by Raphael and Sondheimer[7] in the preparation of 2-octyne-1-methanesulfonate. However, by the slow addition of methanesulfonyl chloride to an allyl alcohol–ether solution of sodium alloxide, yields up to 68% of allyl methanesulfonate were finally achieved.

Experimental

Allyl Methanesulfonate.—Sodium, 6.9 g. (0.3 mole), was allowed to dissolve in anhydrous allyl alcohol, 100 g., and the resulting solution was diluted with 100 ml. of anhydrous ether. This solution was cooled to 0° and rapidly stirred while methanesulfonyl chloride, 36 g. (0.31 mole), dissolved in 200 ml. of anhydrous ether, was added over a 2-hr. period. The reaction mixture was held at about −5° for 2 hr. and allowed to warm to room temperature overnight. The salt was removed by filtration, the filtrate was evaporated under 20 mm. pressure and the residue was distilled over a little potassium carbonate; b.p. 70–75° (3 mm.), 28 g. (68.5%), n^{20}D 1.4414.

Anal. Calcd. for $C_4H_8O_3S$: C, 35.30; H, 5.92. Found: C, 35.39; H, 5.78.

Lower yields were obtained when the allyl alcohol was not freshly distilled or when the methanesulfonyl chloride was added too rapidly with inefficient stirring. Yields from 55 to 68% were consistently obtained by the above procedure.

Allyl Hydroperoxide.—The following procedure was con-

ducted in Pyrex, low actinic, glassware in a room illuminated with a red photographic light bulb. Care was taken so that the reaction mixture never came into contact with metal such as nickel from a spatula, iron or rust from a metal stirrer, etc. At any point where the allyl hydroperoxide was being heated or concentrated by evaporation, the apparatus was surrounded by a safety shield and sand bags.

Allyl methanesulfonate, 10.8 g. (0.08 mole), was dissolved in methanol, 30 ml., and 30% reagent grade hydrogen peroxide, 44 g. (0.44 mole), was added after the temperature had reached 0° by cooling with an external ice–salt-bath. While the temperature was kept at 0°, 50% potassium hydroxide solution, 10.1 g. (0.09 mole), was added slowly dropwise with vigorous stirring over a fifteen-minute period. The mixture was stirred for 1 hr. at 0° and then allowed to warm to 20° over a 2-hr. period. The reaction mixture was cooled to 0°, made strongly basic with 50% potassium hydroxide solution, 10.1 g., and subjected to vacuum evaporation at 15° or below until 30 g. of distillate had been collected in the Dry Ice trap. Most of the methanol, some water and a small amount of hydrogen peroxide were removed by this latter operation. Care was taken to ensure that the concentration did not go beyond this point. The residue was extracted with two 15-ml. portions of ether to remove any non-volatile neutral substances and then neutralized at 0° with 15% hydrochloric acid to *p*H 6. The resulting solution was extracted with four 20-ml. portions of peroxide-free ether and the ether extracts were dried over anhydrous sodium sulfate. This ether solution contained 0.06 mole of total peroxide by titration.[8]

The major portion of the ether was removed below 15° at 150 mm. pressure through a 12-inch column packed with Pyrex helices. The residue was then evaporatively distilled at room temperature or below by progressively lowering the pressure to 6 mm. The fractions were collected in a series of traps kept at 0, −20 and −75°. The residue was about 0.5 g.[9] Each fraction was qualitatively analyzed by gas-liquid partition chromatography.[10] The −75° trap contained ether with only a trace of any allyl hydroperoxide. The −20° trap contained 0.93 g. which was estimated to be contaminated with a total of about 35% of water and hydrogen peroxide.[11] The contents of the 0° trap, 1.95 g., showed the presence of about 20% hydrogen peroxide and/or water by gas–liquid partition chromatography. The water and hydrogen peroxide could not be distinguished from each other on this particular column,[10] but both came off together far ahead of the allyl hydroperoxide peak. From 250 mg. of this cut was isolated 110 mg. of purified allyl hydroperoxide. Isolation was accomplished by passing the exit gases through a micro trap cooled in Dry Ice, during the time that the allyl hydroperoxide was exiting from the tube.[12]

This 110 mg. was again passed through the gas chromatography column. The partitionogram indicated only a trace of impurities.[13] The isolated allyl hydroperoxide, 58 mg., $n^{20}D$ 1.4200, was analyzed.[14]

Anal. Calcd. for $C_3H_6O_2$: C, 48.61; H, 8.16; O, 43.23; active oxygen, 21.58. Found: C, 47.87; H, 8.52; O, 43.61 (by difference); active oxygen (determined by titration[8]), 20.8%.

The infrared spectrum of a thin film showed a broad band at 3.0 μ characteristic of the O–H bond of the hydroperoxide molecule. There was moderate absorption at 6.15 μ characteristic of the double bond. This sample showed no discrete absorption at 5.8–6.0 μ indicating the absence of carbonyl impurities. There were strong peaks at 3.5, 7.09, 7.48, 10.12 (shoulder at 9.90), 10.74 and 12.28 μ. All primary hydroperoxides have shown this latter band.[1b] Weaker bands occurred at 5.38, 8.00, 8.70 and 11.64 μ. The latter is at the position assigned to the O–O stretching frequency of the peroxide bond.[1b]

Acknowledgment.—We are grateful to the California Research Corporation for a grant which made this investigation possible.

(8) C. D. Wagner, R. H. Smith and E. D. Peters, *Anal. Chem.*, **19**, 976 (1947).

(9) The amount of residue varied from slight, as in this experiment, to 3 g. if the distillation had been carried out slowly at a bath temperature of 50°. In every case this residue would detonate if a drop was heated in a test-tube over a free flame. Three drops were sufficient to shatter completely an eight-inch Pyrex test-tube. The explosive nature of this residue was lost slowly on standing. In one of the earlier experiments when the distillation was complete but the distillation flask containing the residue was still in an oil-bath at approximately 110°, a detonation occurred which completely destroyed the apparatus. The decomposition of allyl hydroperoxide and the nature of this polymer will be studied further.

(10) The column was a 100 × 0.6 cm. Pyrex tube packed with 60 mesh fire brick.[4] The fire brick had been digested with hydrochloric acid, followed by ammonium hydroxide treatment and thoroughly leached with distilled water, then dried and impregnated with G.E. SF-81 (40) silicone oil. The column was run at 38°, 8 p.s.i. with a helium through-put of 205 ml. min. Under these conditions the retention time for ether was 1.0 min., for allyl alcohol was 1.9 min., for benzene was 5.0 min. and for allyl hydroperoxide was 7.3 min. The samples were injected with an all-glass capillary pipet. The high flow rate was employed so that the temperature could be kept below 40°.

(11) Several previous experiments indicated that the water could not be separated satisfactorily by simple distillation. Successive dryings over anhydrous copper sulfate appeared to be the most efficient way to dry the product but led to extensive decomposition. Therefore anhydrous sodium sulfate was used as the drying agent although it did not appear to be too effective.

(12) Because of the very high flow rate of helium carrier gas during these isolations,[10] the recovery was very poor. On several calibration runs under approximately the same conditions, using allyl alcohol as a standard compound, a recovery of 45 to 50% was realized.

(13) The fact that a second passage of the main fraction through the gas–liquid partition chromatography column gave a partitionogram which indicated only traces of impurities establishes that insignificant decomposition of the allyl hydroperoxide was taking place on the column under the conditions used.[10]

(14) Carbon and hydrogen analyses by Microchemical Specialties Co., Berkeley, Calif. The samples were evaporated slowly and no unusual decomposition was observed during the combustion.

The Constitution of the Grignard Reagent

BY RAYMOND E. DESSY,[1] GEORGE S. HANDLER, JOHN H. WOTIZ AND C. A. HOLLINGSWORTH

RECEIVED JANUARY 12, 1957

The equilibria $Et_2Mg{\cdot}MgBr_2 \rightleftarrows Et_2Mg + MgBr_2 \rightleftarrows 2EtMgBr$ have been investigated by employing magnesium bromide labeled with radioactive magnesium. Only a small amount of exchange was noted between Et_2Mg and Mg^*Br_2. These results, in conjunction with the fact that the same species seems to be present in a solution of Et_2Mg and $MgBr_2$ as is present in the Grignard reagent prepared in the usual manner, indicate that the ethyl Grignard reagent is better represented by a complex $Et_2Mg{\cdot}MgBr_2$ than by EtMgBr.

Despite the fact that the Grignard reagent has been known and utilized for over fifty years, its structure, particularly in ether solution, is unknown. The most widespread hypothesis considers the equilibria[2]

$$R_2Mg{\cdot}MgX_2 \rightleftarrows R_2Mg + MgX_2 \rightleftarrows 2RMgX \quad (1)$$

The addition of dioxane to a Grignard solution results in the precipitation of virtually all of the halogen and part of the magnesium, leaving R_2Mg in the supernatant liquid.[2] It also has been shown[3,4] that equimolar mixtures of diethylmagnesium and magnesium bromide in ether yield almost instantaneously a solution having the same relative rate of reaction and kinetics in a reaction with a given substrate, hexyne-1, as does the Grignard reagent prepared in the normal manner from ethyl bromide and magnesium. This would seem to imply that the same species is/are present in the two solutions. Recalling these two pieces of information, it therefore seemed of interest to investigate equation 1 [R = ethyl, X = Br] employing radioactive magnesium as a tracer, using, for example, Mg^*Br_2.

Methods and Results

Radioactive magnesium (Mg^{28}, $t_{0.5}$ = 21.25 hr.) was prepared by a spallation reaction involving proton irradiation of potassium chloride. The magnesium, diluted with carrier, was separated as the oxinate and ignited to the oxide. The latter was converted to magnesium chloride, and exchange between this and elemental magnesium was accomplished by heating the mixture to 800°. The resulting labeled magnesium metal was then treated with bromine in dry ether to yield magnesium bromide. The specific activity of the magnesium in an aliquot was determined as a function of time. Table I lists the specific activities of the magnesium in the magnesium bromide used in two entirely separate experiments.

Equimolar amounts of this magnesium bromide and diethylmagnesium (prepared from ordinary magnesium) were dissolved in ether so as to give a solution 1.0 *M* in magnesium. The resulting solution was permitted to stand for ten minutes or 36 hr. and an excess of dioxane added, so as to precipitate the elements of magnesium bromide, leaving diethylmagnesium in the supernatant liquid. The specific activity of the magnesium in an aliquot of the diethylmagnesium solution was determined as a function of time. Table I also lists these specific activities, corrected to the same time of counting as the corresponding magnesium bromide sample and corrected for the small amount of magnesium bromide left unprecipitated by the dioxane.

TABLE I

RADIOACTIVITY EXCHANGE BETWEEN $(C_2H_5)_2Mg$ AND Mg^*Br_2

Run	Specific activity (counts/sec.-mg. Mg) Mg^*Br_2	Specific activity (counts/sec.-mg. Mg) Et_2Mg[a]	Contact time, min.	Activity ratio	% Migration	% Exchange (based on statistical exchange)
1	1.65	0.089	10	19:1	5	10
2a	13.05	.444	10	29:1	3	6
2b	4.20	.178	36 hr.	24:1	4	8

[a] The specific activity of the magnesium in the diethylmagnesium sample has been adjusted to the same counting time as that of the companion magnesium in the magnesium bromide sample by means of log (activity) *versus* time plots. It also takes into account the $MgBr_2$ present as a result of incomplete precipitation by the dioxane. This accounted for about 1% of the magnesium present in the sample.

Discussion

Assuming, on the basis of the rate data mentioned previously,[3,4] that an equimolar mixture of diethylmagnesium and magnesium bromide yields the same species as that to which we assign the name "ethyl Grignard" and considering equation 1, one would conclude that in a mixture of $(C_2H_5)_2Mg$ and Mg^*Br_2 there should be a 50% migration of the label (100% exchange). This would arise because of the fact that in the species C_2H_5MgBr we have an equilibrium partner in which all of the magnesium atoms are equivalent. The low percentage of exchange actually found[5] would seem to indicate that forms such as those represented by RMgX in equation 1 play little or no part in the constitution of the ethyl Grignard reagent. Although one is limited by the short

(5) It is impossible at the present to explain why a low percentage of migration, rather than no migration at all was found. One possible explanation would be of course to assume that a very small amount of the species C_2H_5MgBr was present and that the disproportionation of this to the species $(C_2H_5)_2Mg$ and $MgBr_2$ occurs very slowly. However, it is also very likely that a considerable amount of precipitation exchange occurs, that is, migration occurring during the vigorous exothermic precipitation of the $MgBr_2$. The actual mechanism of this step is unknown.

The low percentage of exchange found is also most unexpected in view of the appreciable conductivity of ether solutions of $(C_2H_5)_2Mg$ and $MgBr_2$ (*cf.* Evans and Pearson, THIS JOURNAL, **64**, 2865 (1942)).

half-life of the tracer, the fact that the activity ratios after a contact time of ten minutes or 36 hr. were sensibly the same indicates that equilibrium 2 is at most a very unimportant side

$$(C_2H_5)_2Mg + MgBr_2 \rightleftarrows 2C_2H_5MgBr \quad (2)$$

reaction with respect to the over-all picture. The results are compatible with an equilibrium of the type

$$(C_2H_5)_2Mg + MgBr_2 \rightleftarrows (C_2H_5)_2Mg\cdot MgBr_2 \quad (3)$$

Along the same lines it is interesting to note that the diethylcadmium–cadmium bromide system in tetrahydrofuran shows no exchange under similar conditions.[6]

A more comprehensive investigation of Grignard systems is being contemplated, employing stable isotopes as tracers.

Experimental

Diethylmagnesium.—The diethylmagnesium in ether was prepared by the action of dioxane on an ether solution of ethylmagnesium bromide,[7] followed by removal of the solvents and dissolution in ether.

Labeled Magnesium Bromide.—Mg^{28} was prepared by a spallation reaction involving proton irradiation of a one cc. single crystal of potassium chloride[8] for 1 hr. at a radius equivalent to 350 Mev. in the Synchrocyclotron of the Carnegie Institute of Technology. The crystal was permitted to stand for 2 hr. after it was dismounted from the probe to allow any short-lived material to decay, and it was then dissolved in 50 ml. of water, along with 100 mg. of $Al(NO_3)_3$ and 500 mg. of $MgBr_2$ to serve as carriers. The solution was heated to the boiling point and adjusted to *p*H 8 with ammonium hydroxide in order to precipitate aluminum hydroxide, which was filtered off. The filtrate was diluted to 125 ml. and heated to 60° and 35 ml. of 6 *N* ammonium hydroxide added. Then 30 ml. of 5% 8-hydroxyquinoline in 2 *N* acetic acid was added slowly. The suspension was brought to the boiling point and then permitted to settle for a few minutes. The oxinate of magnesium was collected by filtration and dried.

The greenish-yellow oxinate was mixed intimately with an equal volume of oxalic acid and placed in a fused silica crucible. Careful ignition with a blast burner yielded magnesium oxide as a fine white powder. The magnesium oxide was dissolved in concentrated hydrochloric acid and any excess acid destroyed by adding a few shavings of magnesium metal.

The solution of magnesium chloride was transferred to a graphite crucible enclosed in a Vycor capsule along with 10 g. of Dow atomized magnesium pellets. The capsule was then attached to a vacuum line and carefully pumped out. The capsule was then heated to 800° and kept at that temperature for 1 hr. in order to cause exchange between the Mg and Mg^*Cl_2. The contents of the crucible were permitted to cool, and the capsule was forced open. Under the conditions employed the Mg was obtained as a clean crystalline plug, which had distilled or sublimed from the hot furnace area of the crucible to cooler portions. This plug was crushed and added to 100 ml. of Mallinckrodt Anhydrous Ether in a three-necked flask equipped with a stirrer, addition funnel and Dry Ice–acetone condenser. Bromine was added slowly to the suspension until a considerable quantity of the magnesium had been utilized. Magnesium bromide and ether, in these concentrations, form a two-phase system.[9] The darker lower layer which contains 485 mg. of $MgBr_2$ per ml. at 25° was used.

Exchange Reactions.—The concentrated magnesium bromide solution and the concentrated diethylmagnesium solution were added to a sufficient volume of ether to yield a solution 0.5 molar in each component (1.0 molar in magnesium). This was permitted to stand for various time periods, and then 1.5 mole equivalents of 1,4-dioxane was added slowly over a 15-minute period with constant agitation. The suspension was agitated slowly for 15 minutes and then centrifuged at 2000 r.p.m. for five minutes. The supernatant solution was analyzed for basic magnesium using the technique described by Gilman[10] and was found to be approximately 0.5 *M* in magnesium. A potentiometric titration for halogen indicated that the supernatant liquid was approximately 0.01 *M* in bromine.[11]

Sampling and Counting.—A portion of the supernatant liquid was transferred to a glass planchet, air hydrolyzed, treated with concentrated hydrobromic acid and dried. A similar planchet was prepared from the original magnesium bromide solution.

The activity of the samples was determined using an Amperex Type 200 CB halogen filled Geiger tube. The activity of the samples was followed for 60 hr. A plot of log(activity) *versus* time indicated high radiochemical purity and a $t_{0.5}$ of 21.2 hr. The reported $t_{0.5}$ of Mg^{28} is 21.25 hr.[12]

Acknowledgment.—The authors are indebted to the staff and crew of the Carnegie Institute of Technology Synchrocyclotron at Saxonburg, Pennsylvania, for their aid and coöperation.

The Condensation of Grignard Reagents with 3-Pyridyl and 3-Quinolyl Ketones

BY REYNOLD C. FUSON AND JOHN J. MILLER

RECEIVED JANUARY 18, 1957

Phenylmagnesium bromide was found to condense in the 1,4-manner with 3-benzoyl-, 3-mesitoyl- and 3-duroylpyridine and with 3-benzoyl- and 3-mesitoylquinoline. Benzylmagnesium chloride reacted in a similar way with the hindered pyridyl ketones, but gave the 1,2-addition product with 3-benzoylpyridine. The products with the phenyl reagents were the corresponding dihydro aromatic compounds; they were dehydrogenated readily with chloranil. 2-Azafluorenone (III) was produced when either 3-mesitoyl-4-phenylpyridine or 3-duroyl-4-phenylpyridine was treated with polyphosphoric acid. The action of polyphosphoric acid on 3-mesitoyl-4-phenylquinoline provided 3,4-benzo-2-azafluorenone (X).

In a search for diaryl ketones that might be unusually receptive to conjugate attack by Grignard reagents, attention was directed to the 3-pyridyl ketones. That these compounds would undergo condensation with organomagnesium halides in the 1,4-manner was indicated clearly by the

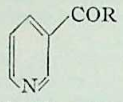
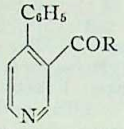
Digitized by Arya Samaj Foundation Chennai and eGangotri

observation of Frank and Weatherbee,[1] that *n*-propylmagnesium bromide reacted with nicotinonitrile to give *n*-propyl 4-*n*-propyl-3-pyridyl ketone.

In the present work it was found that 3-duroylpyridine (Ia) reacted with phenylmagnesium bromide to yield a light yellow solid, the infrared spectrum of which indicates the presence of an >NH group, consistent with the structure of a dihydro phenyl substituted 3-duroylpyridine. The yield was 88% of theoretical. Dehydrogenation of the



Ia, R = Dur
b, R = Mes

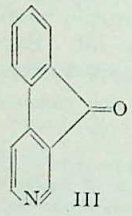


IIa, R = Dur
b, R = Mes

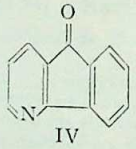
dihydro compound with chloranil gave 3-duroyl-4-phenylpyridine (IIa) in nearly quantitative yield.

Similar results were obtained with 3-mesitoylpyridine (Ib). The dihydro compound, isolated in a yield of 63%, underwent dehydrogenation smoothly with chloranil to give 3-mesitoyl-4-phenylpyridine (IIb).

The possibility existed that the products of the above reactions were pyridines phenylated in the 2- rather than the 4-position. That the materials were substituted in the 4-position was proved by the isolation of 2-azafluorenone (III) from the reaction of either phenylated ketone (IIa or IIb) with polyphosphoric acid.[2] 4-Azafluorenone (IV) would have been produced if the ketones had been phenylated in the 2-position.



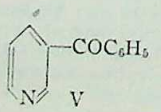
III



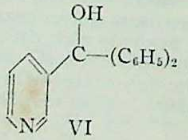
IV

It is assumed that the 2-azafluorenone (III) is obtained by cyclization of 4-phenylnicotinic acid, the product which would be expected from cleavage of the ketones with polyphosphoric acid.

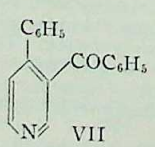
As might have been anticipated from the work of Frank and Weatherbee, conjugate addition was realized also with the unhindered ketone, 3-benzoylpyridine (V). Treatment of this material with phenylmagnesium bromide gave rise to diphenyl-3-pyridylcarbinol (VI), the 1,2-addition product, in 22% yield and to a dihydro 1,4-addition product in a yield of 45%. Dehydrogenation of this conjugate addition product gave 4-phenyl-3-benzoylpyridine (VII).



V

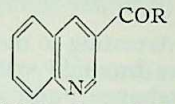


VI

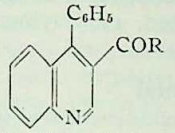


VII

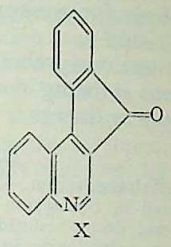
It was thought that conjugate addition to ketones in the quinoline series would be even more facile than to those in the pyridine series. This expectation was borne out by the addition of phenylmagnesium bromide to 3-benzoylquinoline (VIIIa). A dihydro derivative of 3-benzoyl-4-phenylquinoline was isolated in a yield of 90%. Dehydrogenation to 3-benzoyl-4-phenylquinoline (IXa) was accomplished with chloranil.



VIIIa, R = C_6H_5
b, R = Mes



IXa, R = C_6H_5
b, R = Mes



X

The addition of the phenyl reagent to 3-mesitoylquinoline (VIIIb) gave the expected dihydro derivative, which was aromatized to 4-phenyl-3-mesitoylquinoline (IXb) in excellent yield. Cleavage of this hindered ketone with polyphosphoric acid provided 3,4-benzo-2-azafluorenone (X).

The 3-pyridyl ketones were synthesized by the method of Friedel and Crafts. Nicotinyl chloride hydrochloride, prepared by the action of thionyl chloride on nicotinic acid,[3] was used with benzene and mesitylene, respectively, in the synthesis of 3-benzoyl- and 3-mesitoylpyridine. It was found necessary to employ free nicotinyl chloride[4] in tetrachloroethane as a solvent for the preparation of 3-duroylpyridine. 3-Benzoylquinoline, which has not been described previously, was obtained in 65% yield from the corresponding free acid chloride. 3-Mesitoylquinoline was prepared by treatment of the corresponding acid chloride hydrochloride with mesitylene and aluminum chloride in carbon disulfide.

The action of benzylmagnesium chloride on 3-benzoylpyridine proved interesting in that no conjugate addition product was isolated. It has been observed in many cases that the benzyl reagent brings about 1,2- rather than 1,4-addition even with hindered ketones.[5] With 3-mesitoylpyridine, the benzyl reagent produced a yellow solid, which, on the basis of infrared and combustion analyses, was assigned the structure of a dihydro-4-benzyl-3-mesitoylpyridine. Dehydrogenation of this material has not been accomplished. The position of the double bonds in this and other dihydro compounds has not been established definitely. The reaction of the benzyl reagent with 3-benzoylquinoline also proceeded in the conjugate manner.

drochloride, produced by the action of excess thionyl chloride on 85.5 g. (0.7 mole) of nicotinic acid, was added 500 ml. of mesitylene. The mixture was cooled in an ice–salt-bath, and 348 g. (2.6 moles) of aluminum chloride was introduced in small amounts. The deep red solution was heated on a steam-bath for 6 hr. and then decomposed with ice and hydrochloric acid. Addition of an excess of sodium hydroxide to the aqueous layer caused the separation of a brown oil, which was extracted by shaking the mixture successively with five 100-ml. portions of chloroform. The chloroform extracts were combined, washed with water and dried over sodium sulfate. Evaporation of the solvent left a brown oil. Distillation of this material under reduced pressure gave 79 g. (50.5%) of 3-mesitoylpyridine, a light yellow oil, b.p. 96–98° (0.1 mm.).

Anal.[7] Calcd. for $C_{15}H_{15}NO$: C, 79.97; H, 6.71; N, 6.22. Found: C, 80.13; H, 6.72; N, 6.32.

The infrared spectrum[8] of the oil supports the proposed structure. Absorption bands assignable to a hindered, conjugated carbonyl group (1675 cm.$^{-1}$) and to the mesitylene group (850 cm.$^{-1}$) are present.

The picrate of the ketone crystallized from ethanol in yellow needles, m.p. 167–168°.

Anal. Calcd. for $C_{21}H_{18}N_4O_8$: C, 55.51; H, 3.99; N, 12.33. Found: C, 55.79; H, 4.07; N, 12.36.

Dihydro-3-mesitoyl-4-phenylpyridine.—To the Grignard reagent prepared from 16.84 g. (0.1072 mole) of bromobenzene and 2.61 g. (0.1072 g. atom) of magnesium was added 12.08 g. (0.0536 mole) of 3-mesitoylpyridine. The addition was completed in 10 min. The yellow solid, which formed in the solution while the ketone was being added, changed to a brown gum as the reaction mixture was stirred for 10 min. Saturated ammonium chloride solution was introduced, and the yellow solid which separated was collected on a filter. Evaporation of the ether left additional yellow material, m.p. 174–181°. Recrystallization from ethanol gave 10.22 g. (63%) of a light yellow powder, m.p. 182–188°. Vacuum sublimation or recrystallization did not decrease the melting range.

An absorption band assignable to an N—H stretching frequency (3260 cm.$^{-1}$) is present in the infrared spectrum. The intensity of the carbonyl band (1668 cm.$^{-1}$) is extremely low. The structure proposed is a dihydro-3-mesitoyl-4-phenylpyridine.

Anal. Calcd. for $C_{21}H_{21}NO$: C, 83.13; H, 6.98; N, 4.62. Found: C, 82.90; H, 7.20; N, 4.43.

3-Mesitoyl-4-phenylpyridine (IIb).—Benzene solutions of 3.03 g. (0.01 mole) of dihydro-3-mesitoyl-4-phenylpyridine and 2.46 g. (0.01 mole) of chloranil were mixed in a 500-ml., round-bottomed flask. The mixture was heated at the reflux temperature for 8 hr. and then allowed to cool. Extraction of the solution with five 100-ml. portions of 10% aqueous sodium hydroxide removed 1.83 g. of tetrachlorohydroquinone. A brown oil (2.3 g.), which was left when the benzene was evaporated, was crystallized from an ethanol–water mixture. Vacuum sublimation of this crude material at 95° (0.05 mm.) gave white prisms, m.p. 94–95.2° (77% yield).

Anal. Calcd. for $C_{21}H_{19}NO$: C, 83.69; H, 6.35; N, 4.65. Found: C, 83.91; H, 6.20; N, 4.67.

The return of the carbonyl band (1668 cm.$^{-1}$) to normal intensity in the infrared spectrum is striking.

3-Duroylpyridine (Ia).—Nicotinyl chloride was prepared by the method of Wingfield, Harlan and Hammer[4] from 32.2 g. (0.2 mole) of potassium nicotinate and 25.2 g. (0.2 mole) of oxalyl chloride. Two hundred and fifty grams of tetrachloroethane was added to the acid chloride, and 22.8 g. (0.17 mole) of durene was then introduced. The mixture was cooled in an ice–salt-bath, and 50 g. (0.38 mole) of aluminum chloride was added in small portions. The solution was allowed to come to room temperature and was then heated on a steam-bath for 5 hr. The mixture was decomposed with ice and hydrochloric acid, and the organic layer was subjected to steam distillation to remove the tetrachloroethane. The ketone was extracted from the brown, tarry residue with low-boiling petroleum ether. The brown solution, after repeated treatment with decolorizing carbon and evaporation of the solvent, gave 3-duroylpyridine in the form of colorless plates. After recrystallization from low-boiling petroleum ether, the product weighed 13.93 g. (32% yield), m.p. 80.5–81.5°.

Anal. Calcd. for $C_{16}H_{17}NO$: C, 80.30; H, 7.16; N, 5.85. Found: C, 80.37; H, 7.15; N, 5.90.

The picrate was prepared and purified by recrystallization from ethanol, m.p. 183–185°.

Anal. Calcd. for $C_{22}H_{20}N_4O_8$: C, 56.41; H, 4.30; N, 11.96. Found: C, 56.66; H, 4.17; N, 11.92.

Dihydro-3-duroyl-4-phenylpyridine.—Phenylmagnesium bromide, prepared from 3.93 g. (0.025 mole) of bromobenzene and 0.608 g. (0.025 g. atom) of magnesium, was added to 2.99 g. (0.0125 mole) of 3-duroylpyridine. The subsequent procedure was similar to that described for the mesitoyl compound. The dihydro-3-duroyl-4-phenylpyridine, a yellow solid, m.p. 198–207°, was obtained in 88% yield.

Anal. Calcd. for $C_{22}H_{23}NO$: C, 83.24; H, 7.30; N, 4.41. Found: C, 82.97; H, 7.19; N, 4.34.

The infrared spectrum is similar to that of dihydro-3-mesitoyl-4-phenylpyridine; the carbonyl group absorption is again very weak.

3-Duroyl-4-phenylpyridine (IIa).—Treatment of 0.4 g. (0.0012 mole) of dihydro-3-duroyl-4-phenylpyridine with 0.295 g. (0.0012 mole) of chloranil provided 0.39 g. (99%) of the aromatized product, 3-duroyl-4-phenylpyridine, m.p. 168–169.5°.

Anal. Calcd. for $C_{22}H_{21}NO$: C, 83.77; H, 6.71; N, 4.44. Found: C, 83.51; H, 6.71; N, 4.29.

The picrate, m.p. 214–215°, was recrystallized from ethanol.

Anal. Calcd. for $C_{28}H_{24}N_4O_8$: C, 61.76; H, 4.44; N, 10.29. Found: C, 61.58; H, 4.52; N, 10.21.

3-Benzoylpyridine (V).—This ketone was prepared from nicotinic acid in a yield of 87.5% by the method of Villani, King and Papa.[3] The boiling point is 154–156° at 2.5–2.7 mm. **The picrate,** after recrystallization from ethanol, melted at 163–165°; reported 164–166°[3] and 161°.[9]

Dihydro-3-benzoyl-4-phenylpyridine and Diphenyl-3-pyridylcarbinol (VI).—The addition of 4 g. (0.022 mole) of 3-benzoylpyridine to the Grignard reagent prepared from 7.22 g. (0.046 mole) of bromobenzene and 1.09 g. (0.045 g. atom) of magnesium was followed in 20 min. by hydrolysis with saturated ammonium chloride solution. When the ethereal layer was concentrated, a yellow solid and a tan oil were obtained. Recrystallization of the solid from a large volume of ether gave 2.57 g. (45% yield) of dihydro-3-benzoyl-4-phenylpyridine, m.p. 142–148°. Vacuum sublimation of the yellow plates at 140° (0.1 mm.) provided a solid melting at 147–150°.

Anal. Calcd. for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36. Found: C, 82.94; H, 6.07; N, 5.30.

The oil obtained from the reaction crystallized from ether. Recrystallization from ethyl acetate gave 1.27 g. (22% yield) of lustrous, white plates of diphenyl-3-pyridylcarbinol, m.p. 115–116°, reported[10] 115–116°.

Anal. Calcd. for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36. Found: C, 82.74; H, 5.89; N, 5.37.

The melting point of the picrate of this carbinol, m.p. 195–197°, agrees with that reported.[10]

3-Benzoyl-4-phenylpyridine (VII).—Dehydrogenation of the corresponding dihydro compound with chloranil gave 3-benzoyl-4-phenylpyridine in a yield of 83%, m.p. 89.5–90°.

Anal. Calcd. for $C_{18}H_{13}NO$: C, 83.37; H, 5.05; N, 5.40. Found: C, 83.36; H, 5.08; N, 5.29.

The picrate, m.p. 203–205°, crystallized from ethanol.

Anal. Calcd. for $C_{24}H_{16}N_4O_8$: C, 59.02; H, 3.30; N, 11.47. Found: C, 59.11; H, 3.46; N, 11.23.

2-Azafluorenone (III).—A mixture of an excess of polyphosphoric acid and 0.5 g. of 3-mesitoyl-4-phenylpyridine was heated with stirring for 1.5 hr. at 185–200° (25 mm.) in a flask equipped for downward distillation. When the dark brown oil, produced in the reaction flask, was poured

(7) Microanalyses were performed by Mr. Joseph Nemeth, Mrs. R. Maria Benassi, Mrs. Lucy Chang, Mrs. Ruby Ju, Mr. Rollo Nesset and Miss Claire Higham.

(8) The infrared data were obtained and interpreted by Mr. James Brader, Mrs. Louise Griffing and Mr. Sy Portnoy.

on ice, an orange solution formed. The solution was filtered and neutralized with 5% sodium hydroxide. An orange solid, 2-azafluorenone, precipitated (48% yield). Vacuum sublimation of the solid gave yellow plates, m.p. 155.5–156.5°. The melting points reported for 2-azafluorenone are 156–158°[11] and 130°.[12]

The infrared spectrum of a Nujol mull of the material contains bands assignable to a carbonyl group of the fluorenone type (1707 cm.$^{-1}$) and to an *o*-disubstituted benzene ring (735 cm.$^{-1}$). The carbonyl band is at 1720 cm.$^{-1}$ in 5% chloroform solution.

Anal. Calcd. for $C_{12}H_7NO$: C, 79.55; H, 3.89; N, 7.73. Found: C, 79.46; H, 4.01; N, 7.88.

Treatment of 3-duroyl-4-phenylpyridine with polyphosphoric acid gave the same product.

3-Bromoquinoline.—Quinoline hydrobromide perbromide was pyrolyzed to 3-bromoquinoline hydrobromide in 36.5% yield according to the method of Claus and Collischon.[13] The amine was liberated quantitatively by treatment with base.

3-Quinolinecarboxylic Acid.—Treatment of 3-bromoquinoline with cuprous cyanide provided 3-cyanoquinoline, m.p. 106–107°, in a 60% yield.[14] Hydrolysis of the nitrile gave the acid, m.p. 272–273°, in 89% yield.[15]

3-Benzoylquinoline (VIIIa).—The potassium salt of 3-quinolinecarboxylic acid was treated with oxalyl chloride, and the acid chloride produced was condensed with benzene and aluminum chloride according to the method for the preparation of 3-duroylpyridine. 3-Benzoylquinoline, m.p. 76–77°, was isolated in 65% yield.

Anal. Calcd. for $C_{16}H_{11}NO$: C, 82.38; H, 4.75; N, 6.01. Found: C, 82.51; H, 4.70; N, 6.04.

The picrate, m.p. 216–218°, was recrystallized from ethanol.

Anal. Calcd. for $C_{22}H_{14}N_4O_8$: C, 57.15; H, 3.05; N, 12.12. Found: C, 57.01; H, 3.06; N, 12.02.

Dihydro-3-benzoyl-4-phenylquinoline.—The reaction of 1.81 g. (0.0078 mole) of 3-benzoylquinoline with phenylmagnesium bromide, prepared from 2.48 g. (0.0158 mole) of bromobenzene and 0.384 g. (0.0158 g. atom) of magnesium, gave 2.17 g. (90% yield) of dihydro-3-benzoyl-4-phenylquinoline, m.p. 201–204°.

Anal. Calcd. for $C_{22}H_{17}NO$: C, 84.86; H, 5.50; N, 4.50. Found: C, 84.58; H, 5.51; N, 4.44.

3-Benzoyl-4-phenylquinoline (IXa).—Dehydrogenation of 0.31 g. (0.001 mole) of dihydro-3-benzoyl-4-phenylquinoline with 0.25 g. (0.001 mole) of chloranil gave 0.23 g. (75% yield) of 3-benzoyl-4-phenylquinoline, m.p. 115–116°.

Anal. Calcd. for $C_{22}H_{15}NO$: C, 85.41; H, 4.89; N, 4.53. Found: C, 85.12; H, 5.19; N, 4.33.

3-Mesitoylquinoline (VIIIb).—3-Quinolinecarboxylic acid chloride hydrochloride was prepared from 3 g. (0.0173 mole) of 3-quinolinecarboxylic acid and excess thionyl chloride. After the excess thionyl chloride was removed by vacuum distillation, 150 ml. of carbon disulfide, 2.1 g. (0.0174 mole) of mesitylene and 4.62 g. (0.0346 mole) of aluminum chloride was introduced and the mixture was stirred at room temperature for 19 hr. Decomposition of the mixture was accomplished with ice and hydrochloric acid. The aqueous layer was made basic with sodium hydroxide and extracted with ether. Removal of the ether by distillation left 1.76 g. (37% yield) of a yellow-white solid, m.p. 87–91°. Vacuum sublimation gave white crystals of 3-mesitoylquinoline, m.p. 90.5–92°.

Anal. Calcd. for $C_{19}H_{17}NO$: C, 82.88; H, 6.22; N, 5.09. Found: C, 83.06; H, 6.29; N, 5.07.

Dihydro-4-phenyl-3-mesitoylquinoline.—Treatment of 1 g. (0.0036 mole) of 3-mesitoylquinoline with the Grignard reagent prepared from 0.175 g. (0.0072 g. atom) of magnesium and 1.13 g. (0.0072 mole) of bromobenzene gave 1.07 g. (84.5% yield) of a dihydro-4-phenyl-3-mesitoylquinoline. A sublimed sample exhibited a melting range of 268–274°.

Anal. Calcd. for $C_{25}H_{23}NO$: C, 84.95; H, 6.56; N, 3.96. Found: C, 84.78; H, 6.48; N, 3.95.

4-Phenyl-3-mesitoylquinoline (IXb).—Dehydrogenation of 0.75 g. (0.002 mole) of dihydro-4-phenyl-3-mesitoylquinoline was accomplished with 0.49 g. (0.002 mole) of chloranil to give 0.65 g. (92.5% yield) of 4-phenyl-3-mesitoylquinoline, m.p. 98.5–100°.

Anal. Calcd. for $C_{25}H_{21}NO$: C, 85.44; H, 6.02; N, 3.99. Found: C, 85.55; H, 5.97; N, 3.98.

3,4-Benzo-1-azafluorenone (X).—The procedure described for the preparation of 2-azafluorenone was followed. The ketone was obtained in 55.7% yield from 4-phenyl-3-mesitoylquinoline. Recrystallization from ethanol gave yellow needles, m.p. 223–224°, reported[16] 216–217°.

Anal. Calcd. for $C_{16}H_9NO$: C, 83.10; H, 3.92; N, 6.06. Found: C, 83.25; H, 3.74; N, 5.93.

The 2,4-dinitrophenylhydrazone of 3,4-benzo-2-azafluorenone, crystallized from ethanol, melted at 293° dec., reported[16] 290° dec.

Dihydro-4-benzyl-3-mesitoylpyridine.—A yellow solid, dihydro-4-benzyl-3-mesitoylpyridine, m.p. 169–172°, was obtained in 32% yield when 3-mesitoylpyridine was treated with benzylmagnesium chloride. The conditions employed were the same as those described in the other Grignard reactions. The infrared spectrum of the dihydro compound is similar to that of the corresponding phenyl compound.

Anal. Calcd. for $C_{22}H_{23}NO$: C, 83.24; H, 7.30; N, 4.41. Found: C, 82.71; H, 7.29; N, 4.67.

Benzylphenyl-3-pyridylcarbinol.—The introduction of 1.83 g. (0.01 mole) of 3-benzoylpyridine to a solution of benzylmagnesium chloride, prepared from 0.535 g. (0.022 g. atom) of magnesium and 2.77 g. (0.022 mole) of benzyl chloride, followed by hydrolysis with hydrochloric acid provided 1.5 g. of a colorless solid, m.p. 240–241° dec. The infrared spectrum contains a band at 2100 cm.$^{-1}$ which indicates the presence of a hydrochloride. A silver nitrate test confirmed the presence of halogen.

Anal. Calcd. for $C_{19}H_{18}ClNO$: C, 73.19; H, 5.82; N, 4.49. Found: C, 72.72; H, 5.55; N, 4.34.

Treatment of the hydrochloride with 5% aqueous sodium hydroxide gave almost quantitative liberation of benzylphenyl-3-pyridylcarbinol as white plates, m.p. 154–155°. The over-all yield was 48.5%.

Anal. Calcd. for $C_{19}H_{17}NO$: C, 82.88; H, 6.22; N, 5.09. Found: C, 82.82; H, 6.32; N, 5.02.

Dihydro-4-benzyl-3-benzoylquinoline.—The action of the benzyl Grignard reagent, prepared from 1.34 g. (0.0106 mole) of benzyl chloride and 0.26 g. (0.0106 g. atom) of magnesium, on 1.23 g. (0.0053 mole) of 3-benzoylquinoline gave a brown oil from which 0.22 g. of a yellow solid, m.p. 195–200°, was obtained. The structure dihydro-4-benzyl-3-benzoylquinoline was assigned on the basis of the similarity of the infrared spectrum to that of dihydro-4-benzyl-3-mesitoylpyridine.

The Metalation of 4-*t*-Butyldiphenyl Sulfone with *n*-Butyllithium[1]

BY DAVID A. SHIRLEY AND ERWIN A. LEHTO

RECEIVED JANUARY 23, 1957

The metalation of 4-*t*-butyldiphenyl sulfone by *n*-butyllithium results in introduction of the lithium atom in the positions *ortho* to the sulfone group, 69% of the metalation occurring in the unsubstituted ring and 31% in the ring containing the *t*-butyl group. This orientation is due to the deactivating influence toward metalation exerted by the *t*-butyl group through its inductive effect.

A large amount of experimental data has accumulated on the position of metalation of aromatic and heterocyclic nuclei by organoalkali compounds. These results have been rather well correlated by a mechanistic picture of the reaction involving nucleophilic[2] or perhaps better "protophilic"[3] attack by the alkyl carbanion assisted by the metal cation. This picture further states that the principal factor controlling orientation and reactivity in the molecule being metalated is the inductive effect of substituents already present in the ring in increasing or decreasing the polarity of the carbon-to-hydrogen bonds at the various positions. Thus, such otherwise unrelated materials as trifluoromethylbenzene,[2] anisole,[4] diphenyl sulfone[5] and resorcinol dimethyl ether[6] all metalate in the position *ortho* to the substituent(s) present due to the inductive electron-withdrawing tendency of the substituents allowing maximum polarization at the adjacent C–H bond.

An important test of these ideas has been offered in the metalation of compounds containing electron-releasing alkyl substituents. Conflicting reports have appeared in the literature on the results of metalation of isopropylbenzene. Morton and co-workers[7,8] reported *ortho* and *para* metalation while Bryce-Smith[3] indicated *meta* and *para* attack. These workers[3,8] agree that *t*-butylbenzene metalates predominantly in the *p*-position and Bryce-Smith has shown by intermolecular competitive metalation that benzene is metalated in preference to *t*-butylbenzene.

It is the purpose of this paper to present some new evidence that the *t*-butyl group deactivates the ring to which it is attached. In order to do this we have adopted the technique used by Truce[5,9] involving an intramolecular competition reaction on a monosubstituted diphenyl sulfone, namely, 4-*t*-butyldiphenyl sulfone. The sulfone group activates strongly the adjacent rings toward metalation, and the ratio of metalation in the two rings reflects the influence of a substituent present in the *p*-position of one ring. Thus Truce[9] was able to demonstrate that the methyl group of phenyl *p*-tolyl sulfone caused a larger amount of metalation to occur in the unsubstituted ring. If the metalation reaction is under the control of the inductive effect of groups already present in the ring, then the *t*-butyl group should show a stronger deactivation of the ring to which it is attached than that shown by the methyl group.

The metalation of 4-*t*-butyldiphenyl sulfone (I) (0.024 mole) was carried out with 0.010 mole of *n*-butyllithium at 0° for 15 minutes. The mixture was carbonated and the resulting mixed carboxylic acids isolated without disturbing the isomer ratio by crystallization. Neutralization equivalents of the mixed metalation acids indicated no dicarboxylic acid to be present. It was necessary to carry out the metalation so as to avoid demetalation since: (1) separation of the dicarboxylic acid might involve some loss of monocarboxylic acid and (2) further metalation of the monometalated product would probably occur at different rates in the two isomers thus disturbing the isomer ratio. Construction of a melting point–composition diagram using synthetic samples of 4-*t*-butyl-2′-carboxydiphenyl sulfone (II) and 4-*t*-butyl-2-carboxydiphenyl sulfone (III) indicated the mixed monocarboxylic acids from metalation to consist of 69% II and 31% III. Thus metalation of I occurs somewhat more than twice as fast in the unsubstituted benzene ring and this substantiates the idea that the *t*-butyl group deactivates the ring to which it is attached. This deactivation is greater than that exhibited by a methyl group, since Truce and Norman[9] have shown that the metalation of 4-methyldiphenyl sulfone occurs 59% in the unsubstituted ring and 41% in the methyl substituted ring. It should be pointed out that these latter experiments were carried out so that at least 9 mole per cent. of dicarboxylic acid was formed and separated. The mixed monocarboxylic acids were subjected to crystallization before analysis, and no neutralization equivalent or other data were presented to show the ab-

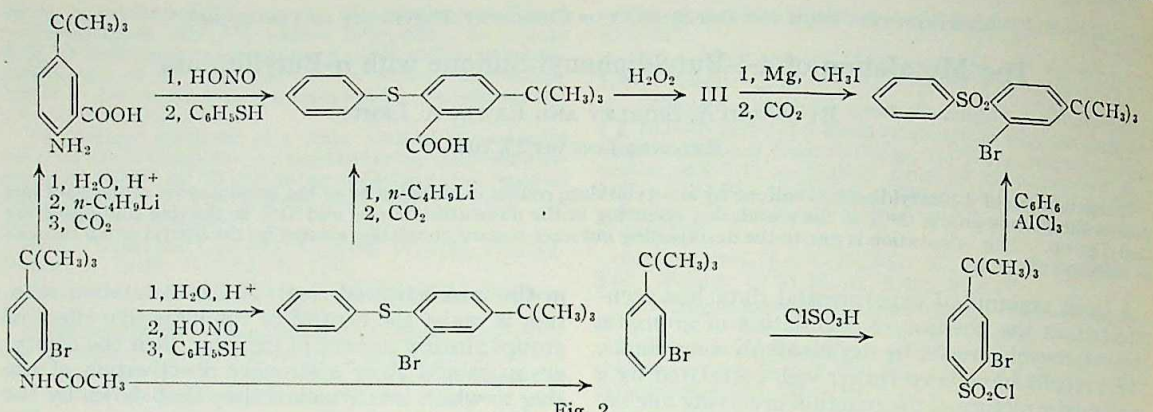

Fig. 2.

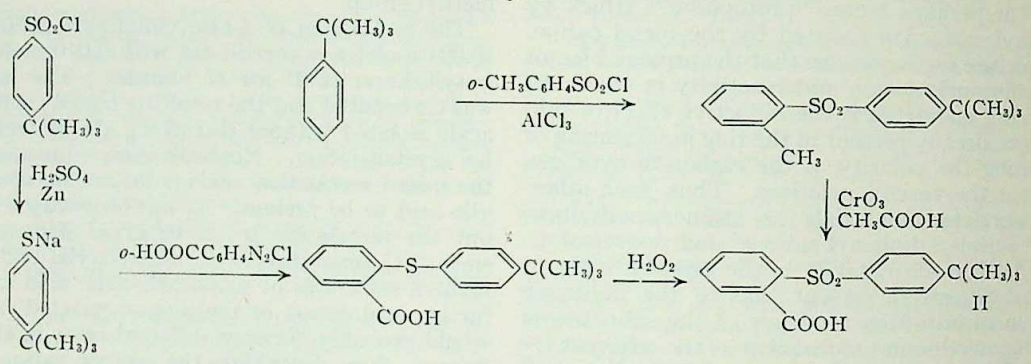

Fig. 3.

sence of some dicarboxylic acid in this fraction. Consequently, the results of our experiments and those of Truce and Norman[9] may not be strictly comparable.

The acid III was synthesized by three independent routes (Fig. 2) of which only the method starting from 2-bromo-4-*t*-butylaniline and proceeding through the halogen–metal interconversion reaction[10] of 2-bromo-4-*t*-butyldiphenyl sulfide and *n*-butyllithium gave the product in good yield. The isomeric acid II was prepared by two independent routes as indicated in Fig. 3. The route involving coupling of sodium *p*-*t*-butylthiophenolate with diazotized anthranilic acid was the better one.

The authors wish to express their appreciation to the Research Corporation of New York for financial support of this investigation.

Experimental[11]

p-t-Butylbenzenesulfonyl Chloride.—The chlorosulfonation of *t*-butylbenzene followed the general procedure of Huntress and Carten.[12] To 67 g. (0.5 mole) of *t*-butylbenzene in 150 ml. of chloroform at 0° was added dropwise with stirring 175 g. (1.5 moles) of chlorosulfonic acid. After the chlorosulfonic acid had been added, the reaction mixture was allowed to warm slowly (12 hours) to room temperature with stirring. It was then poured over an excess of ice and the resulting organic and aqueous layers separated. The aqueous layer was extracted once with chloroform and the combined chloroform solutions washed with water. The volume of the chloroform solution was reduced by evaporation on the steam-bath, the solution cooled and crystallization allowed to occur. The crystallized solid weighed 93.5 g. (81%) and melted at 78–80° after drying *in vacuo* over concentrated sulfuric acid. Another preparation carried out in a similar fashion resulted in a 77% yield of the sulfonyl chloride.

A small amount of the sulfonyl chloride was converted to the sulfonamide which melted at 135–136° after crystallization from aqueous ethanol. The reported[13] m.p. is 136–137°.

4-t-Butyldiphenyl Sulfone.—A solution of 58.1 g. (0.25 mole) of *p*-*t*-butylbenzenesulfonyl chloride in 300 ml. of benzene was placed in a 1-l. round-bottomed flask fitted with mechanical stirrer and reflux condenser. To this solution was added slowly with stirring 75 g. of anhydrous aluminum chloride. The reaction mixture was stirred at room temperature for one hour and then heated to reflux for two hours on the steam-bath. It was poured over an excess of ice and the unreacted benzene removed by steam distillation. The residue from the distillation, after two recrystallizations from methanol, weighed 49.2 g. (75%) and melted at 129–130°. Another run carried out in a similar manner resulted in a 68% yield.

Anal. Calcd. for $C_{16}H_{18}O_2S$: C, 70.07; H, 6.57. Found: C, 70.03, 69.84; H, 6.46, 6.76.

The method of preparation given above was found superior in yield of product to the Friedel–Crafts reaction of benzenesulfonyl chloride and *t*-butylbenzene.

Metalation of 4-t-Butyldiphenyl Sulfone.—To a well-stirred suspension of 6.7 g. (0.024 mole) of 4-*t*-butyldiphenyl sulfone in 250 ml. of dry ether at ice-bath temperature was added slowly 0.010 mole of an ethereal solution of *n*-butyllithium.[14] A nitrogen atmosphere was used. After the *n*-butyllithium had been added, the reaction mixture was stirred at ice-bath temperature for 15 minutes and then carbonated by the addition of crushed solid carbon dioxide directly into the reaction flask. After removal of the ether and carbon dioxide, the residue was treated with water and filtered. The insoluble material weighed 5.7 g. and was unreacted sulfone melting at 128–130°. The aqueous filtrate

was extracted with ether and acidified with dilute hydrochloric acid. The resulting aqueous mixture was extracted with ether and the ether extract washed twice with water. The ether layer was extracted with dilute aqueous sodium carbonate and the sodium carbonate extract acidified with dilute hydrochloric acid. The precipitated colorless semi-solid was extracted with ether, the ether extract washed three times with cold water and dried over anhydrous sodium sulfate. After removal of the ether, the residue was dried *in vacuo* over anhydrous calcium chloride. After a short time, it partially crystallized. This material still possessed the odor of valeric acid and it was heated on the steam-bath with 200 ml. of water. The residue liquefied and on continued heating, a colorless solid separated. A further treatment with 200 ml. of water in a similar manner, followed by collection of the solid material, yielded 0.7 g. melting at 154–190°. A mixture melting point with a small amount of 2-carboxy-4-*t*-butyldiphenyl sulfone gave a final melting point of 196° and with 2-carboxy-4′-*t*-butyldiphenyl sulfone, 186°.

Anal. Calcd. for $C_{17}H_{18}O_4S$: C, 64.15; H, 5.66; neut. equiv., 318. Found: C, 64.01, 64.29; H, 5.77, 5.74; neut. equiv., 320.

The aqueous filtrates (from treatment of the acidic solid above) were concentrated to approximately 100 ml., filtered (no residue) and cooled. There was obtained by crystallization approximately 80 mg. of crystalline solid melting at 153–177°.

Anal. Calcd. for $C_{17}H_{18}O_4S$: C, 64.15; H, 5.66. Found: C, 64.33; H, 5.64.

Further concentration and cooling of the aqueous mother liquor yielded no solid material.

Treatment of the crude mixed acids with cold water was found not to effect complete removal of valeric acid.

Several other metalation conditions were tried in which a larger molar proportion of *n*-butyllithium to sulfone was used at longer reaction times. In all cases appreciable dimetalation resulted as indicated by low neutralization equivalents on mixed metalation acids free of valeric acid.

A melting point–composition diagram (Fig. 4) was constructed from samples of 2-carboxy-4-*t*-butyldiphenyl sulfone and 2-carboxy-4′-*t*-butyldiphenyl sulfone from the data shown in Table I.[15] The 0.7 g. of mixed acid, m.p. 154–190°, corresponds to a composition of 68% 2-carboxy-4′-*t*-butyldiphenyl sulfone and 32% of the 2,4-isomer. The 80 mg. isolated later, m.p. 153–177°, contains 74% of the 2,4-isomer II and 26% of the 2,4-isomer III. Addition of these fractions represents 69% of II and 31% of III. The data of Table I were collected by dissolving the weighed samples of acid in dry ether and evaporating the solvent. The melting range of the resulting mixture was determined on a Kofler hot-stage microscope. A plot of the data shows a smooth curve with a single eutectic at 20 mole per cent. 2-carboxy-4-*t*-butyldiphenyl sulfone (III).

2-*t*-Butylthioxanthone-5-dioxide.—Following the procedure described by Ullmann and Lehner,[16] 1.0 g. of a mixture of monocarboxylic acids from metalation was heated on the steam-bath with 10 ml. of concentrated sulfuric acid until solution was effected. The solution was heated between 190 and 200° for 15 minutes and then poured over an excess of ice. The precipitated solid, after collection and recrystallization from absolute ethanol, weighed 0.6 g. and melted at 109–110°.

Anal. Calcd. for $C_{17}H_{16}O_3S$: C, 68.00; H, 5.33. Found: C, 68.01; H, 5.01.

2-Bromo-4-*t*-butylbenzenesulfonyl Chloride.—*m*-Bromo-*t*-butylbenzene was prepared in general accordance with the procedure of Larner and Peters[17] by the sequence *p*-nitro-*t*-butylbenzene → *p*-*t*-butylaniline → *p*-*t*-butylacetanilide → 2-bromo-4-*t*-butylacetanilide → 2-bromo-4-*t*-butylaniline → *m*-bromo-*t*-butylbenzene.

To a well-stirred solution of 24.8 g. (0.12 mole) of *m*-bromo-*t*-butylbenzene in 200 ml. of chloroform was added slowly at room temperature 50 g. of chlorosulfonic acid. After the addition was complete, the reaction mixture was stirred at room temperature for two hours and then heated to reflux on the steam-bath for two hours. It was poured over an excess of ice and the resulting organic and aqueous layers separated. After removal of the chloroform from the organic layer, an oily residue remained which crystallized on standing. Recrystallization from petroleum ether yielded 25.1 g. (67%) of crystalline solid melting at 67–68°. Conversion of a small amount of the sulfonyl chloride to the corresponding sulfonamide in the usual manner[18] gave a crystalline solid, after recrystallization from dilute aqueous ethanol, melting at 109–110°.

Anal. Calcd. for $C_{12}H_{14}BrNO_2S$: C, 41.10; H, 4.79; N, 4.79. Found: C, 41.04; H, 4.68; N, 4.93.

2-Bromo-4-*t*-butylphenyl Sulfone.—A solution composed of 5.0 g. (0.016 mole) of 2-bromo-4-*t*-butylbenzenesulfonyl chloride and 50 ml. of benzene was warmed to 70° on the steam-bath. After removal from the bath, 10 g. of anhydrous aluminum chloride was added slowly with stirring. The reaction mixture was stirred at room temperature until the evolution of hydrogen chloride had ceased and then heated to reflux on the steam-bath for 30 minutes. The mixture was poured over an excess of ice and the excess benzene was removed by distillation with steam. Recrystallization of the solid residue from the distillation from 95% ethanol yielded 3.6 g. (63%) melting at 110–111°.

Anal. Calcd. for $C_{16}H_{17}BrO_2S$: C, 54.39; H, 4.82. Found: C, 54.43, 54.48; H, 4.74, 4.91.

2-Bromo-4-*t*-butyldiphenyl Sulfide.—The procedure followed for the preparation of this compound was in general that employed by Ziegler[19] for the preparation of 2-carboxydiphenyl sulfide. A solution of 19.0 g. (0.07 mole) of 2-bromo-4-*t*-butylanilinium hydrochloride in 200 ml. of water and 15 ml. of concentrated hydrochloric acid was diazotized in the usual manner at 0° by the slow addition (with stirring) of a solution of 4.8 g. of sodium nitrite in 30 ml. of water. After completion of diazotization, a solution of aqueous sodium acetate was added to neutralize the free acid.[20] The solution was filtered and added slowly to a solution of 8.4 g. (0.08 mole) of thiophenol and 30 g. of sodium hydroxide in 100 ml. of water kept at 70° on the steam-bath. After the addition was complete, the mixture was heated on the steam-bath for two hours, made acidic with concentrated hydrochloric acid, cooled and extracted with ether. The ether extract, after removal of the ether, was dissolved in a solution composed of 150 ml. of 95% ethanol and 30 ml. of concentrated hydrochloric acid. The solution was heated to boiling on the steam-bath and 35 g. of zinc dust was added at such a rate that the mixture was kept at vigorous ebullition. After the zinc had been added, the mixture was heated to reflux for 15 minutes and then filtered while hot. The filtrate was distilled with steam to remove any unreacted thiophenol and the residue from the distillation, after cooling, was extracted with ether. The ethereal extract was washed with dilute aqueous sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After removal of the ether, there remained 5.2 g. of a yellow oil. This compound was characterized by its conversion to 2-carboxy-4-*t*-butyldiphenyl sulfide.

2-Carboxy-4-*t*-butyldiphenyl Sulfide. a. From 2-Bromo-4-*t*-butyldiphenyl Sulfide.—A solution of 5.2 g. (0.016 mole) of crude 2-bromo-4-*t*-butyldiphenyl sulfide in 100 ml. of dry ether was added slowly with stirring to an ethereal solution of 0.05 mole of *n*-butyllithium.[14] A nitrogen atmosphere was used and the reaction flask was immersed in an acetone–solid carbon dioxide bath kept between −50 and −60°. After the solution of *n*-butyllithium had been added, the reaction mixture was stirred at a bath temperature of −50 to −60° for 15 minutes. Carbonation was accomplished by pouring over a slurry of ether and crushed solid carbon dioxide. After the carbon dioxide had evaporated, water was added and the ethereal and aqueous layers were separated. The aqueous layer on acidification with concentrated hydrochloric acid yielded 2.1 g. of a light brown solid melt-

ing at 174–201°. Recrystallization of this material from benzene gave 1.6 g. (35%) of an almost colorless crystalline solid melting at 205–206°.

Anal. Calcd. for $C_{17}H_{18}O_2S$: C, 71.33; H, 6.29. Found: C, 71.24, 71.09; H, 6.46, 6.41.

b. From 2-Bromo-4-*t*-butylaniline.—Following the procedure described by Gilman and Stuckwisch,[21] an ethereal solution of 0.32 mole of *n*-butyllithium was added slowly with stirring to a solution of 19.2 g. (0.08 mole) of 2-bromo-4-*t*-butylaniline in 200 ml. of dry ether at room temperature. An atmosphere of nitrogen was used. After the addition of *n*-butyllithium was complete, the reaction mixture was carbonated by pouring over a slurry of ether and crushed solid carbon dioxide. After the carbon dioxide had evaporated, excess water was added and the aqueous layer was extracted twice with ether and acidified with 1:1 hydrochloric acid until just neutral. This resulted in the separation of a light yellow solid which was collected by filtration and diazotized in the usual manner at 0°. After completion of diazotization, an aqueous solution of sodium acetate was added to neutralize the free acid[20] and the resulting solution was added to a solution of 4.8 g. of thiophenol and 25 g. of sodium hydroxide in 100 ml. of water kept at 70° on the steam-bath. The mixture was heated on the steam-bath for one hour and then filtered. The filtrate was acidified with concentrated hydrochloric acid and the precipitate collected by filtration. This material, after one crystallization from benzene, weighed 0.7 g. and melted at 194–201°. A recrystallization from methanol yielded 0.3 g. melting at 205–206°. A mixture melting point with the product obtained from 2-bromo-4-*t*-butyldiphenyl sulfide, melting point 205–206°, was 205–206°.

2-Carboxy-4-*t*-butyldiphenyl Sulfone (III). a. From 2-Bromo-4-*t*-butyldiphenyl Sulfone.—To 0.5 g. of magnesium turnings in 25 ml. of dry ether was added slowly with stirring 1.5 g. of 2-bromo-4-*t*-butyldiphenyl sulfone. There was no apparent reaction even on heating the mixture to reflux. A small amount of methyl iodide was added and the mixture heated once more to reflux. Presently reaction commenced and continued without the application of heat. When there was no further visible indication of reaction, crushed solid carbon dioxide was added to the mixture. After the removal of the ether and carbon dioxide, the residue was acidified with 20% sulfuric acid. When the magnesium had dissolved completely, the mixture was made alkaline by the addition of aqueous sodium hydroxide and the solution filtered. Acidification of the filtrate with 1:1 hydrochloric acid resulted in the precipitation of a tan-colored solid. It was collected by filtration and reprecipitated from an aqueous solution of sodium carbonate by means of dilute hydrochloric acid. This gave a small amount of colorless crystalline solid melting at 241–242°.

Anal. Calcd. for $C_{17}H_{18}O_4S$: C, 64.15; H, 5.66. Found: C, 64.00; H, 5.45.

b. From Oxidation of 2-Carboxy-4-*t*-butyldiphenyl Sulfide.—One and one-half grams (0.005 mole) of 2-carboxy-4-*t*-butyldiphenyl sulfide dissolved in 50 ml. of glacial acetic acid was heated to 80° on the steam-bath and then 15 ml. of 30% hydrogen peroxide was added slowly. The solution was heated on the steam-bath for one hour and, after the addition of another 10 ml. of 30% hydrogen peroxide, then to reflux for one hour. The reaction mixture was poured into an excess of water and the precipitated solid, weighing 0.8 g. (45%) and melting at 241–242°, was collected by filtration. A mixture melting point with the product obtained from 2-bromo-4-*t*-butyldiphenyl sulfone, melting at 241–242°, was 241–242°. The yield obtained from another preparation carried out in a similar manner was 55%.

2-Methyl-4′-*t*-butyldiphenyl Sulfone.—*o*-Toluenesulfonyl chloride (b.p. 143–145° at 25 mm.) was prepared in 75% yield in accordance with the procedure of Lee and Dougherty[22] for conversion of aromatic thiols to the corresponding sulfonyl chlorides. A solution of 38.0 g. (0.20 mole) of *o*-toluenesulfonyl chloride and 35 g. of *t*-butylbenzene was warmed to 70° on the steam-bath. After removal from the steam-bath, 50 g. of anhydrous aluminum chloride was added in small portions with vigorous stirring. Shortly after the addition was complete, the reaction mixture partially solidified and was poured immediately into an excess of cold water. The unreacted *t*-butylbenzene was removed by steam distillation. The water-insoluble residue was washed with petroleum ether and recrystallized twice from methanol, yielding 30.7 g. (52%) melting at 103–104°.

Anal. Calcd. for $C_{17}H_{20}O_2S$: C, 70.83; H, 6.94. Found: C, 70.76; H, 7.03.

Following in general the procedure described by Newell,[23] 14.4 g. (0.05 mole) of 2-methyl-4′-*t*-butyldiphenyl sulfone was dissolved in the minimum amount of glacial acetic acid and heated almost to boiling. Then a solution of 15 g. of chromium trioxide dissolved in the minimum amount of glacial acetic acid was added slowly with stirring. After the addition was complete, the reaction mixture was heated to reflux for 16 hours and then poured into an excess of cold water. The precipitated crystalline solid was collected by filtration, dissolved in aqueous sodium carbonate solution, the solution filtered and the filtrate acidified with dilute hydrochloric acid. The solid precipitate was recrystallized from benzene giving 0.3 g. of crystalline acid melting at 168–169°. This material is further characterized below.

***p*-*t*-Butylthiophenol.**—This compound was prepared according to the procedure given by Senear, Rapport and Koepfli[24] for the preparation of *p*-chlorothiophenol. To a mixture of 23.2 g. (0.10 mole) of *p*-*t*-butylbenzenesulfonyl chloride, 240 g. of ice and 50 ml. of concentrated sulfuric acid was added (30 minutes) with stirring 40 g. of zinc dust. The temperature of the reaction mixture was held at 0° throughout this operation and for two hours after the addition of the zinc. The mixture was then heated carefully to reflux and the resulting crystalline precipitate separated by filtration. The precipitate was suspended in a boiling mixture of 240 ml. of water and 45 ml. of concentrated sulfuric acid and then 40 g. of zinc was added in small portions. After the mixture had been steam distilled, the distillate was extracted with ether and the ether extract dried over anhydrous sodium sulfate. Removal of the ether left 9.8 g. (59%) of a colorless liquid. This compound was characterized by conversion to 2-carboxy-4′-*t*-butyldiphenyl sulfide.

2-Carboxy-4′-*t*-butyldiphenyl Sulfide.—Following the general procedure of Ziegler[19] and using some modifications reported by Hilbert and Johnson,[20] 8.1 g. (0.59 mole) of anthranilic acid was added to a solution of 60 ml. of water and 10 ml. of concentrated hydrochloric acid. The solution was diazotized at 0° by the slow addition of a solution of 5.6 g. of sodium nitrite in 25 ml. of water. After completion of diazotization, an aqueous solution of sodium acetate was added to neutralize the free acid. The solution of the diazonium salt was added to a solution (warmed to 70°) of 9.8 g. (0.059 mole) of *p*-*t*-butylthiophenol and 5.0 g. of sodium hydroxide in 30 ml. of water. After the addition was complete, the reaction mixture was heated on the steam-bath for one hour. The mixture was filtered and the filtrate acidified with concentrated hydrochloric acid. The precipitate was collected by filtration and, after one recrystallization from glacial acetic acid and one from benzene, there was obtained 4.6 g. (27%) of crystalline solid melting at 193–194°. Another run carried out in a similar manner resulted in a yield of 36%.

Anal. Calcd. $C_{17}H_{18}O_2S$: C, 71.33; H, 6.29; neut. equiv., 286. Found: C, 71.37, 71.45; H, 6.19, 6.14; neut. equiv., 288.

2-Carboxy-4′-*t*-butyldiphenyl Sulfone.—To a solution of 3.5 g. of 2-carboxy-4′-*t*-butyldiphenyl sulfide in 50 ml. of glacial acetic acid heated to 80° on the steam-bath was added slowly 15 ml. of 30% hydrogen peroxide. The resulting solution was heated on the steam-bath for 30 minutes and, after the addition of another 15 ml. of 30% hydrogen peroxide, for 30 additional minutes. The solution was heated to reflux for two hours and poured into an excess of cold water. The precipitated solid was collected by filtration and recrystallized from benzene, yielding 2.6 g. (67%) of a crystalline solid melting at 168–169°. A mixture melting point of this solid with the material obtained from chromic acid oxidation of 2-methyl-4′-*t*-butyldiphenyl sulfone, melting point 168–169°, was 168–169°.

The Preparation of Some 10-Substituted Phenoxazines[1]

BY HENRY GILMAN AND LEONARD O. MOORE[2]

RECEIVED FEBRUARY 13, 1957

An improved procedure for the synthesis and purification of phenoxazine has been developed which is applicable to the preparation of larger amounts than previously reported. Several 10-alkyl- and 10-arylphenoxazines have been prepared. Iodine has been shown to have little, if any, catalytic activity in the preparation of 10-arylphenoxazines from aryl bromides.

In the study of the chemistry of phenoxazine it was desired to use variously 10-substituted compounds for comparison of substitution reactions and also to use the aryl derivatives for testing as solutes in liquid scintillators.[3]

Phenoxazine was made first by Bernthsen[4] in 1887, and, though known for many years, has not had a systematic study made of its chemistry. Oxazine dyes, which are derivatives of phenoxazine, are widely used at present as biological stains.[5] They have been studied for staining brain tumors,[6] and as tuberculostatic agents.[7] In general the reactions of phenoxazine which have been studied have related directly to these dyes. The majority of reactions studied have been cyclization, oxidation–reduction to oxazonium salts, and some substitution of the oxazonium compounds.

Related heterocycles containing an N–H bond have been used quite extensively in reactions to prepare N-substituted compounds. Carbazole[8] and phenothiazine[9] both have had various alkyl and aryl groups substituted for the hydrogen on the nitrogen. Relatively few N-substituted derivatives of phenoxazine have been prepared. Morris and Snyder[10] prepared several 10-sulfolanyl- and 10-sulfolenylphenoxazines from phenoxazine and various sulfolene compounds in a basic solution. All other 10-substituted phenoxazines have been prepared by cyclization. Some 10-benzyl derivatives[11] were prepared for testing as tuberculostatic agents; some 10-(nitrophenyl)-phenoxazines[12] and one 10-methyl derivative[13] were prepared in studies of a cyclization mechanism.

We have studied the preparation of phenoxazine, varying the methods reported in the literature.[14] The best method for large amounts is to heat an equimolar mixture of *o*-aminophenol and *o*-aminophenol hydrochloride, allowing the water produced to distil. The completion of the reaction can be determined by measuring the amount of water produced. The addition of sea sand to facilitate extraction of the mass decreased the yield as also did heating the reaction for an extended length of time. The purification by chromatography was much less tedious than the methods reported in the literature. This procedure consistently gave 26 to 30% of a relatively pure product in runs of 0.5 to 2.5 moles.

In light of the patent by Waterman and Vivian[15] as well as their articles[16] on the preparation of phenothiazines and carbazoles from aromatic nitro compounds, attempts were made to produce phenoxazine from *o*-nitrophenyl phenyl ether. Heating this ether with powdered iron or ferrous oxalate yielded no phenoxazine.

The alkyl phenoxazines were prepared in liquid ammonia using 10-phenoxazylsodium, prepared from sodium amide and phenoxazine, with an alkyl iodide or a benzyl chloride.[17] Phenoxazine, similar to carbazole, is not acidic enough to condense with ethyl iodide in a refluxing acetone solution of potassium hydroxide, as do nitrocarbazoles.[18]

In the preparation of 10-ethylphenoxazine it was thought that perhaps 2,2′-dilithiodiphenyl ether[19] might react with ethyl dichloramide in the same way that other organometallic reagents do with haloamines[20] to give 10-ethylphenoxazine, but none of the desired product was obtained even though multiple fractional distillations were made in an attempt to isolate even a small amount.

The 10-aryl derivatives were prepared by heating phenoxazine and an aryl iodide or bromide with anhydrous potassium carbonate and a small amount of copper bronze powder as a catalyst. The aryl bromides required higher temperatures for reaction than did the aryl iodides, and even so did not usually give as good yields. Since iodine had been added in preparing some N-arylcarbazoles from aryl bromides, it was thought that perhaps iodine might act as a catalyst for the aryl bromides. But when 4,4′-dibromobiphenyl was heated with phenoxazine as described above with and without added iodine, it was found that the iodine had no observable effect on the yield. The effect of temperature, however, is very marked, since heating *p*-bromoiodobenzene with phenoxazine to 200° for 24 hr. gave a good yield of 10-(*p*-bromophenyl)-phenoxazine and no 1,4-bis-(10-phenoxazyl)-benzene; heating in the same manner except for a period of 30 min. at 300° gave 7% of the disubstituted compound.

Attempts to use nitrobenzene as a solvent were not successful. When used in the preparation of 10-phenylphenoxazine none of the expected product was found; in the preparation of 4,4′-bis-(10-phenoxazyl)-biphenyl only a 4% yield was obtained; and in the attempted preparation of 10-*p*-biphenylylphenoxazine an amino compound with a high nitrogen content was the only product isolated.

A comparison of the melting points of the derivatives prepared with the corresponding ones of carbazole and phenothiazine show no definite relationship but some trends. The methyl and ethyl derivatives melt much lower than those of the other heterocycles, but the benzyl and phenyl melt higher (see Table I).

TABLE I

MELTING POINTS OF N-SUBSTITUTED DERIVATIVES OF RELATED HETEROCYCLES, °C.

Substituted group	Phenothiazine[a]	Phenoxazine	Carbazole

Experimental[21]

Phenoxazine.—In a 2-l. round-bottom flask with a three-hole cork, through which was inserted a nitrogen inlet tube, a thermometer, and a short tube leading to a distilling condenser, were mixed 500 g. (4.59 moles) of *o*-aminophenol and 185 ml. (2.23 mole) of concentrated hydrochloric acid. This mixture was heated in a slow stream of nitrogen and water distilled off, first at a mass temperature of 115° for 4.33 hours; then, as a fine white solid began to sublime, the temperature rose slowly to 265° and was maintained at 265–290° for 4 hours or until the expected 180 ml. of water had distilled over. The mass was extracted with 1.5 l. of refluxing benzene for 48 hours and then with 1 l. more for 48 hours. The combined solution was chromatographed on a 50 × 450 mm. column of alumina with benzene as the eluent. There was collected 3 l. of solution which was distilled to 150 ml. and chilled. Filtration yielded 103 g. of light tan solid, m.p. 149–153°. From a fourth liter eluted there was obtained 7.1 g., m.p. 140–146°. The total represents a 26% yield. In several other runs, yields of 26 to 30% were obtained consistently. Sublimed white platelets had a m.p. 158–159°.

This compound formed a very dark green picrate, m.p. 141.5–142.0°.

Reaction of *o*-Nitrophenyl Phenyl Ether with Ferrous Oxalate.—In a 2-l. flask with air condenser 21.5 g. (0.1 mole) of *o*-nitrophenyl phenyl ether, 120 g. (0.40 mole) of ferrous oxalate dihydrate[22] and 250 g. of lead shot were heated to 370–400° for two hours.[23] Extraction by benzene and chromatography of the resulting solution on an alumina column with benzene as the eluent produced a red-brown oil, which was shown to be mainly *o*-nitrophenyl phenyl ether by the infrared spectrum.

Chromatography of a known mixture of phenoxazine and *o*-nitrophenyl phenyl ether with benzene showed that the *o*-nitrophenyl phenyl ether was the first eluted, but that the phenoxazine was washed off the column immediately after with only a relatively small amount of eluent.

Reaction of *o*-Nitrophenyl Phenyl Ether with Iron Powder.—In a thick wall flask with air condenser and solids trap at the top, were placed 200 g. of 20 mesh iron filings, 250 g. of hydrogen-reduced iron powder and 100 g. (0.47 mole) of *o*-nitrophenyl phenyl ether. These were heated slowly to 360° at which temperature fumes came off, first white then brown, with refluxing in the air condenser. Extraction with benzene and chromatography on an alumina column with benzene as eluent gave only red tars which could not be made to crystallize. The infrared spectrum indicated the presence of some N–H but had no other spectral bands indicative of phenoxazine. The major substance was the starting ether.

10-Ethylphenoxazine.—To 0.33 mole of sodium amide[24] in a 1-l. flask was added 54.96 g. (0.3 mole) of phenoxazine in small portions and this mixture stirred for 1 hour. Ethyl iodide (88.3 g., 0.57 mole) was added dropwise and the mixture allowed to stir while the ammonia evaporated. The residue was extracted with benzene, filtered and chromatographed on an alumina column. This gave a violet solution, from which the benzene was distilled and the residue distilled under reduced pressure, b.p. 138–143° (0.6 mm.). This gave 56.7 g. (89.4%) of a yellow liquid which solidified on chilling to give a yellow solid, m.p. 46–47°. If the liquid is not cooled below 20° nor seeded, then physical constants can be measured on the supercooled liquid, $n^{25}D$ 1.6445, d^{25}_{25} 1.1584; *MR* calcd. 63.6, found 66.0.

Anal. Calcd. for $C_{14}H_{13}NO$: C, 79.59; H, 6.65; N, 6.63. Found: C, 79.77, 79.79; H, 6.85, 6.96; N, 7.22, 7.15.

This compound formed a very dark green picrate, m.p. 93.5–94.0°.

The reaction of phenoxazine (9.16 g., 0.05 mole), ethyl iodide (14.7 g., 0.095 mole) and potassium hydroxide (5.7 g., 0.1 mole) in 250 ml. of refluxing acetone for 6 hours gave only phenoxazine (mixed melting point).

Reaction of 2,2′-Dilithiodiphenyl Ether with Ethyl Dichloramide.—To 0.17 mole of 2,2′-dilithiodiphenyl ether[19] in 1500 ml. of anhydrous ether was added with vigorous

stirring an ether solution of ethyl dichloramide.[25] After stirring for 72 hours, Color Test I[26] was negative and the mixture was hydrolyzed, the layers separated, and the ether layer washed with water and 10% sulfuric acid until a sample on neutralization failed to become turbid. The ether was distilled and the residue distilled three times under reduced pressure using the fraction boiling nearest to that expected for 10-ethylphenoxazine. Physical constants on the liquid obtained from the last distillation did not indicate any 10-ethylphenoxazine. Infrared spectra of the various fractions indicated the product of the reaction to be mainly diphenyl ether, with some ethylaminodiphenyl ether, since there were some bands for the N–H bond and for the ethyl group, though these were weak. Neutralization of the sulfuric acid solution gave only a small amount of brown tarry material.

10-Methylphenoxazine.—Using the method described for 10-ethylphenoxazine for a 0.05-mole run, there was obtained 7.0 g. (71%) of a yellow liquid, b.p. 151–154° (3.0 mm.), which solidified on chilling to give a yellow solid, m.p. 35–37°.

Anal. Calcd. for $C_{13}H_{11}NO$: N, 13.14. Found: N, 13.20, 13.21.

This compound formed a dark green picrate, m.p. 101–102°.

10-Benzylphenoxazine.—Using the same method described for 10-ethylphenoxazine for a 0.05-mole run, there was obtained on distillation of the eluted solution 5.5 g. (40%) of white crystals, m.p. 126.5–128.0°. Recrystallization from 95% ethanol gave an analytical sample, m.p. 127.5–128.0°.

Anal. Calcd. for $C_{19}H_{15}NO$: C, 83.49; H, 5.54; N, 5.13. Found: C, 83.59, 83.30; H, 5.60, 5.72; N, 4.97, 5.02.

10-(*p*-Bromobenzyl)-phenoxazine.—Using the method described for 10-ethylphenoxazine for a 0.1-mole run, there was obtained on distillation of the eluted solution 8.0 g. (45.5%) of brown solid, melting range 73–111°. Recrystallization from petroleum ether (b.p. 60–70°) gave 3.49 g. of white needles, m.p. 113–114°.

Anal. Calcd. for $C_{19}H_{14}BrNO$: N, 3.98. Found: N, 4.25, 4.24.

10-Phenylphenoxazine.—In a 500-ml. flask were mixed 45.8 g. (0.25 mole) of phenoxazine, 68.3 g. (0.33 mole) of iodobenzene, 35 g. of potassium carbonate and 2.0 g. of copper bronze powder and this mixture heated to 200° for 48 hr. The mixture was extracted with 200 ml. of benzene, filtered and chilled to give 59.6 g. of white solid, m.p. 134.5–137.5°. Concentration of the filtrate gave 9.49 g. more of pale tan solid, m.p. 130–135°. This represents a crude yield of 81.5%. Recrystallization from benzene gave an analytical sample, m.p. 138–139°.

Anal. Calcd. for $C_{18}H_{13}NO$: C, 83.37; H, 5.05; N, 5.40. Found: C, 83.45; H, 5.13; N, 5.39.

10-(*o*-Bromophenyl)-phenoxazine.—*o*-Bromoiodobenzene was used in the procedure described for 10-phenylphenoxazine for a 0.05-mole run except that the reaction time was cut to 24 hr. The product was purified by chromatography on a column of alumina using benzene as the eluent. Concentration of the eluted solution gave 6.60 g. (39%) of light brown solid, melting range 159–187°, which was recrystallized from ethyl acetate to give 2.35 g. of white solid, m.p. 213–214°. Multiple recrystallizations gave an analytical sample, m.p. 214.5–215.5°.

Anal. Calcd. for $C_{18}H_{12}BrNO$: N, 4.14. Found: N, 4.21, 4.24.

10-(*p*-Bromophenyl)-phenoxazine.—Using the same method as described for the *o*-isomer, there was obtained 5.18 g. (61%) of a brown solid, m.p. 190–200°, which was recrystallized from benzene to give 2.63 g. of pale pink prisms, m.p. 200–202°.

Anal. Calcd. for $C_{18}H_{12}BrNO$: C, 63.92; H, 3.66; N, 4.14. Found: C, 63.96, 64.02; H, 3.53, 3.37; N, 3.83, 3.86.

The use of a higher temperature (same as above except for 30 min. at 300°) and addition of iodine gave 7% of *p*-bis-(10-phenoxazyl)-benzene.

10-(*p*-Biphenylyl)-phenoxazine. Method A.—This compound was prepared in the same manner as 10-phenylphenoxazine in a 0.03-mole run using 4-iodobiphenyl. The mass was extracted with benzene, concentrated to 75 ml. and chilled to give a tarry solid, m.p. 180–186°, which was recrystallized from toluene to give 4.38 g. (43.5%) of yellow needles, m.p. 191.5–193.0°. Further recrystallization raised the melting point to 191.5–194.0°.

Anal. Calcd. for $C_{24}H_{17}NO$: N, 4.18. Found: N, 4.23, 4.24.

Method B. (Attempted).—The use of 4-bromobiphenyl in the reaction as described for 9-(*p*-biphenylyl)-carbazole[5d] gave 0.38 g. (5%) of a white solid, m.p. 217–236°, which was recrystallized from benzene to give 0.16 g., m.p. 255.5–256.2°, of a product containing 8.14% nitrogen. This corresponds very nearly to an aniline-10-(*p*-biphenylyl)-phenoxazine. The infrared spectrum of this compound has bands for an N–H bond, and bands very similar to those of 10-(*p*-biphenylyl)-phenoxazine.

***p*-Bis-(10-phenoxazyl)-benzene.**—Using the procedure as for 10-(*o*-bromophenyl)-phenoxazine but substituting *p*-diiodobenzene for *p*-bromoiodobenzene, for a 0.02-mole run, there was obtained 10.05 g. (100%) of a tan solid, m.p. 215–240°, which was recrystallized several times from benzene to give only 17% of white needles, m.p. 249.0–250.5°.

Anal. Calcd. for $C_{30}H_{20}N_2O_2$: N, 6.36. Found: N, 6.38, 6.51.

4,4′-Bis-(10-phenoxazyl)-biphenyl.—In a 200-ml. flask 5.04 g. (0.0275 mole) of phenoxazine, 3.90 g. (0.0125 mole) of 4,4′-dibromobiphenyl, 7.6 g. of anhydrous potassium carbonate and 0.5 g. of copper bronze powder were heated to 300° for 23 hours. The mass was extracted with hot benzene, then with hot water and the water solution and solid were washed with benzene. The total of 175 ml. of benzene solution was chromatographed on a 35 × 350 mm. column of alumina using benzene as the eluent. There was collected 150 ml. of a forerun then 1000 ml. of yellow solution. Distillation of solvent and chilling gave 2.13 g. (33%) of pale yellow crystals, m.p. 332.0–335.5°.

In a second run, identical with the above except that 0.75 g. of iodine was added as a possible catalyst, there was obtained 2.09 g. (32.4%) of pale yellow crystals, m.p. 332.5–336.0°. The iodine appears to have no catalytic activity in this reaction.

Recrystallization of an analytical sample from benzene gave a solid, m.p. 339–342°.

Anal. Calcd. for $C_{36}H_{24}N_2O_2$: N, 5.42. Found: N, 5.30, 5.29.

Acknowledgment.—We are indebted to R. McCord and E. Miller Layton of the Ames Laboratory of the Atomic Energy Commission for assistance in the infrared spectra determinations.

Chemical Composition of Lemon Oil. I. Isolation of a Series of Substituted Coumarins[1]

BY W. L. STANLEY AND S. H. VANNIER

RECEIVED DECEMBER 26, 1956

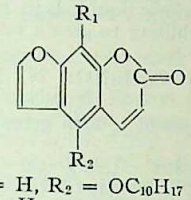
Seven substituted coumarin compounds have been isolated from domestic cold-pressed lemon oil by chromatographic separation on a column of powdered silicic acid. The identity of four of the compounds has been established, *viz.*, 5-geranoxypsoralen, 5,7-dimethoxycoumarin, 5-geranoxy-7-methoxycoumarin and byakangelicin. A fifth compound has been tentatively identified as 8-geranoxypsoralen, the geranyl group still being in doubt. The remaining two compounds were recovered in too small a quantity for analysis. However, they appear, from comparison of ultraviolet spectra, to be related to 5-geranoxypsoralen and 5-geranoxy-7-methoxycoumarin.

The presence of coumarin compounds in various citrus oils has been well established. Thus, for example, 5,7-dimethoxycoumarin, 5-methoxypsoralen, 5-hydroxypsoralen and 5-geranoxypsoralen have been isolated from oil of bergamot[2]; 5,7-dimethoxycoumarin, 5-geranoxy-7-methoxycoumarin and 5,8-dimethoxypsoralen from lime oil[3]; auraptene from orange oil[4]; and 7-hydroxycoumarin from grapefruit oil.[9] Also, 5,7-dimethoxycoumarin (limettin)[5,6] and an unidentified coumarin[7] have been reported in lemon oil.

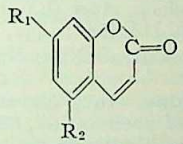
The present study was undertaken as part of a comprehensive investigation of the composition of lemon oil. By chromatography of whole cold-pressed lemon oil on a silicic acid column, seven crystalline solids were obtained. The ultraviolet spectra in neutral solution (Fig. 1)[3,8,9] and chemical properties indicated they were substituted coumarins. Furthermore, on addition of aluminum chloride and caustic soda to their cold alcoholic solution, there was no bathochromic shift in the spectral absorption. It was therefore apparent that the compounds did not contain free phenolic hydroxyl groups. All seven compounds gave a negative magnesium–hydrochloric acid test for flavones.

The spectra of II, IV and VI were closely similar to those of the 5,7-hydroxy and alkoxy coumarins (Fig. 1). Analyses of VI established the empirical formula $C_{11}H_{10}O_4$ and the presence of two methoxyl groups. The melting point, 146–147°, indicated the identity of this compound with the previously reported 5,7-dimethoxycoumarin. It was identical with material isolated from lime oil and oil of bergamot.

Compound II contained one methoxyl group. It was cleaved by mild acid treatment, indicating the presence of an allylic ether linkage. The phenol VIII thus produced was methylated with diazomethane and the product found to be identical with VI, 5,7-dimethoxycoumarin. The compound



I, R_1 = H, R_2 = $OC_{10}H_{17}$
III, R_1 = H, R_2 = OCH_2—CH = $C(CH_3)_2$(?)
V, R_1 = $OC_{10}H_{17}$; R_2 = H
VII, R_1 = OCH_2—CHOH—COH $(CH_3)_2$, R_2 = OCH_3
IX, R_1 = H; R_2 = OH
X, R_1 = H; R_2 = OCH_3
XI, R_1 = H; R_2 = $OCOCH_3$
XII, R_1 = OH; R_2 = H
XIII, R_1 = $OCOCH_3$; R_2 = H
XIV, R_1 = OCH_3; R_2 = H



II, R_1 = OCH_3; R_2 = $OC_{10}H_{17}$
IV, R_1 = OCH_3; R_2 = OCH_2—CH = $C(CH_3)_2$(?)
VI, R_1 = R_2 = OCH_3
VIII, R_1 = OCH_3; R_2 = OH

7-methoxy-5-geranoxycoumarin was then isolated from lime oil in the manner similar to that described by Caldwell and Jones[3] and found to be identical with II.

Compound IV was not isolated in amounts sufficient for elemental analysis. However, its ultraviolet spectrum suggested that it was also a 5,7-dialkoxycoumarin. Its R_f value, intermediate between that of II and VI, suggested that it is possibly a lower isoprene homolog of II, *viz.*, 5-γ,γ-dimethylallyloxy-7-methoxycoumarin. Such an allyl ether group is present in brayleyanin.[10]

The ultraviolet spectra of I and III were similar to the spectrum reported for 5-methoxypsoralen[9] (Fig. 1). Compound I did not contain a methoxyl group and was hydrolyzed readily with acids to give a phenol IX. This phenol gave a product X which was identical with authentic 5-methoxypsoralen.[11] Consideration of these data supported the identity of I with 5-geranoxypsoralen. This identity was confirmed by direct comparison of I

with authentic 5-geranoxypsoralen isolated from oil of bergamot.[2,11]

An insufficient amount of III was isolated for analytical study. From chromatographic behavior and similarity of ultraviolet spectra with that of I, it may be a lower homolog of I.

Compound V was isomeric with I. It did not contain a methoxyl group. Acid hydrolysis of V gave a phenol XII, the acetate of which XIII had an ultraviolet spectrum closely similar to that of psoralen[9] (Fig. 2). Since Nakabayshi[12] has shown that the spectra of the acetates of phenolic coumarins resemble the spectrum of coumarin, it was apparent that V was probably a mono-ether of psoralen. This was confirmed by preparation of the mono-ether XIV of the phenol XII. Direct comparison of this methyl ether with 8-methoxypsoralen[13] showed them to be identical. Compound V is, therefore, an 8-alkoxypsoralen. The C_{10} allylic alkoxy group, by analogy with other compounds, is probably geranyl, but this has not been proved.

Compound VII, m.p. 119–123°, had an ultraviolet spectrum (Fig. 1) similar to that reported for 5,8-dimethoxypsoralen.[9] It was optically active, having an $[\alpha]^{25}D$ 25.61°, and did not migrate on chromatostrips with hydrophobic solvents. Noguchi[14] reported that the 5,8-diether of psoralen (byakangelicin) melts at 125°, forms a monohydrate melting at 117–118° and has an $[\alpha]^{25}D$ 24.62. Subsequently, direct comparison of VII with an authentic sample of byakangelicin[15] indicated they were identical.

Experimental

Chromatographic Fractionation of Lemon Oil.—A 300-g. sample of domestic cold-pressed lemon oil was added to a column of silicic acid 8 cm. in diameter and 25 cm. long prepared from a slurry in hexane.[16] When the oil had penetrated the column, hexane was added and the eluted solvent leaving the column was collected in a fraction cutter (about 20 ml. per tube). Every fifth tube from the fraction cutter was tested for unsaturation with chromatostrips[17] developed with 15% ethyl acetate in hexane and sprayed with a fluorescein-bromine test reagent.[18] When it was observed by this test that the mixture of unsaturated hydrocarbons (chiefly limonene) had passed through the column, a solution of 1% ethyl acetate in hexane was added, followed by gradually increasing amounts of ethyl acetate in hexane, and finally by a solution of 10% ethanol in ethyl acetate. After removal of the terpene hydrocarbons, the fractions were tested by development on chromatostrips containing small amounts of luminescent mineral phosphors. The developed strips were examined under ultraviolet light (maximum emission at 253 mμ) for fluorescent compounds and for compounds capable of absorbing the rays of the exciting illumination. These latter compounds appeared as purple shadows on a yellow background. Compounds II, IV and VI fluoresced a brilliant blue, and I, III, V and VII appeared as purple spots. The strips were also tested for carbonyl

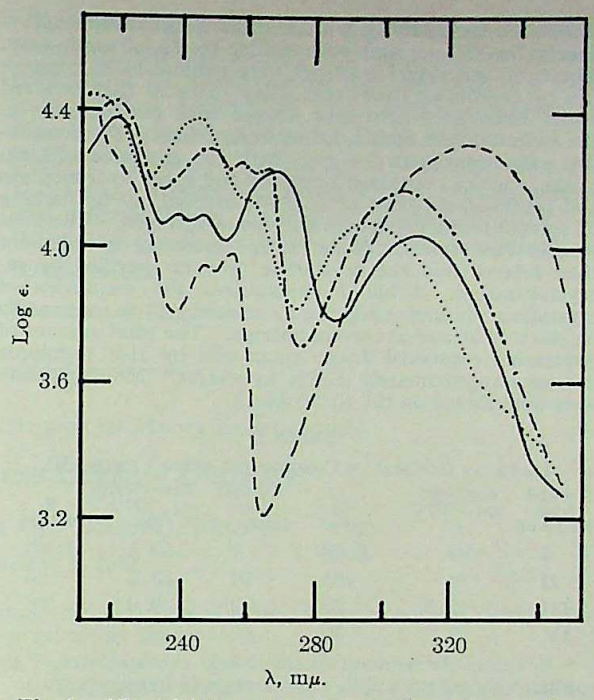

Fig. 1.—Ultraviolet spectra of coumarin compounds from lemon oil: –.–.–.–.–.–.–, 5-geranoxypsoralen (I) in absolute ethanol. Also characteristic for 5-geranoxypsoralen from oil of bergamot, 5-methoxypsoralen from oil of bergamot and synthetic from I, and unknown compound III. – – – – – – –, 5-geranoxy-7-methoxycoumarin (II) in absolute ethanol. Also characteristic for 5,7-dimethoxycoumarin (VI) and unknown IV. . . . . , 8-Geranoxypsoralen (V) in absolute ethanol. Also characteristic for 8-methoxypsoralen[13] and 8-γ,γ-dimethylallyloxypsoralen.[11] ————, Byakangelicin (VII). Also characteristic for 5,8-dimethoxypsoralen,[9] byakangelicol[14] and 5,8-dimethoxypsoralen from lime oil.

compound by spraying with acidified 2,4-dinitrophenylhydrazine in ethanol and *o*-dianisidine in glacial acetic acid. The 1,037 individual fractions were reduced to 25 composites by combining tubes containing material that behaved under ultraviolet light and reacted with test reagents in the same manner and had similar R_f values. The composites were reduced to 3–5 ml. (with the exception of composite 1 which contained limonene and other hydrocarbons and represented about 85% of the original oil) by flashing off solvent under vacuum in a stream of nitrogen. The composites were stored at 5° and those depositing crystals were then filtered and the crystalline products purified by recrystallization. Table I summarizes the recoveries of crystalline coumarins and the R_f values for these compounds on silicic acid coated chromatostrips. The total amount of coumarins recovered from lemon oils by this technique averages approximately 0.38% by weight. Melting points were determined on the Kofler block.

TABLE I

DATA ON COUMARIN COMPOUNDS FROM LEMON OIL

Compd. from lemon oil	Recovery, mg./100 g. oil	R_f value[a]	Compd. from lemon oil	Recovery, mg./100 g. oil	R_f value[a]
I	90	0.68	V	59.3	0.40
II	116	.64	VI	53.2	.25
III	2.5	.57	VII	9.0	.00
IV	3.0	.50			

[a] R_f values determined on silicic acid chromatostrips[15] by capillary ascent with 25% ethyl acetate in hexane (v./v.).

Isolation of 5-Geranoxypsoralen (I).—The product crystallizing from composite 10 at refrigerator temperatures (5°) was washed on a filter with cold petroleum ether and recrystallized from petroleum ether to yield the analytical sample (long needles) of 5-geranoxypsoralen, m.p. 53.5–54.5°.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.55; MeO–, 0.0. Found: C, 74.5; H, 7.14; MeO–, 0.26.

5-Hydroxypsoralen (IX).—Two drops of sulfuric acid was added with stirring to a solution of 5-geranoxypsoralen (0.490 g.) in glacial acetic acid (5 ml.). A tan precipitate formed in a few minutes and the reagent solution turned light brown. The reaction mixture was stirred at room temperature for 1 hr., cooled to about 10° and filtered with suction. The melting point of the crude material (0.278 g.) was approximately 270°. A series of solvents was tried in attempts to recrystallize the phenol, but only amorphous nodules were produced. Minute shiny platelets were obtained from ethanol but with poor recovery.

Preparation of 5-Methoxypsoralen (X).—A solution of the crude 5-hydroxypsoralen (0.040 g.), dimethyl sulfate (1 ml.) and anhydrous potassium carbonate in acetone (dried over anhydrous potassium carbonate) (20 ml.) was refluxed 3 hr. and allowed to cool. About 50 ml. of water was added in increments and the fine needles which formed were filtered off and taken up in ethanol, whereupon frond-like clusters of thin platelets were obtained (0.011 g.), m.p. 185–192°. A mixture of the product with 5-methoxypsoralen from bergamot oil (m.p. 186.5–188°) had m.p. 186–187°, with authentic material from wild parsnip, m.p. 186–187°.[11]

5-Acetoxypsoralen (XI).—The acetate was prepared from 5-hydroxypsoralen with an excess of acetic anhydride and freshly fused sodium acetate. Fine colorless needles were obtained from methanol, m.p. 177–179°.

Anal. Calcd. for $C_{13}H_8O_5$: C, 63.9; H, 3.30. Found: C, 64.0; H, 3.30.

Isolation of 5-Geranoxy-7-methoxycoumarin (II).—During the removal of solvent from composite 12, white crystals were deposited. The crystals redissolved when the concentrate was warmed but again appeared at room temperature. On recrystallization from petroleum ether–ethyl acetate fine colorless needles (0.348 g.) were obtained, m.p. 86–87°. The melting point of a mixture of II with 5-geranoxy-7-methoxycoumarin isolated from lime oil was not depressed. By comparison of infrared spectra the two compounds were judged to be identical.

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.15; H, 7.35; 1 MeO–, 9.4. Found: C, 72.7; H, 7.33; MeO–, 9.5.

7-Methoxy-5-hydroxycoumarin (VIII).—A sample of 7-methoxy-5-geranoxycoumarin (0.519 g.) was dissolved in glacial acetic acid (5 ml.), allowed to react with two drops of concentrated sulfuric acid with stirring for 1.5 hr. The product phenol (0.228 g.), m.p. 227–228°, gave, with ferric chloride, a yellow-green solution darkening with time, and with 1% sodium nitrate in concentrated sulfuric acid a bright yellow solution which turned orange-red when the solution was made alkaline with sodium hydroxide.

Preparation of 5,7-Dimethoxycoumarin.—To a methanol solution of 7-methoxy-5-hydroxycoumarin (0.065 g.) was added an ethereal solution of diazomethane. Recrystallized from acetone–hexane the product had m.p. 145–146°. The mixed melting point with compound VI (5,7-dimethoxycoumarin) was not depressed. Their infrared spectra were identical.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89; 2 MeO–, 30.10. Found: C, 63.5; H, 5.11; MeO–, 29.5.

Isolation of Compound III.—Composite 14 obtained from fractions 360 to 365 was concentrated under vacuum to about 1 ml. On standing overnight at about 5° the concentrate deposited crystals (7.5 mg.) which, on recrystallization from hexane–ethyl acetate (colorless blades), melted at 94–96°.

Isolation of Compound IV.—Composite 16 from fractions 380 to 405 was reduced to about 2 ml. under vacuum. On standing overnight at 5°, the concentrate deposited crystals (9 mg.). This material was recrystallized from hexane–ethyl acetate, yielding nodules, m.p. 90–92°.

Isolation of 8-Geranoxypsoralen (V).—Composite 17, made up of fractions 406 to 475, was reduced to about 5 ml. by flashing off solvent under vacuum in a stream of nitrogen. The concentrate was allowed to stand overnight at 5° whereupon a copious deposit of crystals was obtained (0.178 g.). Recrystallized from hexane–ethyl acetate this material (long blades) melted at 59–60°.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.55; MeO–, 0.0. Found: C, 74.7; H, 6.75; MeO–, 0.32.

Preparation of 8-Hydroxypsoralen (XII).—A sample of 8-geranoxypsoralen (V) (0.275 g.) was dissolved in glacial acetic acid (4 ml.), and a drop of concentrated sulfuric acid was added with stirring. A precipitate began to appear within five minutes. Stirring was continued at room temperature for 1 hr. whereupon the solution was cooled to about 10°, the solid was filtered off and washed on the filter with a small amount of ethyl acetate followed by cold ethyl ether (product (0.115 g.).

Preparation of 8-Methoxypsoralen (XIV).—The methyl ether XIV of the phenol XII was prepared by the addition of an ethereal solution of diazomethane to a methanol solution of the phenol. Recrystallized from hexane–acetone solution the product (long hollow needles) had m.p. 145–146°. The melting point of a mixture with an authentic sample of 8-methoxypsoralen was not depressed.[13] A comparison of the infrared spectra of the two compounds indicated that they were identical.

Anal. Calcd. for $C_{12}H_8O_4$: C, 66.7; H, 3.73. Found: C, 66.5; H, 3.87.

Preparation of 8-Acetoxypsoralen (XIII).—A mixture of the 8-hydroxypsoralen (XII) (0.019 g.), acetic anhydride (1.0 ml.) and freshly fused sodium acetate (0.01 g.) was heated in a water-bath for 1 hr. The mixture was allowed to cool and water was gradually added with shaking until the acetic anhydride had hydrolyzed. The pale yellow solid that appeared was filtered off and dried *in vacuo* (0.014 g.). Recrystallized from methanol the pale yellow prisms melted at 177–180°.

Recovery of 5,7-Dimethoxycoumarin (VI).—Fractions 500 to 605 were composited (composite 18) and reduced under vacuum to about 6 ml. During concentration a crystalline solid appeared. The residue mixture was warmed, enough warm ethyl acetate added to dissolve the crystals and the clear solution was allowed to crystallize at room temperature. The product (0.160 g.) recrystallized from ethyl acetate had m.p. 146–147°.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89; 2 MeO–, 30.10. Found: C, 64.0; H, 5.00; MeO–, 29.9.

Recovery of Byakangelicin (VII).—During the final development of the chromatogram with a solution of 10% (v./v.) ethanol in ethyl acetate, material appeared in the chromatostrip tests which indicated the possible presence of 2 coumarins. Fractions 937 to 1037 were composited

Digitized by Arya Samaj Foundation Chennai and eGangotri

(composite 25) and concentrated to about 3 ml. under vacuum. After storage at 5° a pale yellow crystalline product formed which was filtered off (0.027 g.). The material recrystallized from ethanol melted at 119 to 123° and had an $[\alpha]^{25}D$ of 25.61 in pyridine. A negative Molisch test for sugars and glycosides was obtained. In alcoholic solution the compound gave no coloration when warmed with a chip of magnesium turnings and concentrated hydrochloric acid (a negative test for flavones). The mixed melting point of VII with an authentic sample of byakangelicin[15] was not depressed, and a comparison of the infrared spectra of the two compounds indicated they were identical.

Anal. Calcd. for $C_{17}H_{18}O_7$: C, 61.1; H, 5.43; 1 MeO–, 9.3. Found: C, 61.6; H, 5.59; MeO–, 8.9.

Acknowledgments.—The authors wish to thank Leonard Jurd and R. W. Horowitz of this Laboratory and T. A. Geissman of the University of California in Los Angeles for their helpful suggestions. They are also indebted to Fred Stitt and Glen Bailey, Western Utilization Research Branch, U.S.D.A., Albany, California, for measurements and interpretation of infrared spectra and to L. M. White of the same laboratory for analytical determinations.

The Preparation of Some Organic Diazides

BY ARMIGER H. SOMMERS AND JAMES D. BARNES

RECEIVED FEBRUARY 9, 1957

The polymethylene diazides containing five to ten carbon atoms and examples of other classes of organic diazides have been prepared through displacement of halogen or arenesulfonoxy groups by the azide ion.

A recent review[1] of the literature on organic azides lists no diazidoalkanes other than 1,2-diazidoethane.[2] We have prepared a series of eight aliphatic diazides containing five to ten carbon atoms for pharmacologic testing as hypotensive agents. Examples of the oxa and aza analogs of these diazides were also synthesized, as was α,α'-diazido-*p*-xylene. Pharmacologic studies in these laboratories have shown that some of these diazides possess marked hypotensive action in normal animals.[3]

The treatment of polymethylene dibromides with sodium azide in aqueous methanol[4] generally gave the corresponding diazides in good yield.

$$Br{-}(CH_2)_n{-}Br + 2NaN_3 \rightarrow N_3{-}(CH_2)_n{-}N_3 + 2NaBr$$

Replacing one or both primary alkyl bromide groups in the reactant by secondary groups gave progressively lower yields of product. Table I summarizes the data obtained from these diazidoalkanes. α,α'-Diazido-*p*-xylene, in which an aromatic ring joins two azidoalkyl groups, was obtained in the same manner from α,α'-dichloro-*p*-xylene and sodium azide.

The displacement of an arenesulfonoxy group by azide ion, a method recently applied to the preparation of cyclohexyl azide,[5] is an effective alternate method of synthesis. The benzenesulfonic acid or *p*-toluenesulfonic acid esters of 1,6-hexanediol and 1,7-heptanediol were thus converted to the corresponding diazidoalkanes.

$$Ar{-}SO_3{-}(CH_2)_n{-}O_3S{-}Ar + 2NaN_3 \longrightarrow N_3{-}(CH_2)_n{-}N_3 + 2ArSO_3Na$$

Because 1,7-diazidoheptane possesses greater hypotensive potency than its homologs,[3] an isoster, di-3-azidopropyl ether, was prepared by the following reactions.

$$(ClCH_2CH_2CH_2)_2O + 2NaI \longrightarrow (ICH_2CH_2CH_2)_2O$$
$$(ICH_2CH_2CH_2)_2O + 2NaN_3 \longrightarrow (N_3CH_2CH_2CH_2)_2O$$

Treatment of N-methyl- and N-phenyl-N,N-bis-(β-chloroethyl)-amines with sodium azide gave the corresponding amino diazides, one of which was converted to a diazide quaternary ammonium salt.

$$RN(CH_2CH_2Cl)_2 + 2NaN_3 \longrightarrow RN(CH_2CH_2N_3)_2 \xrightarrow{CH_3I} [R(CH_3)N(CH_2CH_2N_3)_2]^+ I^-$$

No fires or explosions were experienced in working with these diazides. However, because of the reported sensitivity to heat of diazidoethane they were regarded as potentially explosive materials and handled accordingly.

Acknowledgment.—We are grateful to Mr. E. F. Shelberg and staff of the Microchemical Department for the analyses reported here.

Experimental

Dibromoalkanes.—With two exceptions these were commercially available. 1,7-Dibromoheptane and 1,8-dibromoöctane were made by the action of anhydrous hydrogen bromide[6] upon the corresponding glycols. The latter compounds were obtained by reduction of methyl or ethyl esters of pimelic and suberic acids with lithium aluminum hydride.[7] In the synthesis of diethyl pimelate from pimelonitrile using alcoholic hydrogen chloride there was obtained, along with the desired ester (75%), **ethyl pimelamate**, m.p. 76–77°, in 4% yield.

Anal. Calcd. for $C_9H_{17}NO_3$: C, 57.73; H, 9.15; N, 7.48; O, 25.64. Found: C, 58.29; H, 9.16; N, 7.47; O, 25.43.

Arenesulfonic Esters.—**1,6-Dibenzenesulfonoxyhexane**, prepared by a procedure described for alkyl esters,[8] decomposed upon attempted distillation and was purified by crystallization from alcohol which gave crystals melting at 58–60°.

Diazidoalkanes. From Dibromoalkanes.—To a solution of 0.1 mole of the dibromoalkane in 225 ml. of methanol, there was added a slurry of 16.3 g. (0.25 mole) of sodium azide in 15 ml. of water. The mixture was refluxed for 24 hr., the methanol removed and the residue diluted with 50 ml. of water. The resultant oil was extracted by 200 ml. of ether, dried over calcium chloride and distilled. Table I describes the diazidoalkanes obtained by this procedure.

1,7-Diazidoheptane was prepared also by the following method.[11] A solution containing 78 g. (1.2 moles) of sodium azide and 27 g. of sodium acetate in 270 ml. of water was added to a warm solution of 129 g. (0.5 mole) of 1,7-dibromoheptane in 460 ml. of absolute ethanol. The mixture was refluxed for 24 hr. on a steam-bath, and 375 ml. of alcohol was then distilled from the mixture. The residue was poured into 0.5 l. of water and shaken with three 200-ml. portions of benzene. Distillation of the extract gave 83 g. (95%) of the product, b.p. 80–81° at 0.3 mm., $n^{25}D$ 1.4698.

From Arenesulfonic Esters. 1,7-Diazidoheptane.—A mixture of 22 g. (0.05 mole) of 1,7-di-*p*-toluenesulfonoxyheptane, 9.8 g. (0.15 mole) of sodium azide, 150 ml. of acetone and 20 ml. of water was refluxed on a steam-bath for 24 hr. The condenser was removed and acetone was allowed to evaporate during 15 minutes. Water (100 ml.) was added and the oil which formed was extracted into benzene and distilled. There was obtained 8.5 g. (93%) of product, b.p. 72° at 0.2 mm., $n^{25}D$ 1.4701.

By this method the benzene- and *p*-toluenesulfonic acid diesters of 1,6-hexanediol were converted to 1,6-diazidohexane in yields of 74 and 83%.

α,α′-Diazido-*p*-xylene.—The general method described for the preparation of diazidoalkanes was applied to α,α′-dichloro-*p*-xylene. The product, a colorless oil, b.p. 82–83° at 0.1 mm., $n^{25}D$ 1.5590, was obtained in 90% yield.

Anal. Calcd. for $C_8H_8N_6$: N, 44.66. Found: N, 44.10.

Di-3-azidopropyl Ether. Di-3-iodopropyl Ether.—To a solution of 45 g. (0.3 mole) of sodium iodide in 250 ml. of acetone was added 20 g. (0.12 mole) of di-3-chloropropyl ether, and the mixture was refluxed for 19 hr. The salt was removed by filtering and the filtrate was concentrated and distilled. Redistillation of material (25 g.), b.p. 141–154° (10 mm.), gave 15 g. (36%) as a center cut, b.p. 134–142° (7 mm.), $n^{25}D$ 1.5638. This material was used for the next reaction without further purification.

Anal. Calcd. for $C_6H_{12}I_2O$: I, 71.70. Found: I, 69.10.

Di-3-azidopropyl Ether.—A mixture of 14.5 g. (0.04 mole) of di-3-iodopropyl ether, 6.5 g. (0.1 mole) of sodium azide, 75 ml. of ethanol and 15 ml. of water was heated to reflux for 25 hr. After the mixture had been diluted with 200 ml. of water, the oil which separated was extracted by benzene. Two distillations of the oil remaining after concentration of the extract gave 5 g. (68%) of product, b.p. 116–117° at 8 mm., $n^{25}D$ 1.4661.

Anal. Calcd. for $C_6H_{12}N_6O$: C, 39.12; H, 6.57; N, 45.63. Found: C, 38.99; H, 6.59; N, 45.47.

Diazido Amines. N,N-Bis-(β-azidoethyl)-aniline.—A mixture of 21.8 g. (0.1 mole) of N,N-bis-(β-chloroethyl)-aniline, 16.3 g. (0.25 mole) of sodium azide, 225 ml. of methanol and 15 ml. of water was refluxed for 24 hr. on the steam-bath. The methanol was removed under reduced pressure, and the residue was diluted with 225 ml. of water and shaken with 200 ml. of ether. The extract was dried over sodium sulfate and distilled to obtain 18 g. (79%) of product, b.p. 132–134° at 0.2 mm., $n^{25}D$ 1.5748. A redistilled sample was analyzed.

Anal. Calcd. for $C_{10}H_{13}N_7$: C, 51.93; H, 5.67; N, 42.40. Found: C, 52.66; H, 5.86; N, 41.09.

N,N-Bis-(β-azidoethyl)-methylamine.—A solution of 16.3 g. (0.25 mole) of sodium azide in 100 ml. of water was added to 39 g. (0.2 mole) of N,N-bis-(β-chloroethyl)-methylamine hydrochloride. After the mixture had stood 6 hr., it was warmed on the steam-bath and an additional 26 g. (0.4 mole) of sodium azide was added. The mixture was heated another hour, cooled and treated with 60 ml. of aqueous 25% sodium hydroxide. The oil was extracted by three 100-ml. portions of ether, dried over potassium hydroxide pellets and distilled. By redistillation of the material boiling at 97–100° at 5 mm., there was obtained 15 g. (44%) of product, b.p. 98–99° at 5 mm., $n^{25}D$ 1.4824.

Anal. Calcd. for $C_5H_{11}N_7$: C, 35.49; H, 6.55; N, 57.95. Found: C, 35.77; H, 6.65; N, 57.51.

Its oxalate, prepared in ether and recrystallized in isopropyl alcohol, melted at 95–97°.

Anal. Calcd. for $C_7H_{13}N_7O_4$: N, 37.83. Found: N, 37.17.

N,N-Bis-(β-azidoethyl)-dimethylammonium Iodide.—A solution of N,N-bis-(β-azidoethyl)-methylamine and methyl iodide in absolute ethanol was allowed to stand several days. Dilution with dry ether gave a small amount of white crystalline solid, m.p. 72–74°.

Anal. Calcd. for $C_6H_{14}IN_7$: C, 23.16; H, 4.54; N, 31.51. Found: C, 23.52; H, 4.58; N, 31.76.

The Free Radical Addition of Thiolacetic Acid to Some Cyclic Olefins

BY F. G. BORDWELL AND W. A. HEWETT[1]

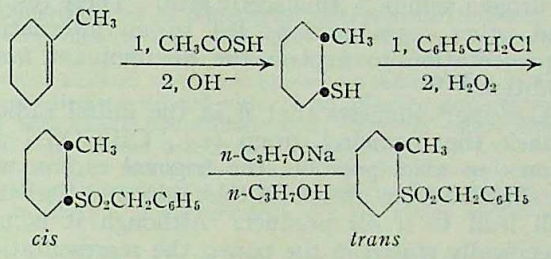
RECEIVED AUGUST 21, 1956

The free radical addition of thiolacetic acid to 1-methylcyclohexene gave about 85% of *cis*- and 15% of *trans*-2-methylcyclohexyl thiolacetate as judged from the composition of the thiol mixture obtained on hydrolysis. Under similar conditions 1-methylcyclopentene gave about 70% of *cis*- and 30% of *trans*-2-methylcyclopentyl thiolacetates. Radical addition of thiophenol to 1-methylcyclohexene also occurred predominantly in a *trans* manner. Addition of thiolacetic acid to camphene, β-pinene and α-pinene appears to have taken place with little or no rearrangement. However, two thiolacetates are formed with each of the pinenes.

As part of a program of synthesis of divalent sulfur compounds it was of interest to study the reaction of thiolacetic acid with several cyclic olefins including 1-methylcyclohexene, 1-methylcyclopentene, camphene, β-pinene and α-pinene.

The first free radical additions of thiolacetic acid to olefins were reported at about the same time by Holmberg[2] and by Ipatieff and Friedman.[3] Since that time similar additions to a large variety of olefins have been reported.[4] In this Laboratory preparation of thiolacetates has been found to provide an excellent general synthetic route to pure thiols, since yields are normally high and orientation is exclusively anti-Markownikoff.[5]

Addition of thiolacetic acid to 1-methylcyclohexene and 1-methylcyclopentene was of interest in connection with the stereoselectivity of free radical addition reactions, as well as for the preparation of the thiols. Cunneen[4b] reported the addition of thiolacetic acid to 1-methylcyclohexene, but did not attempt to decide the stereorelationships of the groups in the product. In the present work the additions were initiated at ordinary temperatures with the aid of light. Excellent yields of thiolacetates were obtained from 1-methylcyclohexene and from 1-methylcyclopentene. These were hydrolyzed with aqueous alcoholic alkali to the thiols. The crude thiols were converted to the corresponding benzyl sulfides and these were oxidized to the sulfones, which were purified by fractional crystallization. In each instance the sulfone formed could be isomerized almost completely by heating with sodium propoxide in *n*-propyl alcohol solution. It seems reasonable to suppose that the original sulfone had the *cis* structure, and was isomerized, by way of the carbanion, to the more stable *trans* isomer on heating with alkali. The sequence of reactions is shown for 1-methylcyclohexene.



Careful fractional distillation[6] separated each thiol into two fractions. For 2-methylcyclohexanethiol 17% of a lower boiling and 83% of a higher boiling fraction were collected. For 2-methylcyclopentanethiol the percentages of the lower and higher boiling materials were 29 and 71%.

The lower boiling 2-methylcyclohexanethiol and 2-methylcyclopentanethiol in each instance gave the more stable benzyl sulfone derivative. The higher boiling thiol was in each instance converted to the less stable benzyl sulfone, identical with that prepared from the crude thiol sample. It is clear, then, that thiolacetic acid gives predominantly *cis*-2-methylcyclohexyl and *cis*-2-methylcyclopentyl thiolacetates (*trans*-addition), but that this is by no means the exclusive product.

Allinger[7] in a restatement of von Auwers' rule states with respect to *cis* and *trans* isomers in cyclic systems: "That isomer which has the higher boiling point, higher index of refraction and higher density is the isomer which possesses the least stable configuration." Our assignment of *cis* and *trans* structures is consistent with this modified von Auwers rule.

Cunneen[4b] reported the addition of thiophenol to 1-methylcyclohexene and oxidation of the resulting sulfide to a sulfone. Reaction of *cis*-2-methylcyclohexanethiol with iodobenzene and oxidation of the resulting sulfide gave a sulfone identical with that prepared by the method of Cunneen. This sulfone was isomerized by heating with sodium propoxide in propyl alcohol, which indicates a *cis* structure. Therefore, thiophenol also adds to 1-methylcyclohexene primarily by *trans* addition.

Goering, Abell and Aycock[8] were first to observe that free radical addition to 1-substituted cyclohexenes occurs by stereoselective *trans* addition. They reported that free radical addition of hydrogen bromide to 1-bromocyclohexene and 1-methylcyclohexene was completely stereoselective (*i.e.*, stereospecific), and interpreted these data in terms of a bridged free radical intermediate. Our present results, which were announced several years

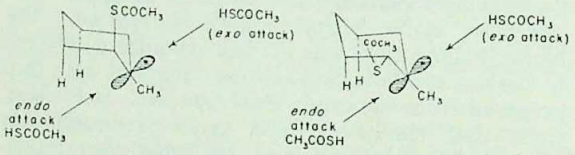
ago,[9] showed that the radical addition of thiolacetic acid to such systems is not stereospecific, since some *cis* addition occurs. This indicated that the concept of a bridged radical intermediate would not provide an entirely satisfactory explanation of the course of such additions. Recently Goering, Relyea and Larsen[10] have reported other examples of radical additions of this type which are not stereospecific. They have found that the degree of stereoselectivity increases with increased concentration for the addition of hydrogen sulfide, and varies with the reagent in the order thiophenol > hydrogen sulfide > thiolacetic acid. These results and other considerations led to an alternative representation to explain the predominant *trans* addition.[10,11]

Goering[10] suggests that if in the initial radical attack the incoming group (*e.g.*, CH_3COS–) assumes an axial position, the trigonal carbon will be shielded from attack on that side, and that this will lead to a *cis* product. Although it is not specifically stated in the paper, the representation given by Goering[10] implies a planar configuration, for the trigonal carbon. In terms of the diagram shown this would amount to *endo* attack by CH_3COSH on Ia. However, if a planar configuration is assumed for this carbon in the free radical inter-

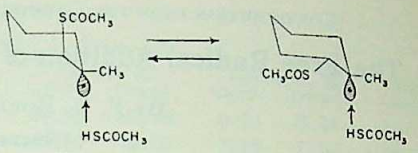


Ia Ib

Planar free radical intermediate

mediate, it does not necessarily follow that *endo* attack on Ia would be preferred. A closely analogous situation exists in the ketonization of enols, and here Zimmerman[12] has shown that due to the hindrance effect of the β-hydrogens (shown in Ia and Ib) *endo* attack of an acid HA is prohibited in an intermediate like Ib ($SCOCH_3$ equatorial). With the $SCOCH_3$ group axial (Ia) *exo* attack becomes less likely, but examination of models indicates that, unless it is assumed that the $SCOCH_3$ group is rotated so as to provide maximum hindrance, *exo* attack may still be favored over *endo*. If this is the correct picture, the *cis* product (predominant) would arise from *exo* attack on Ib rather than *endo* attack on Ia. It is difficult to account for the change in stereoselectivity with changing concentration[11] on this basis, however.

It is not at all certain that the carbon atom holding the odd electron does not maintain a tetrahedral rather than assume a planar configuration. If this carbon is tetrahedral the reaction would be represented as in IIa or IIb rather than as in Ia or Ib. If the methyl group assumes an equatorial



IIa IIb

Tetrahedral free radical intermediate

position, as seems logical, formation of the *cis* isomer would result from attack on IIa. The predominant, but not exclusive, *trans* radical additions to these systems would then be explained by assuming that the $-SCOCH_3$ group initially takes an axial position (IIa) and that conversion to IIb may occur to some extent. Steric hindrance to attack of CH_3COSH would not play an important role according to this mechanism. Increased stereoselectivity with increasing concentration[10] could result from less conversion of IIa to IIb.

No clear-cut choice between the mechanisms illustrated appears to be possible at present. A bridged radical intermediate[8] in these additions is made highly unlikely, however, by the failure of radical addition in non-cyclic alkenes to occur by stereoselective paths.[13]

The reactions of thiolacetic acid with camphene, β-pinene and α-pinene were carried out primarily to see whether or not free radical type rearrangements occur in these systems, which are notorious for their ease of carbonium ion rearrangements. Rearrangements during free radical additions are rare, one of the few well-established examples occurring in the addition of carbon tetrachloride to β-pinene.[14] Addition of thiolacetic acid to camphene followed by hydrolysis gave an over-all yield of 64% of a thiol, which appeared to be a single compound. Desulfurization yielded isocamphane, which indicates that no rearrangement occurred.

Addition of thiolacetic acid to β-pinene and hydrolysis gave a mixture of two thiols, as indicated by the isolation of two 2,4-dinitrophenyl sulfide derivatives. However, the original thiol mixture showed no band at 12.5 μ (characteristic of the olefinic band of Δ^1-*p*-menthene), which would be present if rearrangement of the type previously observed[14] had occurred (to give III). Infrared bands characteristic of norpinane were present, and it seems likely that no rearrangement of the carbon skeleton to III took place. The two thiols are probably *cis–trans* isomers (comparable to I and II) which are formed as a result of a partially stereoselective addition, as with 1-methylcyclohexene (I–III).

The infrared spectra of the 2,4-dinitrophenyl sulfide derivatives of these thiols were nearly identical, which shows a very close structural relationship. Addition of thiolacetic acid to α-pinene and hydrolysis also gave two thiols, as indicated by isolation of two 2,4-dinitrophenyl sulfide derivatives. These also are believed to be *cis–trans* isomers.

It has been shown by Seubold[15] that the life time of a radical under a particular set of conditions is an important factor in determining whether or not it will rearrange. The absence of rearrangement may be due to a very short half-life for the intermediate free radical. In this connection it is also of interest that carbon tetrachloride does not enter into the free radical chain of this type addition reaction, since chlorine was not incorporated into the product in an addition carried out in carbon tetrachloride solution, even when the ratio of carbon tetrachloride to thiolacetic acid was ten to one.

Experimental[16]

cis- and *trans*-2-Methylcyclohexanethiols.—2-Methylcyclohexyl thiolacetate was prepared by slowly adding 156 g. (2.0 moles) of practical grade thiolacetic acid to 164 g. (1.7 moles) of 1-methylcyclohexene while irradiating with a 100 watt bulb. Care must be taken as the reaction is highly exothermic and may have an induction period of several minutes. Distillation gave 250 g. (85%) of product, b.p. 110° (14 mm.), $n^{25}D$ 1.495. The reported boiling point of 2-methylcyclohexyl thiolacetate is 110° (14 mm.).[4b] (The thiolacetate is a mixture of *cis* and *trans* isomers.)

The thiolacetate (246 g., 1.43 moles) was hydrolyzed by refluxing for one hour in 2 l. of 10% aqueous alcoholic (50% by volume) potassium hydroxide. The solution was neutralized with glacial acetic acid and the non-aqueous phase separated. The aqueous portion was extracted three times with pentane and the pentane extracts were dried over anhydrous magnesium sulfate. The combined non-aqueous phase and pentane extracts were distilled giving 155 g. (82%) of 2-methylcyclohexanethiol, b.p. 71–72° (23 mm.); a b.p. of 165° was reported.[4b]

Careful fractionation[6] gave 16% of the charge as a fraction (*trans* isomer) boiling at 138.7° (300 mm.), $n^{20}D$ 1.4851, and 76% of the charge as a fraction (*cis* isomer) boiling at 143.4° (300 mm.), $n^{20}D$ 1.4937. Ignoring intermediate cuts the percentage of *trans* and *cis* isomers based on 92% of the charge are 17% and 83%, respectively.

The 2,4-dinitrophenyl sulfide derivatives of the pure thiols were prepared in the usual manner.[17]

Recrystallization of the derivative from the lower boiling fraction gave *trans*-2-methylcyclohexyl 2,4-dinitrophenyl sulfide, m.p. 140–140.5°.

Anal. Calcd for $C_{13}H_{16}O_4N_2S$: C, 52.69; H, 5.44. Found: C, 52.32; H, 5.65.

Recrystallization of the derivative from the higher boiling fraction gave *cis*-2-methylcyclohexyl 2,4-dinitrophenyl sulfide, m.p. 100–100.5°. This derivative also was obtained from the crude thiol prior to fractionation.

Anal. Calcd. for $C_{13}H_{16}O_4N_2S$: C, 52.69; H, 5.44. Found: C, 52.31; H, 5.31.

cis-2-Methylcyclohexyl Benzyl Sulfone.—The benzyl sulfide was prepared by dissolving the higher boiling thiol in 95% alcohol containing an equimolar quantity of sodium hydroxide and treating with an equimolar quantity of benzyl chloride. The solution was poured into water and the sulfide obtained by extraction with pentane. Oxidation of the crude sulfide, obtained by evaporation of the pentane, with a sixfold excess of 30% hydrogen peroxide in glacial acetic acid followed by addition of the reaction mixture to water gave the crude benzyl sulfone in 72% yield. One recrystallization from glacial acetic acid gave *cis*-2-methylcyclohexyl benzyl sulfone, m.p. 74–74.5°.

Anal. Calcd. for $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99. Found: C, 66.50; H, 7.74.

This benzyl sulfone was also obtained from the thiol mixture prior to fractionation, but the melting point of the crude sulfone was low (58–65°), and repeated recrystallizations were necessary to raise the melting point to that of the pure *cis*-sulfone.

Isomerization of *cis*-2-Methylcyclohexyl Benzyl Sulfone.—The *cis*-sulfone (5.0 g., 0.02 mole) was dissolved in a solution of 1.6 g. (0.02 mole) of sodium *n*-propoxide in 30 ml. of *n*-propyl alcohol, and the solution was refluxed for 44 hr. The solution was diluted with 150 ml. of water and neutralized with dilute hydrochloric acid. The oil which separated was induced to crystallize by cooling with Dry Ice. After several recrystallizations from glacial acetic acid *trans*-2-methylcyclohexyl benzyl sulfone melting at 84–84.5° was obtained. A mixture with the *cis*-sulfone melted at 47–57°.

Anal. Calcd. for $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99. Found: C, 66.57; H, 7.98.

The *trans*-sulfone also was obtained starting with the lower boiling thiol fraction using the method described above for the *cis*-sulfone.

2-Methylcyclopentyl Thiolacetate.—Starting with 1.9 moles of 1-methylcyclopentene and 2.1 moles of practical grade thiolacetic acid, 240 g. (80%) of 2-methylcyclopentyl thiolacetate, b.p. 98–101° (25 mm.), $n^{25}D$ 1.4900, was obtained by the procedure described above. This is a mixture of *cis* and *trans* isomers.

Anal. Calcd. for $C_8H_{14}OS$: C, 60.71; H, 8.92. Found: C, 61.05; H, 9.01.

cis- and *trans*-2-Methylcyclopentanethiols.—Hydrolysis of the thiolacetate as described above gave a mixture of *cis*- and *trans*-thiols in 96% yield, b.p. 146–148°.

Anal. Calcd. for $C_6H_{12}S$: C, 62.00; H, 10.41. Found: C, 62.37; H, 10.32.

Careful fractional distillation[6] gave 27% of the charge as a lower boiling fraction (*trans* isomer), b.p. 135.8° (590 mm.), $n^{20}D$ 1.4783, and 65% as a higher boiling fraction (*cis* isomer), b.p. 142.5° (590 mm.), $n^{20}D$ 1.4884. Based on 92% of the charge, 29% of *trans* isomer and 71% of *cis* isomer were obtained.

trans-2-Methylcyclopentyl 2,4-dinitrophenyl sulfide, prepared from the lower boiling fraction,[17] melted at 112.5–113° after crystallization from absolute alcohol.

Anal. Calcd. for $C_{12}H_{14}O_4N_2S$: C, 51.05; H, 5.00. Found: C, 51.02; H, 5.00.

cis-2-Methylcyclopentyl 2,4-dinitrophenyl sulfide, prepared from the higher boiling fraction,[17] melted at 99–100° after crystallization from absolute alcohol.

Anal. Calcd. for $C_{12}H_{14}O_4N_2S$: C, 51.05; H, 5.00; N, 9.93. Found: C, 50.52; H, 4.82; N, 10.02.

The 2,4-dinitrophenyl sulfide derivatives prepared from the thiol before fractionation melted at ranges between 70–90° despite repeated crystallizations from hexane. Carbon and hydrogen analysis of this mixture checked the theoretical for $C_{12}H_{14}O_4N_2S$, supporting the view that it is a mixture of the derivatives of the *cis*- and *trans*-thiols.

cis- and *trans*-2-Methylcyclopentyl Benzyl Sulfones.—These sulfones were prepared by the general method described above starting with the pure thiols. The *cis* isomer melted at 74.5–75° after crystallization from aqueous methanol or hexane.

Anal. Calcd. for $C_{13}H_{18}O_2S$: C, 65.51; H, 761. Found: C, 65.71; H, 7.41.

The *trans* isomer melted at 101–101.5° after recrystallization from methanol.

Anal. Calcd. for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61. Found: C, 65.75; H, 7.42.

The crude thiol mixture yielded a benzyl sulfone which was purified only with difficulty. Repeated recrystallizations

Digitized by Arya Samaj Foundation Chennai and eGangotri

from glacial acetic acid gave material melting sharply at 61–62°, but several additional recrystallizations from methanol gave the pure *cis* isomer, m.p. 74–74.5°. Carbon and hydrogen analysis of the material melting at 61–62° supported the conclusion that it was a mixture of *cis*- and *trans*-benzyl sulfones. A mixture of the *cis*- and *trans*-sulfones melted at 62–76°.

Isomerization of *cis*-2-Methylpentyl Benzyl Sulfone.—Treatment of either the pure *cis*-benzyl sulfone or the mixture of benzyl sulfones melting at 61–62° according to the method used to isomerize *cis*-2-methylcyclohexyl benzyl sulfone gave a 91% conversion to the *trans*-sulfone, m.p. 98–100°.

Attempts to isomerize the *cis*-thiol or *cis*-benzyl sulfide by this procedure were unsuccessful.

***cis*- and *trans*-2-Methylcyclohexyl Phenyl Sulfones.**—*cis*-2-Methylcyclohexylphenyl sulfide was prepared by heating a mixture of *cis*-2-methylcyclohexanethiol with iodobenzene and copper powder at 220° according to the procedure described by Cunneen.[4b] The sulfide also was prepared in 50% yield from 1-methylcyclohexene and thiophenol by heating on the steam-bath in the presence of *t*-butyl peroxide. Oxidation of each of these samples with 30% hydrogen peroxide in glacial acetic acid gave the same sulfone, m.p. 107–108° after recrystallization from methanol; Cunneen[4b] reports the melting point as 108°. Isomerization of the sulfone by the method described above gave an 85% yield of *trans*-**2-methylcyclohexyl phenyl sulfone** (m.p. 82–86°), which melted at 90–90.5° after recrystallization from methanol.

Anal. Calcd. for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61. Found: C, 65.40; H, 7.30.

A mixture of the *cis*- and *trans*-sulfones melted at 88–95°.

Addition of Thiolacetic Acid to 1-Hexene in Carbon Tetrachloride Solution.—Thiolacetic acid (28 g., 0.3 mole) was added slowly to a solution of 25 g. (0.3 mole) of 1-hexene in 461.5 g. (3 moles) of carbon tetrachloride under irradiation. The yield of *n*-hexyl thiolacetate, b.p. 88° (13 mm.), $n^{25}D$ 1.4591, was 83%; Wenzel and Reid[18] reported b.p. 205.8° (760 mm.), $n^{25}D$ 1.4591.

2-Mercaptomethyl-3,3-dimethylbicyclo[2,2,1]heptane.—Addition of 90 g. (1.2 moles) of thiolacetic acid to 136 g. (1 mole) of camphene in the usual manner gave 164 g. (77%) of 2-(S-thiolacetoxymethyl)-3,3-dimethylbicyclo[2,2,1]heptane, b.p. 93–95° (0.8–1.0 mm.); Behringer[4c] reports a boiling point of 147–148° (14 mm.). Alkaline hydrolysis gave 109 g. (83%) of 2-mercaptomethyl-3,3-dimethylbicyclo[2,2,1]heptane, b.p. 116° (20 mm.).

Anal. Calcd. for $C_{10}H_{18}S$: C, 70.52; H, 10.65. Found: C, 70.68; H, 10.64.

The 2,4-dinitrophenyl sulfide[17] of this thiol melted at 126–126.5° after crystallization from alcohol.

Anal. Calcd. for $C_{16}H_{20}O_4N_2S$: N, 8.33. Found: N, 8.33.

Isocamphane from the Desulfurization of 2-Mercaptomethyl-3,3-dimethylbicyclo[2,2,1]heptane.—Following the procedure of Papa, Schwenk and Ginsberg[19] a solution of 20 g. (0.117 mole) of thiol in 500 ml. of 10% aqueous sodium hydroxide and 40 ml. of alcohol was heated and stirred vigorously on a steam-bath for two hours, during which time 40 g. of Raney nickel alloy was added to the solution in small increments. The reaction mixture was heated an additional two hours and the product accumulating in the condenser during this time was washed back into the reaction flask with a little alcohol. The mixture was then steam distilled, and the distillate extracted with ether. The ether extracts were dried over anhydrous magnesium sulfate, and then distilled through a 3-plate Vigreux column to yield 3.5 g. (22%) of isocamphane, b.p. 163–164°, m.p. 54–56°. The reported physical constants[20] are b.p. 164.5° and m.p. 65–66° (the expected rearrangement product, camphane, boils at 160–161° and melts at 156–156.5°[20]).

The Addition of Thiolacetic Acid to β-Pinene.—The addition of 25.4 g. (0.33 mole) of freshly distilled thiolacetic acid to 45 g. (0.33 mole) of β-pinene gave 59 g. (84%) of thiolacetate, b.p. 91–92° (0.5 mm.), $n^{25}D$ 1.5090.

Anal. Calcd. for $C_{12}H_{20}OS$: C, 67.87; H, 9.49. Found: C, 68.00; H, 9.44.

Hydrolysis of 53 g. (0.25 mole) of the thiolester gave 40 g. (94%) of thiol, b.p. 124–125° (25 mm.), $n^{25}D$ 1.5100.

Anal. Calcd. for $C_{10}H_{18}S$: C, 70.52; H, 10.65. Found: C, 70.86; H, 10.52.

Neither the thiolacetate nor the thiol showed a band in the 12.5 μ region of the spectra, which indicates the absence of a RR′C=CHR″ type of double bond.

Recrystallization of the 2,4-dinitrophenyl sulfide derivative of the thiol from alcohol gave two different products. The first crop of crystals (compound A) melted at 141–143°, and this melting point was not changed by recrystallization from hexane. The second crop of crystals (compound B) melted at 121–122°, and recrystallization from alcohol did not raise the melting point. A mixture of the derivatives melted at 118–130°.

Anal. Calcd. for $C_{16}H_{20}O_4N_2S$: N, 8.33. Found: N, 8.40 (for A); N, 8.45 (for B).

Addition of Thiolacetic Acid to α-Pinene.—Addition of 22.8 g. (0.3 mole) of freshly distilled thiolacetic acid to 41 g. (0.3 mole) of α-pinene gave 43 g. (70%) of thiolacetate, b.p. 105° (3.2 mm.); Behringer[4c] reported the b.p. to be 135–137° (13 mm.). Hydrolysis of 42 g. of the thiolacetate gave 22 g. (64%) of thiol, b.p. 84° (7 mm.).

Anal. Calcd. for $C_{10}H_{18}S$: S, 70.52; H, 10.65. Found: C, 70.79; H, 11.07.

Crystallization of the 2,4-dinitrophenyl sulfide derivative[17] from alcohol gave two different products. The first crop (compound A′) melted at 154–160°, and recrystallization from hexane gave material melting at 158.5–164°. The second crop (compound B′) melted at 143–145°, and recrystallization from alcohol raised the melting point to 146–148°. A mixture of the two derivatives melted at 138–161°.

Anal. Calcd. for $C_{16}H_{20}O_4N_2S$: N, 8.33. Found: N, 8.40 (for A′); N, 8.53 (for B′).

Exhaustive attempts to purify the derivatives A, B, A′ and B′ were not made. It is probable that some or all might have higher melting points when purified further. A mixture of A (m.p. 141–143°) and B′ (146–148°) melted at 115–130°.

New Analeptics. 1-Benzhydryl-2-alkyl-2-thiopseudoureas[1]

BY STANLEY O. WINTHROP, STELLA SYBULSKI, GREGORY GAVIN AND GORDON A. GRANT

RECEIVED JANUARY 30, 1957

The synthesis of a series of S-alkylated benzhydrylthioureas is reported. The lower members have shown analeptic properties.

During a search for new spasmolytic agents, 1-benzhydryl-2-methyl-2-thiopseudourea hydroiodide (I) was prepared. When tested in animals this compound showed an interesting central stim-

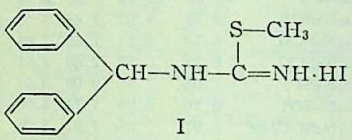
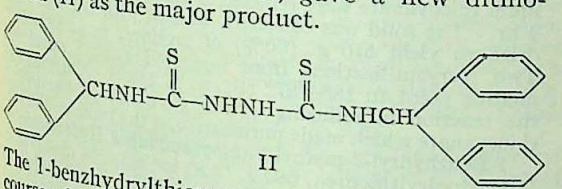
[d] Prepared from the appropriate benzhydrylamine hydrochloride and ammonium thiocyanate.

ulant activity. It appeared desirable therefore to prepare other compounds structurally related to I for pharmacological screening.



I

Schroeder[2] has described several methods for the preparation of thioureas. 1-Benzhydrylthiourea had previously been synthesized from benzhydryl isothiocyanate and ammonia.[3,4] It was found that 1-benzhydrylthioureas can also be conveniently prepared by fusing the benzhydrylamine hydrochloride and ammonium thiocyanate in the presence of an inert solvent. When benzhydryl isothiocyanate was allowed to react with a fivefold excess of hydrazine, a good yield of 4-benzhydrylthiosemicarbazide resulted. Equivalent amounts of these reactants, however, gave a new dithiobiurea (II) as the major product.



II

The 1-benzhydrylthioureas synthesized during the course of this investigation and not reported previously are listed in Table I. Other new miscellaneous thioureas are included in the Experimental section of this paper.

The thiopseudourea salts were prepared for the most part by refluxing an ethanol solution of the appropriate 1-benzhydrylthiourea and an alkyl halide. In the case of halides such as ethyl α-chloroacetate, α-chloroacetamide, α-chloroacetaldehyde and α-chloroacetone we were unable to isolate any thiopseudourea salt since these compounds so readily cyclized to thiazolidines. The cyclized compounds will be the subject of a later paper. When α-bromoacetic acid and 1-benzhydrylthiourea were brought together in an acetone–ether solution at room temperature, the desired thiopseudourea salt resulted. The same reactants gave a thiazolidine in ethanol. The thiopseudourea salts were stable, crystalline, high melting solids.

A thiopseudourea resulted when an aqueous methanolic solution of the thiopseudourea salt was treated with sodium carbonate. The 1-benzhydryl-2-alkyl-2-thiopseudoureas were easily isolated since they were considerably less soluble than their respective salts. In general, the thiopseudoureas were stable compounds. When 1-benzhydryl-2,3,3-trimethyl-2-thiopseudourea hydroiodide was treated with sodium carbonate in the usual manner for the preparation of a thiopseudourea, however, an appreciable amount of 1-benzhydryl-3,3-dimethylurea was obtained as a by-product. The characteristic odor of methyl mercaptan also was present.

Since the 1-benzhydryl-2-alkyl-2-thiopseudoureas appeared to be stable, it was of interest to investigate whether these compounds could be alkylated in the usual manner. There was also a question as to which of the two dissimilar nitrogens would be involved in the reaction. An acetone solution of 1-benzhydryl-2-methyl-2-thiopseudourea and methyl iodide was refluxed for 4 hr. Potassium carbonate was included to serve as the acid acceptor. The resulting product gave a hydroiodide which after purification was identical with 1-benzhydryl-2,3-dimethyl-2-thiopseudourea hydroiodide. This latter compound was prepared in an unambiguous manner from benzhydryl isothiocyanate by way of 1-benzhydryl-3-methyl-2-thiourea.

Pharmacological Acitivity.—Several of the 1-benzhydryl-2-alkyl-2-thiopseudourea salts were found to have central stimulant activity. The compounds were administered to rats and the degree of the stimulation recorded in activity cages.[5] The most active compound was the 1-benzhydryl-2-methyl-2-thiopseudourea hydroiodide. This activity decreased gradually with increasing size of the sulfur substituent. Substitution of a hydrogen atom from either nitrogen by a methyl group caused the activity to drop to about a tenth of its original level. Compounds with substituents on one of the phenyl rings had little or no activity. The other thiopseudourea salts were inactive when screened by this method.

This type of activity is not entirely unexpected in view of the report of some respiratory stimulation by 2-alkyl-2-thiopseudourea salts.[6] These ap-

[a] Calcd.: C, 70.25; H, 6.28; S, 12.52. Found: C, 70.34; H, 6.33; S, 12.59. [b] This compound could not be induced to crystallize. It was purified by repeated precipitations.

Acknowledgments.—The authors would like to thank Dr. C. I. Chappel of our laboratories for the pharmacological data, Mr. W. J. Turnbull for the analyses and Dr. Gilles Papineau-Couture and Mrs. J. Jachner for numerous infrared spectra.

Experimental[7]

Starting Materials.—*p*-Methylbenzophenone,[8] *p*-methoxybenzophenone,[8] *p*-chlorobenzhydrylamine,[8] benzhydrylamine,[8] benzhydryl chloride,[8] α,α-diphenylacetonitrile[9] and *o*-chlorobenzaldehyde[9] were available from commercial sources. The following were prepared but had been previously described in the literature: *o*-chlorobenzhydrol,[10] m.p. 64–66° (lit. m.p. 56–66°), *o*-chlorobenzhydryl chloride,[11] b.p. 150–155° at 2 mm., $n^{24}D$ 1.6020 (lit. b.p. 142–145° at 1.5 mm., $n^{21.5}D$ 1.6028); benzhydrylmethylamine hydrochloride,[11] m.p. 245–246° (lit. m.p. 238°); β,β-diphenylethylamine hydrochloride,[12] m.p. 256–257° (lit. m.p. 256°) *p*-methylbenzhydrylamine hydrochloride,[13] m.p. 256–260° (lit. m.p. 250°); *p*-methoxybenzhydrylamine hydrochloride,[14] m.p. 203° dec. (lit. m.p. 190° dec.); 1-benzylthiourea,[15] m.p. 160–162° (lit. m.p. 161–162°); 1-*p*-methylbenzhydrylthiourea,[16] m.p. 165–167° (lit. m.p. 162–163°); 1-benzhydryl-3-methyl-2-thiourea,[2] m.p. 156–157° (lit. m.p. 152–153°).

1-Benzhydrylthiourea.[3,4]—Benzhydrylamine hydrochloride, 780 g. (3.56 moles) and 300 g. (3.9 moles) of ammonium thiocyanate were refluxed in three liters of toluene for 4 hr. The solid was collected, washed with hot water and dried to yield 510 g. (60%) of product, m.p. 182–183°. Two recrystallizations from isopropyl alcohol raised the melting point to 186–187° (lit. m.p. 189°). Carrying out the reaction in refluxing xylene gave rise to benzhydryl thiocyanate which made purification of the product difficult.

1-Benzhydryl-2-methyl-2-thiopseudourea Hydroiodide.—1-Benzhydrylthiourea, 680 g. (2.83 moles), was dissolved in 12 liters of 1:1 acetone–ether, and 600 g. (4.15 moles) of methyl iodide was added. The reaction was considered complete after 1 hr. at room temperature. The solid was collected and dried to yield 800 g. (75%) of product melting at 175–178°. One recrystallization from isopropyl alcohol raised the melting point to 178–180° (see Table II).

1-Benzhydryl-2-methyl-2-thiopseudourea Hydrochloride.—1-Benzhydrylthiourea, 400 g. (1.67 moles), was dissolved in 2600 ml. of acetone, and 500 g. (10 moles) of methyl chloride was added. The solution was placed in a one-gallon pressure autoclave and heated at 80° for 16 hr. The product was then collected and dried to yield 376 g. (81%) melting at 192–195° dec. One recrystallization from ethanol-ether gave an analytical sample, m.p. 196–197° dec. This compound was also prepared by the addition of hydrogen chloride to an acetone solution of 1-benzhydryl-2-methyl-2-thiopseudourea. Calcd. for $C_{15}H_{17}N_2SCl$: C, 61.45; H, 5.85; N, 9.57; S, 10.94; Cl, 12.09. Found: C, 61.24; H, 5.65; N, 9.56; S, 10.74; Cl, 11.95.

1-Benzhydryl-2-methyl-2-thiopseudourea Methyl Bisulfate.—1-Benzhydrylthiourea, 12 g. (0.05 mole) and dimethyl sulfate, 3.15 g. (0.025 mole), were refluxed in 100 ml. of methanol for 3 hr. The methanol was then removed

in vacuo leaving an oil residue which crystallized on trituration with ether to yield 11 g. of solid, m.p. 110–118°. Two recrystallizations from isopropyl alcohol raised the melting point to 130–132°. Calcd. for $C_{16}H_{20}N_2S_2O_4$: C, 52.25; H, 5.48; N, 7.89; S, 18.06. Found: C, 52.65; H, 5.65; N, 7.83; S, 17.83.

1-Benzhydryl-2-methyl-2-thiopseudourea.—1-Benzhydryl-2-methyl-2-thiopseudourea hydroiodide, 46 g. (0.12 mole), was dissolved in aqueous methanol, and 10% sodium carbonate solution was added in excess. The thiopseudourea was filtered off, washed with water and recrystallized from benzene to yield 17 g., m.p. 160–161°. A second recrystallization raised the melting point to 161–162° (see Table III).

1-Benzhydryl-2-methyl-2-thiopseudourea Salts.—The following salts were prepared by addition of the appropriate acid to an acetone–ether solution of 1-benzhydryl-2-methyl-2-thiopseudourea: hydrobromide: m.p. 198–199°. Calcd. for $C_{15}H_{17}N_2SBr$: N, 8.31; S, 9.51; Br, 23.70. Found: N, 8.56; S, 9.59; Br, 23.76. Hydrogen sulfate: m.p. 202–203°. Calcd. for $C_{15}H_{18}N_2S_2O_4$: N, 7.91; S, 18.10. Found: N, 7.99; S, 18.35. Acetate: m.p. 144–145°. Calcd. for $C_{17}H_{20}N_2SO_2$: N, 8.86; S, 10.13. Found: N, 9.14; S, 10.32. Maleate: m.p. 164–165°. Calcd. for $C_{19}H_{22}N_2SO_4$: N, 7.48; S, 8.56. Found: N, 7.46; S, 8.80.

1-Benzhydryl-2-carboxymethyl-2-thiopseudourea Hydrobromide.—1-Benzhydrylthiourea, 4.8 g. (0.02 mole) and α-bromoacetic acid, 4.16 g. (0.03 mole), were dissolved in 100 ml. of a 1:1 acetone–ether mixture. On five minutes standing at room temperature, a solid started to separate out of solution. After ten minutes the precipitation appeared complete and the product was filtered off and dried to yield 7.3 g., m.p. 162–163° (see Table II).

1-Benzhydryl-2-(β-diethylaminoethyl)-2-thiopseudourea Dihydrochloride.—1-Benzhydrylthiourea, 8.0 g. (0.033 mole) and β-diethylaminoethyl chloride hydrochloride, 5.7 g. (0.033 mole) were refluxed in 150 ml. of isopropyl alcohol for 48 hr. The isopropyl alcohol was then removed *in vacuo* and the residue crystallized from an isopropyl alcohol–ether mixture to yield 6.9 g. of product, m.p. 164.5–165.6°. Three recrystallizations from a mixture of isopropyl alcohol and ether raised the melting point to 176–178° (see Table II).

o-Chlorobenzlhydryl Isothiocyanate.—*o*-Chlorobenzhydryl chloride, 92.5 g. (0.39 mole), and ammonium thiocyanate, 30 g. (0.39 mole), were refluxed in 75 ml. of benzene for five days. The solid material remaining was then collected and the benzene filtrate evaporated down *in vacuo* leaving a high boiling liquid residue. Vacuum distillation gave 46 g. (46%) of product boiling from 186–189° at 1.5 mm. Calcd. for $C_{14}H_{10}NSCl$: N, 5.39. Found: N, 5.60.

1-(o-Chlorobenzhydryl)-thiourea.—*o*-Chlorobenzhydryl isothiocyanate, 26 g. (0.1 mole), was dissolved in 500 ml. of an ethanol solution containing 37 ml. of concentrated ammonium hydroxide. The solution was brought to boiling and then allowed to stand at room temperature for 16 hr. Sufficient water was then added to ensure complete precipitation of the product which was collected, washed and dried to give a quantitative yield, 28 g. of crude product, m.p. 166–167°. Two recrystallizations from isopropyl alcohol raised the melting point to 172–173° (see Table I).

1,6-Dibenzhydryl-2,4-dithiobiurea.—Benzhydryl isothiocyanate, 34 g. (0.15 mole), was dissolved in 500 ml. of ethanol and 7.4 ml. of 85% aqueous hydrazine (0.20 mole) was added. An immediate reaction took place. The reaction was considered complete after 30 minutes. The ethanol was then removed *in vacuo* and the oil residue triturated with a little methanol to yield 22 g. of solid with m.p. 168–172°. Four recrystallizations from acetonitrile raised the melting point to 194–195° dec. Calcd. for $C_{28}H_{28}N_4S_2$: C, 69.75; H, 5.43; S, 13.28. Found: C, 69.55; H, 5.49; S, 13.14.

4-Benzhydrylthiosemicarbazide.[17]—The above procedure was repeated using a fivefold excess of hydrazine in order to increase the yield of product by keeping the formation of the dithiobiurea to a minimum. A solid came out of solution and was collected and dried to yield 32.3 g. (70%) of product, m.p. 150–152° dec. One recrystallization from acetonitrile did not raise the melting point (lit. m.p. 144°).

1-Benzhydryl-3,3-dimethyl-2-thiourea.—Benzhydryl isothiocyanate, 34 g. (0.15 mole), was dissolved in 500 ml. of ethanol, and 9.02 g. (0.2 mole) of dimethylamine (25% aqueous solution) was added. The solution was allowed to stand at room temperature for 70 hr. The ethanol was then removed *in vacuo* and the residue crystallized from isopropyl alcohol to yield 37.5 g. of product, m.p. 131–132°. One recrystallization from ethanol did not raise the melting point. Calcd. for $C_{16}H_{18}N_2S$: C, 71.06; H, 6.71; N, 10.36; S, 11.86. Found: C, 71.42; H, 6.94; N, 10.36; S, 12.11.

1-Benzhydryl-2,3,3-trimethyl-2-thiopseudourea Hydroiodide.—1-Benzhydryl-3,3-dimethyl-2-thiourea, 6.1 g. (0.023 mole), and 4.95 g. (0.035 mole) of methyl iodide were refluxed in 50 ml. of ethanol for 2 hr. On cooling and adding of ether, 8.3 g. of product, m.p. 148–150° dec., precipitated. One recrystallization from isopropyl alcohol did not raise the melting point. Calcd. for $C_{17}H_{21}N_2SI$: N, 6.80; S, 7.77; I, 30.78. Found: N, 6.97; S, 8.09; I, 30.78.

1-Benzhydryl-3,3-dimethyl-2-(α-acetonyl)-2-thiopseudourea Hydrochloride.—1-Benzhydryl-3,3-dimethyl-2-thiourea, 7.11 g. (0.03 mole) and α-chloroacetone, 4.2 g. (0.045 mole), were refluxed in 40 ml. of a 1:1 ether–acetone mixture for 2 hr. The acetone–ether was removed *in vacuo* and the residue crystallized from isopropyl alcohol to yield 6.8 g. of product, m.p. 133–144°. Two recrystallizations from an isopropyl–ether mixture followed by two recrystallizations from acetonitrile raised the melting point to 136–137°. Calcd. for $C_{19}H_{23}N_2SOCl$: N, 7.72; S, 8.84; Cl, 9.78. Found: N, 7.50; S, 8.78; Cl, 9.89.

1-Benzhydryl-2,3,3-trimethyl-2-thiopseudourea.—1-Benzhydryl-2,3,3-trimethyl-2-thiopseudourea hydroiodide, 21 g. (0.015 mole), was dissolved in 75 ml. of methanol, and 2.8 g. (0.052 mole) of sodium methoxide was added portionwise with cooling. On removal of about one-third of the methanol *in vacuo* at room temperature, a solid separated out, was filtered off and dried to yield 9 g. of product, m.p. 55–57°. An attempt at purification by recrystallizing from ethanol resulted in a poor recovery of material melting from 50 to 55° and the production of some methyl mercaptan whose presence was noticed by its characteristic odor. Calcd. for $C_{17}H_{20}N_2S$: C, 71.78; H, 7.08; N, 9.84; S, 11.30. Found: C, 72.19; H, 6.78; N, 9.92; S, 11.03.

On evaporating down the original methanol filtrate, additional 3.5 g. of material melting at 185–186° resulted. Two recrystallizations from ethanol raised the melting point to 194–195°. The infrared spectrum and analytical data indicated this compound was 1-benzhydryl-3,3-dimethylurea. Calcd. for $C_{16}H_{18}N_2O$: C, 75.50; H, 7.13; N, 11.02. Found: C, 76.15; H, 7.27; N, 11.05.

1-Benzhydryl-1-methyl-2-thiourea.—Benzhydrylmethylamine hydrochloride, 10 g. (0.043 mole), and ammonium thiocyanate, 3.6 g. (0.017 mole), were added to 100 ml. of xylene, and the reaction mixture was stirred and heated at 135° for 3 hr. On cooling, the solid material was collected, washed with hot water and dried to yield 3.1 g. of product, m.p. 186–189°. One recrystallization from isopropyl alcohol raised the melting point to 193–195°. Calcd. for $C_{15}H_{16}N_2S$: N, 10.92; S, 12.50. Found: N, 10.97; S, 12.42. The xylene filtrate was evaporated down to yield 5.6 g. of solid melting at 120–130° whose infrared spectrum suggested the benzhydrylmethylamine hydrothiocyanate salt.

1-Benzhydryl-1,2-dimethyl-2-thiopseudourea Hydroiodide.—The compound was prepared in the usual manner. It was recrystallized from an isopropyl alcohol-ether mixture to give an analytical sample melting at 175–176° dec. Calcd. for $C_{16}H_{19}N_2SI$: N, 7.03; S, 8.05; I, 31.86. Found: N, 6.81; S, 8.17; I, 31.92.

1-(β,β-Diphenylethyl)-thiourea.—β,β-Diphenylethylamine hydrochloride, 18.5 g. (0.079 mole), and ammonium thiocyanate, 6.7 g. (0.087 mole), were added to 350 ml. of xylene and stirred and heated at 135° for 6 hr. The xylene was then evaporated down *in vacuo* and the solid residue triturated with hot water, filtered and dried to yield 19.7 g. of product, m.p. 198–200°. One recrystallization from ethanol raised the melting point to 203–204°. Calcd. for $C_{15}H_{16}N_2S$: C, 70.30; H, 6.28; N, 10.92; S, 12.50. Found: C, 70.53; H, 6.42; N, 11.11; S, 12.65.

1-(β,β-Diphenylethyl)-2-methyl-2-thiopseudourea Hydroiodide.—The compound was prepared in the usual manner. Two recrystallizations from an isopropyl alcohol–ether mixture gave an analytical sample melting at 139–141°. Calcd. for $C_{16}H_{19}N_2SI$: N, 7.03; S, 8.05; I, 31.86. Found: N, 6.71; S, 8.06; I, 32.12.

Alkylation of 1-Benzhydryl-2-methyl-2-thiopseudourea.—1-Benzhydryl-2-methyl-2-thiopseudourea, 7.68 g. (0.03 mole), and methyl iodide, 6.4 g. (0.045 mole), were refluxed in 100 ml. of acetone with 2 g. (0.015 mole) of potassium carbonate for 4 hr. Some inorganic material was filtered off and the acetone filtrate was evaporated down *in vacuo* at room temperature to leave a thick oil residue. The residue was taken up in chloroform and the chloroform solution filtered to remove more inorganic solids. The chloroform was then evaporated down *in vacuo* at room temperature and the residue taken up in a little isopropyl alcohol. Upon addition of dilute hydriodic acid to the isopropyl alcohol solution, 4.0 g. of a solid hydroiodide salt, m.p. 162–164°, precipitated. Two recrystallizations from an isopropyl alcohol–ether mixture gave a product, m.p. 173–174°, which was identical in every way with 1-benzhydryl-2,3-dimethyl-2-thiopseudourea hydroiodide.

Reactions with Mercaptans. IV. Reaction of Aromatic Thiols with 3(2H)-Thianaphthenone-1,1-dioxides and 2-Benzylidene-3(2H)-thianaphthenone-1-1-dioxide

BY AHMED MUSTAFA AND SALAH MOHAMED ABDEL DAYEM ZAYED

RECEIVED NOVEMBER 19, 1956

The condensation reaction of 3(2*H*)-thianaphthenone-1,1-dioxides (I) with aromatic aldehydes has been investigated, *e.g.*, 3(2*H*)-thianaphthenone-1,1-dioxide condenses with benzaldehyde to give 2-benzylidene-3(2*H*)-thianaphthenone-1,1-dioxide (IIa). The latter undergoes an addition reaction with thiophenol, yielding the thiol adduct believed to have structure VI. Aromatic thiols react with 3(2*H*)-thianaphthenone-1,1-dioxides, in the presence of anhydrous zinc chloride and hydrogen chloride, to yield the corresponding unsaturated sulfides VII which are readily oxidized to the sulfone derivatives VIII.

Aldehyde condensation products of 3(2*H*)-thianaphthenone-1,1-dioxide (Ia) have not previously been prepared, although Ia has been known since 1912.[1] Weston and Suter[2] were unable to condense benzaldehyde with Ia in an alkaline medium.

We obtained well-defined crystalline products by the reaction of benzaldehyde with Ia and by that of *p*-nitrobenzaldehyde with 7-methyl-3(2*H*)-thianaphthenone-1,1-dioxide (Id). The analytical data indicate that one molecule of aldehyde condenses with one molecule of the thianaphthenone-1,1-dioxide with the elimination of one molecule of water.

The structural assignments for these products are based on their participation in known reactions. When 2-benzylidene-3(2*H*)-thianaphthenone-1,1-dioxide (IIa) was treated with hydroxylamine hydrochloride, the corresponding oxime of 3(2*H*)-thianaphthenone-1,1-dioxide (IIIa)[3] was obtained.[4] The treatment of IIa with phenylhydrazine gave the hydrazone of 3(2*H*)-thianaphthenone-1,1-dioxide (IIIb).[5]

2-Benzylidene-3(2*H*)-thianaphthenone reacted with phenylhydrazine to give [10*H*]-thianaphtheno-[3,2-*b*]-indole (IV), *via* the Fischer indole ring closure of the resulting phenylhydrazone of 3(2*H*)-thianaphthenone.[5,6]

We have also studied the addition, *e.g.*, of benzenethiol, to the double bond at position 2 which is conjugated with the unsaturated group in 2-arylidene-3(2*H*)-thianaphthenone-1,1-dioxides.

IIa, like the 2-arylideneindan-1,3-diones,[7] undergoes addition reaction with thiophenol in absence of a catalyst to give a colorless adduct which can be represented by V or VI.

compounds,[8] structure VI is preferable. The fact that the adduct dissolves in cold aqueous sodium hydroxide solution with a yellow color and is liberated upon neutralization with ice-cold, dilute hydrochloric acid is also in accord with structure VI. When VI was heated above its melting point for a few minutes and then cooled, the styryl derivative IIa was regenerated. The ease of removal of the addend indicates that the substance is the result of simple addition and that no unexpected reaction has occurred. Attempts to oxidize VI with hydrogen peroxide in glacial acetic acid over a water-bath also led to the formation of IIa.[9]

Reaction of Aromatic Thiols with 3(2*H*)-Thianaphthenone-1,1-dioxides (I).—It is generally accepted that a ketone and a thiol react in the presence of an acid catalyst to form a mercaptal,[10] although scattered reports in the literature indicate that certain cyclic ketones, *e.g.*, 4-cholesten-3-one[11] and other ketosteroids,[12] yield unsaturated sulfides (enol thioethers).

Recently,[13] it was observed that 2-methyl-1-indanone and 2-methyl-1-tetralone react with thiophenol, under the conditions of the mercaptal reaction, to produce phenyl-2-methyl-3-indenyl sulfide and phenyl-2-methyl-3,4-dihydro-1-naphthyl sulfide, respectively.

We have investigated the reaction of aromatic thiols with 3(2*H*)-thianaphthenone-1,1-dioxides (I) in the presence of anhydrous zinc chloride and hydrogen chloride and have obtained colorless products, believed to have structure VII. Under these experimental conditions, 2-methyl-3(2*H*)-thianaphthenone-1,1-dioxide (IX) did not react with thiols.

Desoxybenzoin[14] is known to form an unsaturated sulfide when treated with thiophenol. By analogy, a similar mechanism may be presented for the formation of VII, involving the addition of one mole of thiol to form a hemimercaptal followed by elimination of water to give the unsaturated sulfide VII.

The unsaturated sulfides VII, listed in Table II, are oxidized readily by hydrogen peroxide in glacial acetic acid to give the corresponding sulfones,[12] listed in Table III.

When VIIa was treated with aqueous sodium hydroxide and zinc dust, 2,3-dihydrothianaphthene-1,1-dioxide and thiophenol were obtained.[15]

Experimental

3(2*H*)-Thianaphthenone-1,1-dioxides.—The new 3(2*H*)-

thianaphthenone-1,1-dioxides listed in Table I were prepared from the corresponding 3(2*H*)-thianaphthenones which were obtained by known procedures.[16] A solution of 5 g. of the thianaphthenone in 30 ml. of glacial acetic acid was treated with 25 ml. of 30% hydrogen peroxide, and the reaction mixture was heated (steam-bath) for 1 hr., with the exception of 6-methyl- and 7-methyl-3(2*H*)-thianaphthenone, whereby oxidation was complete in 5 minutes. The reaction products, which separated on cooling, were crystallized from a suitable solvent as colorless crystals; they gave no color with concentrated sulfuric acid and a yellow color in alcoholic sodium hydroxide.

Condensation of: (a) 3(2*H*)-Thianaphthenone-1,1-dioxide (Ia) with Benzaldehyde.—A mixture of 1 g. of Ia[17] and 2 ml. of benzaldehyde was heated for 3 hr. over an oil-bath (140° temperature of bath). The reaction mixture was cooled to room temperature and triturated with 5 ml. of cold ethyl alcohol. The resulting pale yellow solid was crystallized from alcohol; m.p. 148° (yellow melt).

Anal. Calcd. for $C_{15}H_{10}O_3S$: C, 66.66; H, 3.70; S, 11.85. Found: C, 66.32; H, 3.61; S, 11.56.

This 2-benzylidene derivative IIa was soluble in benzene but difficultly soluble in ether, cold alcohol and acetic acid. It developed a yellow color in concentrated sulfuric acid.

A solution of 0.5 g. of IIa in 20 ml. of glacial acetic acid was treated with 2 g. of sodium acetate and 0.5 g. of hydroxylamine hydrochloride. The reaction mixture was refluxed for 3 hr., cooled and then poured into ice-cold water. The resulting substance was crystallized from dilute acetic acid (m.p. 245°) and identified as the oxime of 3(2*H*)-thianaphthenone-1,1-dioxide (IIIa)[3] by a mixed m.p. determination with a sample of IIIa, obtained by the reaction of hydroxylamine hydrochloride with Ia under similar experimental conditions.

(b) 7-Methyl-3(2*H*)-thianaphthenone-1,1-dioxide (Id) with *p*-Nitrobenzaldehyde.—A mixture of 1 g. of Id and 1 g. of the aldehyde was heated at 160° for 2 hr. The solid residue obtained after cooling was washed thoroughly with hot benzene and then crystallized from nitrobenzene as yellow crystals (IIb), m.p. 265°. IIb was difficultly soluble in most organic solvents and gave an orange solution in concentrated sulfuric acid.

Anal. Calcd. for $C_{16}H_{11}NO_5S$: C, 58.36; H, 3.34; N, 4.26; S, 9.72. Found: C, 57.97; H, 3.31; N, 4.03; S, 9.39.

Reaction of Thiophenol on IIa.—One g. of IIa was mixed with a slight excess over the calculated amount of the thiol in a test-tube, and the reaction mixture was heated at 100° for 3 hr. The cooled reaction mixture was triturated with boiling light petroleum (b.p. 30–50°, 50 ml.) when the oily reaction product turned into solid powder. It was filtered, washed with hot light petroleum and crystallized from benzene; m.p. 138°, yield *ca.* 88%.

Anal. Calcd. for $C_{21}H_{16}O_3S_2$: C, 66.31; H, 4.21; S, 16.84. Found: C, 66.77; H, 4.50; S, 16.49.

The thiol adduct formed colorless crystals, dissolved readily in hot benzene but was difficultly soluble in cold

ether, ethyl alcohol and acetic acid. It dissolved in aqueous sodium hydroxide (10%) with yellow color and gave an orange yellow solution in cold concentrated sulfuric acid.

Action of Heat on the Thiol Adduct VIII.—Two tenths g. of VIII was heated in a dry test-tube at 140° for 20 minutes (bath-temp.). The adduct melted and then turned into a somewhat solid substance. The cooled reaction mixture was crystallized from ethyl alcohol; m.p. 148° (identified as IIa, m.p. and mixed m.p.).

Reaction of Aromatic Thiols with 3(2*H*)-Thianaphthenone-1,1-dioxides. General Procedure.—To a solution of one gram of the sulfone derivative in the least amount of cold acetic acid, 1 g. of the thiol and 5 g. of powdered anhydrous zinc chloride are added. The reaction mixture was saturated with dry hydrogen chloride gas for 4 to 5 hr., stoppered and kept aside overnight at room temperature. It was poured into three times its volume of ice-cold water and extracted with benzene. The benzene layer was washed with water, dried over anhydrous sodium sulfate and evaporated. The oily residue was treated with cold petroleum ether (b.p. 40–60°, *ca.* 60 ml.). The resulting solid was filtered and crystallized from a suitable solvent.

The 3-arylmercapto derivatives VII, listed in Table II, formed colorless crystals which were readily soluble in cold benzene and chloroform but sparingly soluble in alcohol, acetic acid and ether. When treated with concentrated sulfuric acid, they gave yellow solutions which changed to orange and finally violet on standing for a few minutes. VIIa in acetone solution decolorized potassium permanganate, and in chloroform solution it decolorized bromine dissolved in chloroform.

Oxidation of VII to the Sulfones VIII. General Procedure.—A suspension of 1 g. of the 3-arylmercapto derivative VII in 20 ml. of glacial acetic acid was treated with 4 ml. of 30% hydrogen peroxide and 5 ml. of acetic anhydride. The reaction mixture was heated on a boiling water-bath for 1 hr., cooled, poured into 100 ml. of ice-cold water and kept at room temperature overnight. The resulting solid was collected by filtration, washed with water, dried and crystallized from a suitable solvent.

The oxidation products VIII, listed in Table III, formed colorless crystals and gave no color when treated with cold sulfuric acid; they dissolved readily in glacial acetic but were sparingly soluble in ether and cold ethyl alcohol.

Reduction of 3-Phenylmercaptothianaphthene-1,1-dioxide (VII).—VIIa (0.7 g.) was treated with 50 ml. of aqueous sodium hydroxide (8%) and 10 g. of zinc dust according to the procedure described by Challenger.[15] The reaction mixture was refluxed for 2 hr., during which the solid VIIa changed into an oil. The cooled reaction mixture was diluted with water and extracted with benzene. After the benzene extract had been dried and evaporated, it was treated with cold petroleum ether (b.p. 40–60°, *ca.* 50 ml.) and the resulting solid crystallized from petroleum ether (b.p. 80–100°) as colorless crystals, m.p. 91°, which were identified as 2,3-dihydrothianaphthene-1,1-dioxide by mixed melting point determination.[16] The aqueous alkaline reaction mixture gave, on acidification, an oil which was proved to be thiophenol (m.p. and mixed m.p. determination with an authentic sample of phenyl thiobenzoate).

[Contribution from the Research Laboratories of Farmochimica Cutolo-Calosi S.p.A.]

A New Synthesis of 6-Thioctic Acid (DL-α-Lipoic Acid)

By Augusto Segre, René Viterbo and Giovanni Parisi

Received January 16, 1957

6-Thioctic acid has been synthesized starting from 2-acetoxyethylcyclohexanone by peracid oxidation to the 1 → 6-lactone of 6-hydroxy-8-acetoxyoctanoic acid and reaction, with thiourea and a strong mineral acid, of this lactone, followed by alkaline hydrolysis of the isothiuronium salt and oxidation of the dithiol-acid thus formed. A preparation of 2-acetoxyethylcyclohexanone, starting from cyclohexanone, is also described.

The importance of 6-thioctic acid (VII) in biochemical processes is well known.[1] Thus its clinical application in the therapy of liver diseases[2] and its antitoxic activity combined with its low toxicity[3] have promoted many syntheses.[1,4] The synthetic method of preparation described in the present paper has the characteristics of starting from easily available raw materials, of using inexpensive reagents in simple reactions and of obtaining comparatively high yields.

The first object of a synthesis of 6-thioctic acid (VII) is to obtain a carboxylic acid with a normal chain of eight carbon atoms, with substituents at C_6 and C_8 suitable for the introduction of two thiol groups. The 1→6-lactone of 6-hydroxy-8-acetoxyoctanoic acid (V) is, in this sense, the required substance. Its preparation is a clear case for the application of the well known Baeyer–Villiger peracid ketone oxidation.[5] Indeed we have obtained the lactone V by peracetic acid oxidation of 2-acetoxyethylcyclohexanone (IVb).

The preparation of 2-hydroxyethylcyclohexanone (IVa) is already described,[6] but without mention of details and physical constants. We succeeded in the preparation of its acetate IVb by the following procedure.

Ethyl cyclohexanone-2-acetate (I) was obtained from cyclohexanone-pyrrolidine enamine and ethyl monobromoacetate by the method of Stork, *et al.*[7]; details of this preparation, not described so far, can be found in the Experimental part of this paper. Treatment of the keto-ester I with ethylene glycol yielded the ethylene ketal II. Both compounds I and II gave, as expected, the same 2,4-dinitrophenylhydrazone. The infrared spectrum of II showed presence of ketal[8] and ester bands, but absence of keto-carbonyl band. The ethylene-ketal II could be reduced either by lithium aluminum hydride in ether or, with similar yields, with sodium in ethanol to the ethylene ketal of 2-hydroxyethylcyclohexanone (IIIa). This compound gave a 2,4-dinitrophenylhydrazone corresponding to the derivative of 2-hydroxyethylcyclohexanone, and its infrared spectrum had the characteristic hydroxyl and ketal bands, but no carbonyl band. Direct acid hydrolysis[9] of the hydroxy-ketal IIIa failed to yield the expected ketoalcohol IVa and only mixtures of unsaturated cyclization compounds were obtained. This was avoided by first acetylating the hydroxy-ketal IIIa to the ketal-acetate IIIb, following with a mild hydrolysis to 2-acetoxyethylcyclohexanone IVb. The latter compound gave a 2,4-dinitrophenylhydrazone identical with the one obtained from the ketal-acetate IIIb and showed an infrared spectrum with acetate and keto bands.

The desired cyclohexanone derivative IVb thus obtained was smoothly oxidized by peracetic acid to the 1→6-lactone of 6-hydroxy-8-acetoxyoctanoic acid (V).[10] Its infrared spectrum had a very wide band at 1735 cm.$^{-1}$ and an acetate band at 1250 cm.$^{-1}$; it did not yield any 2,4-dinitrophenylhydrazone and, upon quantitative saponification, used up two equivalents of sodium hydroxide.

Although exceptions are known,[11] in general, lactones treated with thiourea in a strong mineral acid with alkaline hydrolysis of the isothiuronium salt thus obtained, yield thiol-acids.[12] In fact from our acetoxy-ε-lactone V in this way we easily obtained 6,8-dithioloctanoic acid (VI), which, after oxidation, gave 6-thioctic acid (VII) (19% over-all yield from cyclohexanone), with the same infrared spectrum of a sample of 6-thioctic acid synthesized by the method of Reed, *et al.*[13] The two samples, as well as their respective S-benzylisothiuronium salts,[14] did not give any melting point depression on admixture.

Acknowledgments.—The authors are indebted to Professor L. Ruzicka, Zurich, for the infrared spectra, to Professor G. Büchi, Cambridge, Mass., for a stimulating discussion and to the late Professor E. A. Braude, London, for the permission of reading his manuscript prior to publication.

Experimental[15]

Ethyl Cyclohexanone-2-acetate (I).—In a round-bottomed flask fitted with a water separator, 29 g. of cyclohexanone, 85 g. of pyrrolidine and 200 ml. of dry benzene were refluxed for 1.5 hours. At this time the theoretical amount of water (6 ml.) had been separated and no more was evolved on longer heating. The solution was concentrated *in vacuo* to the oily residue of cyclohexanone-pyrrolidine enamine, so as to evaporate all the pyrrolidine in excess.

Thirty-seven and one-half grams of freshly distilled ethyl monobromoacetate was added dropwise to the boiling solution of the crude enamine in 150 ml. of dry benzene. Refluxing was then continued for another hour, the solvent and excess bromoester removed *in vacuo*, the thick residue refluxed for two hours, after addition of 100 ml. of methanol and 20 ml. of water. The solution was then concentrated at reduced pressure; the residue was treated with water and extracted with ether; the organic solution was washed successively with 2 *N* hydrochloric acid, sodium bicarbonate and water, dried over sodium sulfate and evaporated. The residue was fractionated twice *in vacuo* yielding 38.6 g. (71%),[16] b.p. 131–134° (13 mm.), $n^{23}D$ 1.4564; infrared spectrum bands at 1715 (keto-carbonyl), 1735 (ester-carbonyl) cm.$^{-1}$.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75. Found: C, 65.43; H, 8.93.

2,4-Dinitrophenylhydrazone, m.p. 126°. *Anal.* Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53; N, 15.38. Found: C, 52.88; H, 5.55; N, 15.54.

Ethylene Ketal of Ethyl Cyclohexanone-2-acetate (II).—A solution of 38.5 g. of ethyl cyclohexanone-2-acetate (I), 14.5 g. of ethylene glycol and 50 mg. of *p*-toluenesulfonic acid in 100 ml. of dry toluene was refluxed in a round bottomed flask fitted with a water separator. After three hours, 4.5 ml. of water had been collected. The cooled toluene solution was washed with aqueous sodium bicarbonate and water, dried over sodium sulfate and evaporated. The residue was distilled twice at reduced pressure yielding 42 g. (88%), b.p. 145–147° (13 mm.), $n^{23}D$ 1.4630; infrared spectrum: bands at 1070 (ketal), 1735 (ester carbonyl) cm.$^{-1}$.

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83. Found: C, 63.02; H, 8.72.

Upon addition of 2,4-dinitrophenylhydrazine, the 2,4-dinitrophenylhydrazone of the ketoester I, m.p. 126°, was obtained. The mixture of the two samples did not give any melting point depression.

Ethylene Ketal of 2-Hydroxyethylcyclohexanone (IIIa).

a. By Lithium Aluminum Hydride Reduction.—A solution of 32 g. of ethylene ketal (II) in dry ether was added dropwise to a slurry of 4 g. of lithium aluminum hydride in 350 ml. of dry ether. The addition was completed after two hours and the mixture was refluxed for one hour longer. The excess reagent was destroyed with ethyl acetate and 2 *N* hydrochloric acid added. The organic layer, washed with aqueous sodium bicarbonate and water, dried over sodium sulfate, was evaporated. The residue was fractionated twice at reduced pressure yielding 25 g. (96%), b.p. 148–150° (13 mm.), $n^{23}D$ 1.4822; infrared spectrum bands at 1080 (ketal) and 3400 (hydroxyl) cm.$^{-1}$.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74. Found: C, 64.59; H, 9.90.

Addition of 2,4-dinitrophenylhydrazine yielded the expected 2,4-dinitrophenylhydrazone of 2-hydroxyethylcyclohexanone, m.p. 145–146.5°. *Anal.* Calcd. for $C_{14}H_{18}N_4O_6$: C, 52.17; H, 5.63; N, 17.38. Found: C, 52.01; H, 5.83; N, 17.37.

b. By Sodium–Ethanol Reduction.—To a boiling, well-stirred solution of 5 g. of ketal ester II in 25 ml. of absolute ethanol were added simultaneously 5 g. of sodium and 30 ml. of absolute ethanol over a period of a half-hour. Boiling was continued for two hours. After cooling and evaporating the solution almost to dryness, the residue was poured in ice-water and extracted with ether. The organic layer was washed to neutrality with water, dried over sodium sulfate and evaporated. The residue was distilled twice, yielding 3.7 g. (90%), b.p. 148–150° (13 mm.), identical with the product obtained by lithium aluminum hydride reduction, with the same constants and the same 2,4-dinitrophenylhydrazone.

Ethylene Ketal at 2-Acetoxyethylcyclohexanone (IIIb).—Two grams of hydroxy-ketal IIIa dissolved in 6 ml. of pyridine was acetylated with 2 ml. of acetic anhydride at room temperature for two hours. The solution was poured in iced water and extracted with ether. The organic layer was washed successively with 2 *N* hydrochloric acid, aqueous sodium bicarbonate and water, dried over sodium sulfate and evaporated to an oil, which, distilled twice at reduced pressure, yielded 2.1 g. (91%), b.p. 152° (13 mm.), $n^{27}D$ 1.4632; infrared spectrum 1090 (ketal), 1250 (acetate), 1740 (ester carbonyl) cm.$^{-1}$.

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83. Found: C, 63.15; H, 9.13.

Upon addition of 2,4-dinitrophenylhydrazine, the 2,4-dinitrophenylhydrazone of the acetoxy-ketone IVb, m.p. 109–111°, was obtained.

2-Acetoxyethylcyclohexanone (IVb).—A solution of 2 g. of ethylene ketal of 2-acetoxyethylcyclohexanone (IIIb) and 75 mg. of *p*-toluenesulfonic acid in 20 ml. acetone was refluxed for one hour. The solvent was removed *in vacuo*, keeping the bath temperature below 40°; the oily residue was dissolved in ether, washed with aqueous sodium bicarbonate and water, dried over sodium sulfate and evaporated. After two distillations at reduced pressure 1.55 g. (90%) was obtained, b.p. 142–146° (15 mm.), $n^{27}D$ 1.4565; infrared spectrum bands at 1250 (acetate), 1715 (keto-carbonyl), 1740 (ester carbonyl) cm.$^{-1}$.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75. Found: C, 65.04; H, 8.82.

2,4-Dinitrophenylhydrazone, m.p. 109–111°. *Anal.* Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53; N, 15.38. Found: C, 52.79; H, 5.46; N, 15.28.

1→6-Lactone of 6-Hydroxy-8-acetoxyoctanoic Acid (V).—A solution of 4.7 g. of 2-acetoxyethylcyclohexanone (IVb) in 16.3 ml. of peracetic acid[17] (containing 28.0 mg. of active oxygen per ml.) was allowed to stand at room temperature for 24 hours; chloroform was added and the resulting solution was washed to neutrality with aqueous sodium bicarbonate. The organic layer, washed with water, dried over sodium sulfate, was evaporated and the residue distilled twice at reduced pressure; yield 3.3 g. (65%), b.p. 126–130° (0.5 mm.), $n^{23}D$ 1.4595, infrared spectrum bands at 1250 (acetate) and 1724–1750 (acetate and lactone) cm.$^{-1}$.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05; mol. wt., 200.21. Found: C, 60.36; H, 8.21; equiv. wt., 105.0.

6,8-Dithioloctanoic Acid (VI).—A mixture of 2.2 g. of acetoxylactone V, 6.5 g. of thiourea and 8.66 g. of 57% hy-

diiodic acid was refluxed for 36 hours and then hydrolyzed by adding 35 ml. of 30% aqueous potassium hydroxide and refluxing for 12 hours in the dark under nitrogen. The reaction mixture was extracted with ether, the aqueous layer separated, acidified with 2 *N* hydrochloric acid and extracted with chloroform. The chloroform solution, after washing to neutrality with water and drying over sodium sulfate, was concentrated and distilled *in vacuo* yielding 1.84 g. (80%) of 6,8-dithiooctanoic acid (VI), b.p. 180° (bath temperature) (1.5 mm.), $n^{22}D$ 1.5225; infrared spectrum 1285, 1235 (OH-carboxyl), 1710 (CO-carboxyl) cm.$^{-1}$.

Anal. Calcd. for $C_8H_{16}O_2S_2$: C, 46.12; H, 7.74. Found: C, 46.37; H, 7.74.

6-Thioctic Acid (DL-α-Lipoic Acid) (VII).—1.01 g. of dithiol-acid (VI) were dissolved in 2.3 ml. of 2 *N* sodium hydroxide, diluted with 17 ml. of water containing 3.5 mg. of iron trichloride hexahydrate, yielding a dark red solution, through which a slow stream of oxygen was bubbled for 10 hours. The resulting pale yellow solution was washed with chloroform. The aqueous layer, acidified with 2 *N* hydrochloric acid, was extracted with chloroform and this was washed to neutrality and evaporated to dryness. The yellow oily residue crystallized upon trituration with petroleum ether (boiling range 40–60°). After one crystallization from petroleum ether, 0.8 g. of pure 6-thioctic acid (DL-α-lipoic acid) (VII) (80%) was obtained, m.p. 61–62°; ultraviolet spectrum λ_{max}^{EtOH} 333 mμ (ε 147); infrared spectrum bands at 1285, 1235 (OH-carboxyl), 1700 (CO-carboxyl) cm.$^{-1}$.

Anal. Calcd. for $C_8H_{14}O_2S_2$: C, 46.57; H, 6.68; S, 31.13. Found: C, 46.66; H, 6.90; S, 31.20.

Many-membered Carbon Rings. XIV. Transannular Ring Cleavage of Certain Cycloalkane Derivatives[1]

BY A. T. BLOMQUIST AND PETER R. TAUSSIG[2]

RECEIVED DECEMBER 4, 1956

Pyrolysis of cyclononyl acetate at 500° affords mainly 1,8-nonadiene (70%) together with *cis*-cyclononene (27%) and *trans*-cyclononene (1.5%). Thermal decomposition of cyclononyl S-methyl xanthate at various temperatures indicates that formation of 1,8-nonadiene occurs only at temperatures above 400°. Pure *trans*-cyclononene rearranges at 500° to 1,8-nonadiene (85%) and *cis*-cyclononene (15%) while pure *cis*-cyclononene, at 500°, yields only *ca.* 20% 1,8-nonadiene and 80% unchanged *cis*-cyclononene. Conformational analysis suggests two possible paths for the formation of the diene from cyclononyl acetate.

The discovery in recent years of transannular reactions[3,4] has done much to stimulate research in the chemistry of medium size rings. This has included several studies concerned with the course of elimination reactions of various derivatives of the cycloalkanes such as their amines, halides, acetates and xanthates.[5–7] This article presents studies of the thermal decomposition of the acetate and S-methyl xanthate of cyclononanol. In an earlier study of the pyrolysis of cyclodecyl acetate and cyclodecyl xanthate,[6] it was observed that a mixture of *cis*- and *trans*-cyclodecenes was produced rather than exclusively one stereoisomer as might have been expected. Further, it was noted that pyrolysis of cyclodecyl acetate gave, as a minor product, a low boiling "dienoid" substance. The latter was not fully characterized at that time.

Pyrolysis of cyclononyl acetate[8] at 500 ± 10° under the same conditions employed in the thermal decomposition of cyclodecyl acetate[6] afforded a pyrolyzate (78%) which interestingly contained only 30% of the expected mixture of *cis*- and *trans*-cyclononenes (IIa and IIb). The principal constituent (70%) of the pyrolyzate was found to be a low boiling compound analogous to the minor product formed in the thermal degradation of cyclodecyl acetate. This low boiling substance was readily identified as 1,8-nonadiene (I).

The structure of this hydrocarbon I was established as indicated below. Its properties agreed with those reported for 1,8-nonadiene by van Pelt[9] and by Everett.[10] Elementary analysis of I was in accord with the composition C_9H_{16} and quantitative catalytic hydrogenation of I indicated the presence of two double bonds. On oxidative ozonolysis I gave an acid (18%) which did not depress the melting point of an authentic sample of pimelic acid. Finally, the infrared absorption spectrum of I showed maxima at 10.07 and 10.97 μ, characteristic of a vinyl group, and was identical with the spectrum of 1,8-nonadiene obtained by pyrolysis of 1,9-nonanediol diacetate.

After completion of the characterization of I, it became apparent that the "dienoid" product formed in the pyrolysis of cyclodecyl acetate[6] was probably 1,9-decadiene (III). This was confirmed by preparing an authentic sample of III *via* pyrolysis of 1,10-decanediol diacetate and comparing the infrared absorption spectra of the two hydrocarbons. They were indistinguishable.

With the object of ascertaining, to some extent, the generality of this ring cleavage of cycloalkyl esters, the pyrolysis of cycloöctyl acetate[8] was examined. Here it was found that about 10% of the pyrolyzate had properties differing from the cycloöctenes but possessing an infrared absorption spectrum very similar to those of 1,8-nonadiene and 1,9-decadiene. All of the foregoing suggests that ring cleavage in the thermal degradation of medium sized cycloalkyl acetates is general, but it is a major reaction only for the nine-membered ring.

Estimation of the amount of *cis*- and *trans*-cyclononene (IIa and IIb, respectively) in the cyclononene fraction obtained in the pyrolysis of cyclononyl acetate was done by the quantitative infrared analysis method used previously for *cis*- and *trans*-cyclodecene.[1] The per cent. IIa in the mixture of cyclononenes was determined by noting the intensity of the absorption maximum at 13.16 μ with reference to a base line drawn from the minimum at 12.90 μ. The per cent. IIb was determined by measuring the intensity of the absorption maximum at 10.15 μ with reference to a base line drawn from the minimum at 10.60 μ. Application of the method to analyses of known mixtures of pure cyclononenes indicated that it was accurate to about $\pm 5\%$. Using the above method it was found that the cyclononene fraction resulting from the acetate pyrolysis comprised 90% IIa and 5% IIb.

In order to complement the pyrolysis study of cyclononyl acetate, it seemed desirable to examine the thermal decomposition of cyclononyl S-methyl xanthate (IV) at various temperatures. In these experiments (Table II) it was observed that the formation of I did not occur until the pyrolysis temperature was about 400°. At 500° the pyrolyzate from IV contained about 50% I. It was noted further that as the content of I increased in the pyrolyzate of IV, the per cent. IIb in the cyclononene fraction decreased.

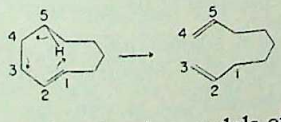
The foregoing suggested that perhaps cyclononenes were intermediates in the formation of I. Accordingly, both IIa and IIb were pyrolyzed under conditions similar to those used for the decomposition of the cyclononyl esters. The pure hydrocarbon IIa at 500° afforded a pyrolyzate comprising *ca.* 20% I, the remainder (80%) being unchanged IIa. The pure hydrocarbon IIb at 500° gave a product which contained 85% I and 15% of a mixture of IIa and IIb. The cyclononene in this latter mixture was very largely the *cis* isomer IIa (see Table I).

Discussion of Results

The observations presented in the foregoing can be accounted for by a careful conformational analysis of the nine-membered carbocycle. The most probable conformation for cyclononane itself would be that in which there is maximum distance between the non-bonded atoms. Stylized projection representations for two views of such a conformation derived from a Fisher–Hirschfelder–Taylor model is given in Fig. 1. According to this model (Fig. 1) there are eight *quasi-axial* hydrogens, attached to carbon atoms 1,2,3,4,5,2′,3′ and 4′, directed inward toward the center of the ring. Four of these are on the upper side of the ring and four below. The eight *quasi-equatorial* hydrogens attached to these carbon atoms and arranged about the periphery of the ring are directed outward and at an angle essentially perpendicular to the ring axis. The hydrogen atoms attached to the carbon labeled 1′ appear to be unique in that they extend away from the ring in a direction midway between the *quasi-axial* and *quasi-equatorial* hydrogens. On the basis of this model three principal conformations are theoretically possible for cyclononyl acetate. The acetoxy group may be *quasi-equatorial*, *quasi-axial* or at the intermediate position on C_1'. At 500° all of these should exist and their interconversion should be facile. From these conformations of the acetate the realization of the requisite transition state for 1,2-elimination of acetic acid, a planar six-membered ring arrangement of the atoms H–C–C–O—C=O,[11,12] would

appear to involve the least amount of "steric strain" under the circumstance that the hydrogen atom and acetoxy group on adjacent carbons both be in *quasi-equatorial* positions. Such a transition state would lead to IIb. Further, according to the models, the formation of *all* of those transition states which would lead to IIa is rendered more difficult because of steric factors. For the above reasons, IIb should be the principal product of the thermal 1,2-elimination of acetic acid from cyclononyl acetate.

The observations that (1) the pyrolyzate from cyclononyl acetate comprises principally I (70%) and IIa (*ca.* 30%) and (2) pyrolysis of the cyclononenes themselves affords I (*ca.* 20% from IIa and *ca.* 85% from IIb), suggests that the formation of I possibly involves two discrete steps. Initially, cyclononyl acetate affords, *via* 1,2-elimination of acetic acid, a mixture of cyclononenes containing mainly the *trans* isomer. Subsequently, the cyclononenes, especially the *trans* isomer, undergo transannular intramolecular rearrangement to the open-chain diene I. A possible path for this rearrangement is indicated in the diagram below. It involves a transannular shift of a *quasi-axial* hydrogen on carbon five to carbon one of the double bond with a concomitant redistribution of electrons.



Examination of molecular models of IIa and IIb indicates that the rearrangement should be particularly facile for IIb. In this olefin IIb the

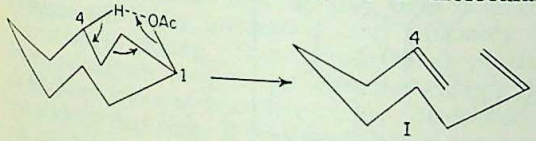
quasi-axial hydrogen at position five appears to be easily within bonding distance of position one, and further the movement of this hydrogen from C_5 to C_1 is not obstructed by other *quasi-axial* hydrogen atoms. The situation with respect to IIa is quite different. The C_5-*quasi-axial*-hydrogen is at a greater distance from C_1 than in IIb, and also there are *quasi-axial* hydrogen atoms on C_3 and C_9 blocking the migration (see Fig. 2).

Although the above rationalizations appear to account satisfactorily for the experimental observations, the possibility of other operating mechanisms cannot be excluded. One of these was suggested in an earlier communication.[1] The proposed mechanism indicated the direct formation of the diene I from cyclononyl acetate by 1,4-transannular elimination of acetic acid *via* a six-membered cyclic transition state developed through interaction of the ethereal oxygen atom in *quasi-axial* cyclononyl acetate and the *quasi-axial* hydrogen atom on C_4. Examination of a molecular



I

model of *quasi-axial* cyclononyl acetate suggests that the requisite transition state could be realized easily.

Acknowledgments.—The authors are indebted to Professor R. M. Hexter for his aid in obtaining and interpreting the infrared spectra data used in these studies. Also, the authors wish to express their sincere appreciation to Dr. Yvonne C. Meinwald for her assistance in the preparation of this article.

Experimental[13]

Materials.—*cis*-Cyclononene (IIa) was obtained by hydrogenation of cyclononyne[14] using Lindlar catalyst following a procedure similar to that described for the preparation of *cis*-cyclodecene.[6] The IIa obtained (83% yield) had $n^{25}D$ 1.4780. *trans*-Cyclononene (IIb), $n^{25}D$ 1.4782, was obtained as described previously.[14] 1,8-Nonadiene (I), prepared by pyrolysis of 1,9-nonanediol diacetate at 500°, showed b.p. 136–138° (740 mm.), and $n^{25}D$ 1.4250.[9,10] 1,9-Decadiene b.p. 162–163° (740 mm.), and $n^{25}D$ 1.4316, was prepared similarly from 1,10-decanediol diacetate. Its properties were in good agreement with those reported for it by Everett and Kon.[10] The cyclononyl acetate used had b.p. 113–116° (12 mm.) and $n^{25}D$ 1.4629.

(13) All b.p.'s are uncorrected. Infrared absorption spectra were obtained by use of a Perkin–Elmer double beam infrared spectrophotometer, Model 21.

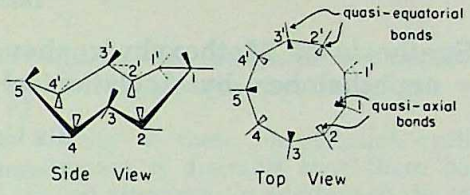

Fig. 1.—Conformation of cyclononane.

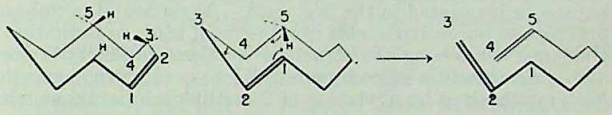

cis-Cyclononene *trans*-Cyclononene

Fig. 2.—Conformations of the cyclononenes.

Cyclononyl S-Methyl Xanthate.—This xanthate was prepared using the same method described for cyclodecyl S-methyl xanthate.[6] From 36.7 g. of cyclononanol 72 g. of crude xanthate was obtained. This crude xanthate was used in the pyrolyses described subsequently. An analytical sample of the xanthate was secured by chromatographing the crude product on alumina and eluting with pentane. It was obtained as a clear, slightly yellow oil.

Anal. Calcd. for $C_{11}H_{20}OS_2$: C, 56.87; H, 8.62; S, 27.62. Found: C, 56.62; H, 8.38; S, 27.40.

Thermal Decomposition of Cyclononyl Acetate.—The pyrolysis was carried out as described previously for the thermal decomposition of cyclodecyl acetate.[6] After the usual workup, the products were distilled through a 36-inch Podbielniak column to give two main fractions: (1) b.p. 140–144°, $n^{25}D$ 1.4260, d^{25} 0.748, which comprised 67–70% of the product, and (2) a mixture of *cis*- and *trans*-cyclononenes, b.p. 172–174°, $n^{25}D$ 1.4770, which comprised 33–30% of the product. The total yield of olefins amounted to 72–78%.

Analysis by infrared spectrophotometry indicated that fraction (2) consisted of 89–91% of IIa and 4–5% of IIb.

Thermal Decomposition of Cyclononenes (IIa and IIb).—The pyrolysis procedure used was identical with that employed in the cyclononyl acetate decomposition. The results are presented in Table I.

Thermal Decomposition of Cyclononyl S-Methyl Xanthate. (A) **Low Temperature Procedure.**—Crude cyclononyl S-methyl xanthate (12 g.) was pyrolyzed in a 100-ml. flask at 120–130° according to the procedure previously described.[6] The product, a yellow liquid, was distilled at 56–64° (15 mm.) and weighed 4.1 g. The yellow contaminant was removed by chromatography. Subsequent distillation through a Podbielniak column at atmospheric pressure yield 2.2 g. (34.4%) of II, b.p. 168–173°, $n^{25}D$ 1.4770. (B). **High Temperature Procedure.**—Crude cyclononyl S-methyl xanthate (14 g.) was dropped through a carborundum packed column heated to the desired temperature as described for the acetate pyrolysis. After completion of the pyrolysis, the column was cooled and washed with pentane. The combined pyrolyzate and washes were worked up as in the low temperature procedure.

The results of the pyrolyses at various temperatures are summarized in Table II.

Synthesis of Methoxyhydrophenanthrenes and Methoxyhydrocyclohepta[a]-naphthalenes by Acylation of Ketones with Homoveratric Anhydride

BY GORDON N. WALKER

RECEIVED JANUARY 24, 1957

Acylation of cyclohexanone and cycloheptanone with homoveratric anhydride in the presence of boron trifluoride etherate is accompanied by cyclization, giving, after dehydration, compounds IIa and IIb, respectively. An intermediate hydroxyketone Ia is isolated in the first case. Acylation of cyclohexanone and cycloheptanone with homoveratric anhydride in the presence of boron trifluoride in acetic acid leads to formation of 1-acetyl-2-naphthol derivatives, XIa and XIb, respectively. Evidence confirming the structures of these products is presented, notably oxidation of compounds II to quinones VIII, and hydrogenation of compounds XI to octahydrophenanthrenes, XII. Angular methyl compounds V and VI have also been synthesized by acylation of 2-methylcyclohexanone with homoveratric anhydride.

There are several methods for synthesizing phenanthrenes and hydrophenanthrenes from simple aromatic compounds, depending upon cyclization reactions of appropriate functional groups with benzene carbon–hydrogen. These methods include the classical Pschorr procedure[1] and its modifications, the Haworth method[2] and cyclizations first described by Bardhan and SenGupta[3] and independently by Bogert[4] and Cook[5] and their collaborators. The Pschorr synthesis,[6,7] and another approach, namely, closure of ring B after elaboration of the A/C system,[8,9] have been adapted to synthesis of methoxy tricyclic compounds incorporating seven-membered rings (colchicine relatives). Efforts to circumvent difficulties inherent in these approaches have now led to discovery of a new cyclodehydration[10] reaction, described in this paper,[11] which accomplishes in one step the synthesis of certain hydrophenanthrenes and their C-ring homologs.

Experimental work was begun, acting upon the premise that if cyclic ketones could be C-acylated with phenylacetic anhydrides, it should be possible to bring about cyclization of resulting β-diketones through interaction of the benzene ring and the cyclic ketone moiety under acid conditions. Exposure of mixtures of phenylacetic anhydride and cyclohexanone to boron trifluoride under various conditions failed to yield recognizable products, an observation which agrees with earlier data.[12] However, it seemed likely that C-acylation did occur, for infrared spectra of the (presumably polymeric) products showed ketone (5.8–5.9 μ) rather than enol ester (5.7 μ) bands. Experiments with homoveratric anhydride were then tried, and these proved to be successful, inasmuch as C-acylation did occur, as supposed, and cyclization of resulting diketones *in situ* took place as well.

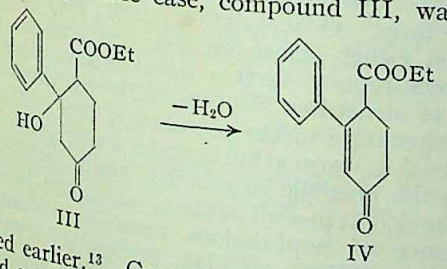
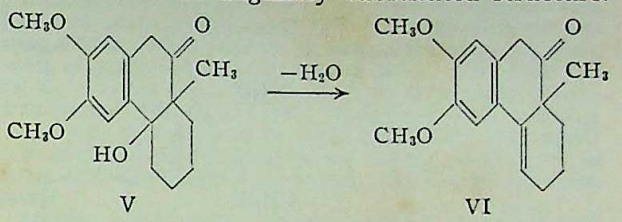
Compound Ia was obtained in 68% yield when a mixture of homoveratric anhydride, cyclohexanone and boron trifluoride etherate was allowed to stand at 0–10° for three days. Evidence leading to assignment of structure Ia and excluding other possibilities was obtained from analysis, spectra and further reactions. While the infrared spectrum of Ia showed only weak absorption at 2.8–2.9 μ, there was present a strong ketone band at 5.79 μ (chloroform solution) or 5.85 μ (mull). A hydroxymethylene derivative was prepared by reaction of Ia with ethyl formate (sodium methoxide), indicating that a methylene position adjacent to a ketone group was present. Attempts to acetylate Ia with acetic anhydride were fruitless, thus making it appear likely that a tertiary alcohol was at hand. As expected, compound Ia lost water rapidly in the presence of mineral acids, polyphosphoric acid being best for the purpose, and formed a β-naphthol, IIa. Infrared and ultraviolet spectra (see Experimental part) showed clearly that IIa was a naphthalene, and the structure was substantiated further by aromatization of IIa to 2,3-dimethoxy-9-phenanthrol in the presence of palladium. O-Acetates of IIa and the phenanthrol again had typical ultraviolet spectra, and the infrared spectra of these compounds disclosed, as anticipated, peaks at 5.70 μ.

Condensation of homoveratric anhydride with cycloheptanone in the presence of boron trifluoride etherate gave IIb directly, and Ib, though perhaps formed first in the reaction, could not be isolated. The fact that the presumed cycloheptanol intermediate Ib dehydrates more readily than does the cyclohexanol Ia is interesting and probably is due to steric effects. Data available at present do not permit an unequivocal statement about the stereochemistry of hydroxyketone Ia. However, it seems likely that rings B and C of Ia are arranged *cis*. A comparable case, compound III, was described earlier.[13] Compound III, in which a presumed equatorial hydroxyl group is located in the benzyl position, beta to a carbonyl group and *cis* with respect to hydrogen at carbon atom 4, is like Ia in being relatively resistant to dehydration, as well as to hydrogenolysis and acetylation. It has now been found that III, like Ia, loses water in the presence of polyphosphoric acid, giving IV.

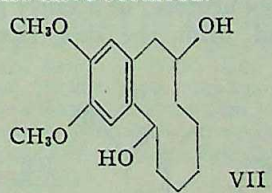


Another compound of the type shown in formula I was synthesized by condensation of homoveratric anhydride with 2-methylcyclohexanone in the presence of boron trifluoride etherate. Reasoning from some data available on methylene *versus* methinyl acylation,[14] it was felt that acylation of a 2-substituted cyclohexanone might as well take place at position 2 as at position 6 of the ketone. This in fact was the case, for the product isolated (63%) was compound V. Dehydration of V did not afford a naphthol, but rather an unsaturated ketone VI, a result readily explained only on the basis of an angularly substituted structure.



Thus it appears that the synthesis is applicable to preparation of angular-methyl compounds such as V or VI.

The novelty of these condensation–cyclization products makes it desirable that there be some proof of their structures in addition to the facts already presented. Attempts to convert Ia or IIa to a known compound, 2,3-dimethoxyphenanthrene,[15,16] were thwarted by the following events. Reduction of IIa under various conditions gave mixtures of products, and 2,3-dimethoxyphenanthrene could not be isolated after subsequent dehydration and aromatization. Hydrogenation of IIa may have taken place in ring A as well as in ring B, and in this connection some results obtained in hydrogenation of phenanthrene-9,10-quinone (see below) may be relevant. Compounds Ia, V and VI resisted catalytic hydrogenation in the presence of 10% palladium–charcoal. Lithium aluminum hydride (or sodium borohydride) reduction of Ia gave a diol, $C_{16}H_{24}O_4$, m.p. 147–149°, having two hydrogen atoms more than expected for a diol corresponding to Ia; it is thought at present that in this reduction reverse aldol reaction, leading to VII, or possibly some other type of cleavage may also have occurred.



A satisfactory demonstration of the correctness of structures II was achieved eventually in a rather unusual way. Although other oxidizing agents for the most part destroyed IIa and IIb, it was found that *ozone* oxidizes these compounds rapidly to corresponding *o*-quinones, VIIIa and VIIIb, respectively. Compound IIa is oxidized in this manner more rapidly than is IIb, and in the same vein quinone VIIIa appears to be somewhat less stable than VIIIb, although both compounds VIII are rather more stable than 1,2-naphthoquinone and 1,2,3,4 - tetrahydrophenanthrene - 9,10 - quinone. Preparation of quinoxaline derivatives IX from quinones VIII provided confirmation of structures VIII. There seemed to be no tendency toward formation of corresponding quinhydrones during oxidation of compounds II, an observation which

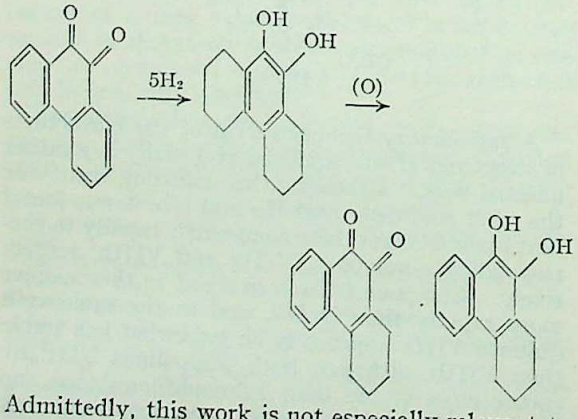
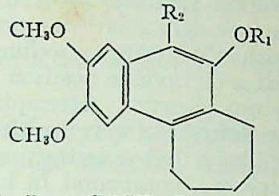
stood in contrast to a report concerning formation of the parent system, 1,2,3,4-tetrahydrophenanthrene-9,10-(quinone-hydroquinone).[17] Therefore, hydrogenation of phenanthrene-9,10-quinone was carried out in an effort to get more information about compounds in this category. After exhaustive hydrogenation of phenanthrene-9,10-quinone in the presence of 10% palladium–charcoal in ethyl acetate at 80°, a diol was obtained which, like the diol described by Skita,[17] oxidized very readily, even upon exposure to air, to tetrahydrophenanthrenequinhydrone. This oxidative transformation appeared at first to be analogous to oxidation of compounds II, and indeed a parallel could be drawn if the unstable reduction product obtained here were 1,2,3,4,9,10-hexahydrophenanthrene-9,-10-diol, as supposed earlier,[17] or 1,2,3,4,4a,9,10,10a-octahydrophenanthrene-9,10-diol, as seemed more likely from present analytical results. However, the diol evidently had neither of these structures but was instead 1,2,3,4,5,6,7,8-octahydrophenanthrene-9,10-diol. This conclusion was necessitated by the elementary composition and, more important, the properties, particularly infrared spectrum (5.70 μ, phenol acetate) of a fairly stable monoacetate obtained from the diol (see Experimental part).



Admittedly, this work is not especially relevant to other results presented here but is included because it has some novelty and represents one attempt to obtain a desired model compound, 1,2,3,4-tetrahydro-10-hydroxyphenanthrene.

Some additional experiments with compound IIb were done in the interest of providing further evidence for the structure and exploring possible means of selectively opening ring B. The O-acetate Xa, methyl ether Xb and a bromo-derivative Xc were prepared by conventional reactions. Nitrous acid converted IIb to the nitroso-compound (quinone monoxime) Xd, catalytic reduction of which, followed by acetylation, provided Xe. Preliminary attempts to carry out inverse Beckmann rearrangement[7] of Xd, and other reactions



Xa, R_1 = $COCH_3$, R_2 = H
b, R_1 = CH_3, R_2 = H
c, R_1 = H, R_2 = Br
d, R_1 = H, R_2 = NO
e, R_1 = $COCH_3$, R_2 = $NHCOCH_3$

designed to selectively cleave the 5,6-double bond in IIb and its derivatives, have been unsuccessful.

Early in exploratory work, condensations of homoveratric anhydride with cyclohexanone and cycloheptanone were carried out using acetic acid, rather than ether, as solvent and complexing agent. The products when analyzed proved to be acetates of IIa and IIb, respectively, but were yellow rather than colorless compounds, gave strong ferric chloride tests and judging from ultraviolet spectra seemed to be C-acylnaphthalenes. The infrared spectra of the compounds lacked hydroxyl and ordinary carbonyl bands, as in spectra of other 1,3-keto-enols, and thus structures XIa and XIb, consistent with this evidence, were assigned to the compounds. Formation of XIa and XIb may have come about either by direct acetylation of IIa and IIb after cyclization or through Fries reaction[18] of O-acetates. O-Acetylation itself may have occurred either before or after cyclization. These matters require further examination. Confirmation of structures XIa and XIb was provided by hydrogenation in the presence of 10% palladium–charcoal in warm ethyl acetate, under which conditions the phenolic ring in XI was reduced as well as the 1,3-keto-enol system, as shown by disappearance of naphthalene ultraviolet absorption, and diols XIIa and XIIb, respectively, were obtained. These crystalline compounds appeared to

consist of only one isomer in each case, and at present it seems likely that they are the all-*cis* isomers, formed by way of initial 1,4-addition, or perhaps even 1,6-addition, of hydrogen. Palladium-catalyzed hydrogenation of other 1,3-keto-enols such as *o*-hydroxyacetophenones,[19] dehydroacetic acids[19] and 2-acetylcyclohexanone (see Experimental part of this paper) under neutral conditions also results in reduction of the acetyl group in each case.

It should be mentioned that successful condensation–cyclization reactions of homoveratric anhydride with cyclopentanone and with 1-tetralone were not achieved, although with 2-tetralone a small amount of rather unstable ketone, $C_{20}H_{20}O_4$, was isolated. Even more disappointing was the failure to isolate any tricyclic compounds after reaction of 3,4,5-trimethoxyphenylacetic anhydride with cyclohexanone and cycloheptanone. The synthesis in its present form appears to be limited in practice to use of relatively simple 6- and 7-membered ring ketones and to use of phenylacetic anhydrides in which the benzene ring carbon atom (6) at which cyclization occurs is activated by suitably placed electron-releasing groups and is not hindered by a group at the adjacent position (5). Even with these limitations the method may prove to be useful in synthesizing a number of new polycyclic compounds, especially if improvements in experimental conditions can be found, and it is hoped to pursue further work in this direction.

Experimental[20]

3,4-Dimethoxyphenylacetic Anhydride.—A solution of 56.5 g. of 3,4-dimethoxyphenylacetic acid in 550 ml. of acetic anhydride was treated with 5.5 ml. of pyridine and was refluxed for 4 hr. The solution was evaporated on a steam-cone to a volume of 70 ml. The cooled residue was diluted with 300 ml. of ether and was stirred and chilled in ice until crystallization was complete. The product was collected and washed with 100 ml. of dry ether; first crop, 23 g., m.p. 79–82°. The filtrates were kept at ice temperature for a week, whereupon a second crop, 18 g., m.p. 77–80°, was obtained after trituration with ether. The yield of anhydride was 41 g. (76%). Recrystallization from ethyl acetate gave colorless crystals, m.p. 83–85°. The infrared spectrum (chf.) had an intense doublet, 5.48 and 5.70 μ.

Anal. Calcd. for $C_{20}H_{22}O_7$: C, 64.2; H, 5.92. Found: C, 64.5; H, 6.04.

2,3-Dimethoxy-4b-hydroxy-9-keto-4b,5,6,7,8,8a,9,10-octahydrophenanthrene (Ia).—A mixture of 10.1 g. (0.027 mole) of homoveratric anhydride and 7.3 g. (0.0745 mole) of redistilled cyclohexanone was treated with 74 ml. of ice-cold, commercial 47% boron trifluoride etherate. The mixture was swirled in an ice-bath for an hour until the solid material dissolved, and the dark solution was kept in an ice-box for 3 days. During this time a solid deposited slowly. The mixture was added to a solution of 60 g. of sodium acetate in 300 ml. of water, and this mixture was heated on a steam-cone and stirred for 15 minutes until the ether evaporated and the remaining dark oil began to crystallize. The mixture was chilled in ice and stirred until crystallization was complete. The crude product was collected and washed with two 50-ml. portions of water. The gummy crystals were triturated with three successive small portions of methanol, which removed dark, oily material and left 5.1 g. (68%) of light-brown crystals, m.p. 133–138°. Recrystallization from aqueous methanol (Norit) gave colorless crystals, m.p. 140–141°. Slow evaporation of solutions of this compound resulted in formation of large, rhombohedral crystals. The infrared spectrum (chf.) showed very weak absorption at 2.8–2.9 μ and an intense peak at 5.79 μ. The infrared spectrum in Nujol mull was devoid of hydroxyl bands, and in this medium the intense carbonyl peak was shifted to 5.85 μ, indicating hydrogen bonding. The ultraviolet spectrum (ethanol) had λ_{max} 232 and 285 mμ (log ϵ 3.88 and 3.57, respectively).

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30; mol. wt., 276. Found: C, 69.55; H, 7.34; mol. wt. (Rast), 285.

Although the compound gave a transient positive test with 2,4-dinitrophenylhydrazine, attempts to prepare derivatives using this and other reagents were unsuccessful, apparently owing to decomposition or formation of IIa. The hydroxyketone was insoluble in dilute alkali and did not give a ferric chloride test. It was virtually unchanged after refluxing for an hour in acetic acid or acetic anhydride. Attempted hydrogenolysis in the presence of palladium–charcoal in acetic acid also resulted in recovery of most of the compound.

Another condensation of homoveratric anhydride and cyclohexanone was carried out as described above, except that the solution was allowed to stand at room temperature, rather than 0–10°, for 3 days. In this case the crude product contained very dark, sparingly soluble, gummy material. Compound Ia was isolated from this mixture in 20% yield by recrystallization from aqueous methanol.

The 10-hydroxymethylene derivative was prepared by reaction of 1.0 g. of Ia with excess ethyl formate in the presence of 0.5 g. of dry, freshly prepared sodium methoxide in 300 ml. of dry ether. The product was isolated as usual by acidification of an ether-washed, aqueous solution of the sodium salt. Trituration with ether gave 1.0 g. of pale yellow crystals, m.p. 131–135°. Recrystallization from ethyl acetate afforded 0.85 g. of colorless crystals, m.p. 159–161°. The infrared spectrum (chf.) had a band at 6.00 μ. The ultraviolet spectrum (ethanol) had λ_{max} 257, 288 and 309 mμ (log ϵ 4.05, 4.08 and 3.95, respectively). The compound was soluble in dilute sodium hydroxide solution and, like 1-hydroxymethylene-2-tetralone, gave a deep-blue color (changing to green) with ferric chloride.

Anal. Calcd. for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62. Found: C, 67.36; H, 6.87.

Efforts to dehydrate this compound with polyphosphoric acid resulted in formation of tars.

2,3-Dimethoxy-5,6,7,8-tetrahydro-9-phenanthrol (IIa).—A mixture of 1.4 g. of Ia and 18 g. of polyphosphoric acid was heated to 80° and stirred for 10 minutes, until a dark-brown solution was obtained. The chilled solution was treated with ice and water, and the resulting purple solid was extracted with ethyl acetate. The organic solution was washed with successive portions of water, sodium bicarbonate solution and water, and was dried over magnesium sulfate. Evaporation of the solvent and trituration of the crude product (0.8 g.) with methanol gave 0.6 g. (46%) of light-brown crystals, m.p. 211–218° dec. Recrystallization from methanol (Norit) gave colorless crystals, m.p. 219–221° dec. The infrared spectrum (chf.) had a peak at 2.76 μ. The ultraviolet spectrum[21] (ethanol) had $\lambda_{max.}$ 237, 272, 282, 293, 322 and 336 mμ (log ϵ 4.86, 3.60, 3.59, 3.46, 3.59 and 3.72, respectively).

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02. Found: C, 74.50; H, 7.09.

Dehydration of Ia also occurred in the presence of warm sulfuric–acetic acids mixture, as indicated by appearance of a deep-red color, but no crystalline product could be isolated after this reaction. Hydrogenation of IIa in the presence of 10% palladium–charcoal in ethyl acetate at 80° gave glassy material, the infrared spectrum of which showed absorption at 2.76 and 2.9–3.0 μ.

Acetylation of IIa with acetic anhydride (refluxed 2 hr.) gave the **O-acetate**, m.p. 170–171°, after recrystallization from methanol. The infrared spectrum (chf.) had a peak at 5.70 μ, and the ultraviolet spectrum (ethanol) had λ_{max} 235, 264, 273, 282, 293, 314 and 328 mμ (log ϵ 4.98, 3.68, 3.72, 3.71, 3.54, 3.49 and 3.69, respectively).

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.03; H, 6.69.

2,3-Dimethoxy-9-phenanthrol.—A mixture of 0.5 g. of IIa, 1.5 g. of 10% palladium–charcoal catalyst and 40 ml. of redistilled *p*-cymene was refluxed vigorously for 2.5 hr.

The catalyst was filtered and was washed with 50 ml. of ethyl acetate. The yellow solution was evaporated to a small volume, and the residual material was taken up in 5 ml. of methanol. The solution was kept at ice temperature overnight, and the product was collected, washed with a small quantity of methanol and air-dried. There was obtained 0.2 g. of nearly colorless crystals, m.p. 244–248° dec. Recrystallization from methanol gave colorless crystals, m.p. 254–256° dec. The infrared spectrum (Nujol) had a strong peak at 2.81–2.87 μ. The ultraviolet spectrum (ethanol) had λ_{max} 241, 265, 282, 323, 338 and 362 mμ (log ϵ 4.62, 4.36, 4.23, 3.68, 3.64 and 3.28, respectively). The compound was first dried at 80° *in vacuo*.

Anal. Calcd. for $C_{16}H_{14}O_3 \cdot {}^1/_2H_2O$: C, 72.99; H, 5.74. Found: C, 73.17; H, 5.70.

When the material was dried at 100° *in vacuo*, it was obtained in anhydrous condition.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.67; H, 5.73.

Acetylation with acetic anhydride (4-hr. reflux) and recrystallization of the product from methanol gave the **O-acetate**, m.p. 197–199°. The infrared spectrum had an intense peak at 5.68 μ. The ultraviolet spectrum (ethanol) had λ_{max} 225, 246, 260, 278, 329, 339 and 355 mμ (log ϵ 4.42, 4.61, 4.59, 4.45, 3.44, 3.30 and 3.23, respectively).

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44. Found: C, 72.68; H, 5.51.

2,3-Dimethoxy-6-hydroxy-8,9,10,11-tetrahydro-7H-cyclohepta[a]naphthalene (IIb).—A mixture of 41 g. (0.110 mole) of homoveratric anhydride and 21.7 g. (0.194 mole) of cycloheptanone was treated with 300 ml. of ice-cold boron trifluoride etherate (47%) in one portion. The solid material dissolved after stirring for 0.5 hr. The solution was allowed to stand at room temperature overnight, then was placed in an ice-box and allowed to stand (at 0–10°) for 24 hr. longer. The mixture was hydrolyzed with a solution of 260 g. of sodium acetate in 500 ml. of water, as described for Ia. Upon chilling the resulting oily mixture, the crude product crystallized. It was collected, washed with cold water and triturated with a small quantity of methanol. Two crops of crystalline product, total weight 8.7 g. (29%), m.p. 198–202°, were obtained. Recrystallization from methanol gave colorless crystals, m.p. 207–208°. The infrared spectrum (chf.) had a peak at 2.76 μ. The ultraviolet spectrum (ethanol) had λ_{max} 237, 274, 285, 296, 324 and 337 mμ (log ϵ 4.91, 3.61, 3.61, 3.49, 3.58 and 3.72, respectively).

Anal. Calcd. for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40. Found: C, 74.93; H, 7.45.

Acetylation with boiling acetic anhydride (2 hr.) gave the **O-acetate, Xa**, m.p. 139–141°, after recrystallization from methanol or cyclohexane–ethyl acetate (Norit). The infrared spectrum showed an intense peak at 5.70 μ, and the ultraviolet spectrum (ethanol) had λ_{max} 238, 267, 276, 285, 296, 315 and 329 mμ (log ϵ 4.78, 3.54, 3.59, 3.58, 3.41, 3.28 and 3.48, respectively).

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.59; H, 7.06. Found: C, 72.84; H, 7.06.

Methylation with excess dimethyl sulfate and potassium hydroxide afforded the **methyl ether Xb**, which, after recrystallization from methanol, was obtained as colorless crystals, m.p. 122–124°. The ultraviolet spectrum (ethanol) had λ_{max} 238, 272, 282, 321 and 330 mμ (log ϵ 4.92, 3.66, 3.62, 3.56 and 3.74, respectively).

Anal. Calcd. for $C_{18}H_{22}O_3$: C, 75.49; H, 7.75. Found: C, 75.43; H, 7.72.

Treatment of IIb with bromine in chloroform at room temperature resulted in rapid consumption of the reagent, hydrogen bromide evolution and formation of **bromo-derivative Xc**. Evaporation of the solvent and recrystallization of the residue from methanol gave colorless crystals, m.p. 164–165°.

Anal. Calcd. for $C_{17}H_{19}O_3Br$: C, 58.13; H, 5.45; Br, 22.75. Found: C, 58.38; H, 5.49; Br, 22.86.

3-Phenyl-4-carbethoxycyclohex-2-ene-1-one (IV).—A mixture of 2 g. of crystalline ethyl benzoylacetate–methyl vinyl ketone adduct,[13] m.p. 127–129°, and 20 g. of polyphosphoric acid was heated on a steam-cone and stirred for 12 minutes. The solid dissolved rapidly and a deep carmine-red color appeared. Hydrolysis in the usual manner with ice and water and isolation of the neutral product in the usual way gave 1.5 g. of yellow oil, the infrared spectrum of which had intense peaks at 5.80 and 6.01 μ. **The 2,4-dinitrophenylhydrazone** was prepared in 95% yield from this crude product. Recrystallization from ethyl acetate gave red crystals, m.p. 169–171°, which did not depress the m.p. of a sample of the derivative prepared as described earlier.[13]

2,3-Dimethoxy-4b-hydroxy-8a-methyl-9-keto-4b,5,6,7,8,-8a,9,10-octahydrophenanthrene (V).—A mixture of 13.6 g. (0.0364 mole) of homoveratric anhydride and 9.9 g. (0.0883 mole) of 2-methylcyclohexanone was treated with 105 ml. of ice-cold, 47% boron trifluoride etherate (one portion). When the mixture was swirled in an ice-bath, the solid material dissolved gradually. The solution was allowed to stand in an ice-box for 5 days. Hydrolysis with a solution of 100 g. of sodium acetate in 350 ml. of water, as described for Ia, gave viscous, orange oil, which did not crystallize. The oil was extracted with ether, and the organic solution was washed with successive portions of water, sodium bicarbonate solution (excess) and water. Evaporation of the dried solution gave material which crystallized rapidly. Trituration with ether afforded 6.7 g. (63%) of pale-yellow crystals, m.p. 127–129°. Recrystallization from ethyl acetate gave colorless needles, m.p. 129–130°. The infrared spectrum (chf.) was very similar to that of Ia, showing weak hydroxyl band at 2.82–2.90 μ, and an intense carbonyl peak at 5.80 μ. The infrared spectrum in Nujol mull had no hydroxyl band and displayed the intense carbonyl peak at 5.82 μ. The ultraviolet spectrum (ethanol) had λ_{max} 231 and 283–287 mμ (log ϵ 3.89 and 3.58–3.59, respectively).

Anal. Calcd. for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64. Found: C, 70.36; H, 7.45.

Like Ia, this compound was insoluble in dilute alkali, gave no ferric chloride test, was inert to acetic anhydride and did not form a 2,4-dinitrophenylhydrazone or semicarbazone. Sodium borohydride reduction (in methanol) gave glassy material, the infrared spectrum of which (chf.) showed fairly strong absorption at 2.7–2.75 and 2.8–2.85 μ, and no carbonyl peak. Attempts to dehydrate this reduction product resulted mainly in decomposition.

2,3-Dimethoxy-8a-methyl-9-keto-6,7,8,8a,9,10-hexahydrophenanthrene 2,4-Dinitrophenylhydrazone.—A mixture of 2.2 g. of V and 30 g. of polyphosphoric acid was heated on a steam-cone and stirred steadily for 7 minutes. The cooled, deep-red solution was hydrolyzed with ice and water, and the neutral product was isolated in the usual way. There was obtained 2.1 g. of bright-red, viscous oil which did not crystallize but on standing gradually became dark brown. The infrared spectrum (chf.) still had an intense peak at 5.80–5.83 μ but was rather different in other respects from the spectrum of V. The 2,4-dinitrophenylhydrazone was prepared in the usual way in approximately 70% yield. Recrystallization from ethyl acetate gave orange, small crystals, m.p. 221–223° dec.; λ_{max} (chf.) 365 mμ, 3.00 μ and 6.19 μ.

Anal. Calcd. for $C_{23}H_{24}N_4O_6$: C, 61.05; H, 5.35. Found: C, 61.25; H, 5.14.

Attempts to prepare other derivatives, for example the semicarbazone, from the crude dehydrated ketone were unsuccessful, apparently because of decomposition.

Lithium Aluminum Hydride Reduction of Ia.—Compound Ia (0.6 g.) was stirred with a mixture of 1.2 g. of lithium aluminum hydride and 500 ml. of dry ether at room temperature for 9 hr. Excess hydride and organic complex were then hydrolyzed by cautious addition of 5 ml. of water (stirring), and the suspension was filtered. Evaporation of the colorless ether solution and trituration of the residue with a few ml. of ethyl acetate gave 0.5 g. of colorless crystals, m.p. 147–149°, not raised after recrystallization from the same solvent. The infrared spectrum (chf.) had a moderately strong band at 2.77–2.86 μ. The ultraviolet spectrum (ethanol) had λ_{max} 232 and 282 mμ (log ϵ 4.07 and 3.59, respectively).

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.53; H, 8.73.

These analytical figures were obtained with a sample which had been dried at 100° in high vacuum for 5 hr., and thus the material evidently is not a hydrate. The same compound was obtained, although less pure and in lower yield, by reduction of Ia with sodium borohydride in methanol.

2,3-Dimethoxy-5,6,7,8-tetrahydrophenanthrene-9,10-quinone (VIIIa).—A rapid stream of air and ozone from a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Welsbach ozonizer was passed into an ice-cold solution of 0.55 g. of IIa in 250 ml. of ethyl acetate. A bright-red color developed soon and did not appear to become any more intense after 3 minutes; the gas stream was discontinued after 4 minutes, and the solvent was evaporated as rapidly as possible. The partly crystalline residue was triturated with a small quantity of ethyl acetate. There was obtained 0.28 g. of deep-red needles. Neither this material nor that purified further by recrystallization from ethyl acetate had a sharp melting point but rather decomposed gradually when heated above 150°. The infrared spectrum of a purified sample (chf.) had a very sharp, intense peak at 6.01 μ with less intense shoulders at 5.94 and 6.07 μ.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92. Found: C, 70.65; H, 6.23.

A small sample of VIIIa, when treated in warm acetic acid with a solution of *o*-phenylenediamine, gave compound IXa; yellow needles from ethyl acetate, m.p. 228–229°.

Anal. Calcd. for $C_{22}H_{20}N_2O_2$: C, 76.72; H, 5.85. Found: C, 76.99; H, 6.00.

2,3-Dimethoxy-5,6-diketo-6,6a,7,8,9,10,11,11a-octahydro-5H-cyclohepta[a]naphthalene (VIIIb).—Compound IIb was exposed to ozone as described in the preceding experiment, except that reaction time was increased to 30 minutes, in view of the fact that the red color developed more slowly. From 0.5 g. of IIb there was obtained 0.4 g. of red crystals, m.p. 140–145°. Recrystallization from ethyl acetate gave deep-red, lustrous needles, m.p. 146–148°. The infrared spectrum (chf.) had a sharp, intense peak at 6.06 μ with shoulders at 5.96 and 6.10 μ.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34. Found: C, 71.35; H, 6.62.

Compound IXb was prepared as described for IXa; yellow crystals from ethyl acetate, m.p. 219–220°.

Anal. Calcd. for $C_{23}H_{22}N_2O_2$: C, 77.07; H, 6.19. Found: C, 76.85; H, 6.18.

Hydrogenation of 9,10-Phenanthrenequinone.—A mixture of 9.8 g. of 9,10-phenanthrenequinone, 6.5 g. of 10% palladium–charcoal and 450 ml. of ethyl acetate was shaken under hydrogen (40 lb.). Somewhat more than one mole of hydrogen was absorbed rapidly (5 minutes) at room temperature, representing, no doubt, reduction to the hydroquinone. Absorption then ceased and was not resumed until the system was heated to about 80°. Additional hydrogen (3–4 moles) was then absorbed slowly (7 hr.), and finally the consumption of hydrogen became extremely slow, whereupon the cooled contents of the bottle were filtered. The yellowish solution thus obtained became somewhat darker in color during evaporation of the solvent. The residue crystallized readily but continued to acquire a darker color; the exact yield of product could not be ascertained. By rapid, repeated crystallization of the crude material from ethyl acetate and then from cyclohexane, there were obtained colorless crystals, m.p. 127–128°. This material, **1,2,3,4,5,6,7,8-octahydrophenanthrene-9,10-diol**, appeared to be stable when purified and dried, but air-oxidized readily in the presence of solvents, especially if warmed above 70°. The infrared spectrum (chf.) had a fairly strong peak at 2.82 μ. The compound gave a positive ferric chloride test and deteriorated rapidly in the presence of aqueous alkali.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31. Found: C, 76.92; H, 8.21.

Some of the original crude material from hydrogenation was treated with excess acetic anhydride (20 ml.) and ethyl acetate (200 ml.), and the solution was allowed to stand at room temperature overnight. Evaporation of solvent and excess reagent and recrystallization of the residue (cyclohexane–ethyl acetate) gave the **monoacetate** of the diol; colorless crystals, m.p. 169–171°. The infrared spectrum (chf.) had peaks at 2.80 and 5.70 μ. The compound did not give a ferric chloride test but was soluble in dilute sodium hydroxide solution.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.60; H, 7.51.

The remainder of the crude diol, upon standing exposed to air, acquired a red-purple color and finally, after a week, became almost black. Trituration with ethyl acetate then afforded (in rather good yield) greenish-black crystals. Recrystallization from the same solvent gave pure **1,2,3,4-tetrahydro-9,10-phenanthrenequinhydrone**[17]; green needles, m.p. 159–161°. Solutions and melts of this compound were deep purple. The infrared spectrum (chf.) had a moderately strong peak at 2.93 μ and a quintet of sharp peaks, 6.07, 6.14, 6.24, 6.29 and 6.40 μ.

Anal. Calcd. for $C_{28}H_{26}O_4$: C, 78.85; H, 6.14. Found: C, 79.12; H, 5.84.

1,2,3,4-Tetrahydrophenanthrenequinone, also prepared by Skita,[17] was found to consist of red-orange needles having no definite m.p. but rather decomposing gradually above 120°. The infrared spectrum of this quinone, after recrystallization from ethyl acetate, showed an intense peak at 6.02 μ with a less intense secondary peak at 5.90 μ.

2,3-Dimethoxy-5-nitroso-6-hydroxy-8,9,10,11-tetrahydro-7H-cyclohepta[a]naphthalene (Xd).—An ice-cold suspension of 1.4 g. of IIb and 2 g. of sodium nitrite in 100 ml. of methanol and 50 ml. of water was treated with 50 ml. of cold 50% sulfuric acid, in 10 portions, over a period of an hour. Additional sodium nitrite (1.5 g.) was added, and the mixture was kept in an ice-box for 4 days, during which time dark red crystals separated gradually. The product was collected and was washed with four 20-ml. portions of water and 20 ml. of methanol. After air-drying, there was obtained 1.4 g. of red crystals, m.p. 170–174°. Recrystallization from ethyl acetate raised the m.p. to 176–178°. The infrared spectrum (chf.), as expected in analogy with 1-nitroso-2-naphthol, showed no absorption near 3 μ and had a peak at 6.23 μ with a shoulder at 6.09–6.13 μ.

Anal. Calcd. for $C_{17}H_{19}NO_4$: C, 67.76; H, 6.36. Found: C, 67.87; H, 6.52.

The corresponding **5-acetylamino-6-acetoxy** compound, Xe, was prepared by hydrogenation of 0.5 g. of Xd in the presence of 1 g. of 10% palladium–charcoal catalyst in ethyl acetate at room temperature for an hour. After filtration, the solution was treated immediately with 30 ml. of acetic anhydride and was allowed to stand at room temperature overnight. Evaporation then gave discolored crystals, trituration of which with ethyl acetate afforded 0.3 g. of product, m.p. 225–227°. Recrystallization from the same solvent gave colorless crystals, m.p. 228–228.5°.

Anal. Calcd. for $C_{21}H_{23}O_5N$: C, 67.91; H, 6.79; N, 3.77. Found: C, 68.11; H, 6.76; N, 3.73.

The infrared spectrum (chf.) displayed peaks at 2.96, 5.69, 5.97 and 6.03 μ.

2,3-Dimethoxy-5,6,7,8-tetrahydro-9-hydroxy-10-acetylphenanthrene (XIa).—Glacial acetic acid (50 ml.) was saturated with anhydrous boron trifluoride at ice temperature. There was added 9.6 g. (0.0257 mole) of homoveratric anhydride and 5.5 g. (0.0561 mole) of cyclohexanone. The mixture was stirred steadily and kept at 35–40° for 20 hr. During this time the anhydride dissolved, and later a brown solid separated. The mixture was treated with a solution of 32 g. of sodium acetate in 250 ml. of water, whereupon bright yellow crystals were formed. The material was collected and washed with two small portions of water. Trituration with methanol, in which the crystals were very sparingly soluble, afforded 3.2 g. of a complex, m.p. 239–241° dec., not changed by recrystallization from dry benzene. The complex was taken up in 100 ml. of methanol, and the suspension was boiled 1 hr. The resulting solution was reduced to 20-ml. volume and was cooled. The crystals which separated were collected, washed with a small portion of methanol and dried; 2.9 g. (38%) of yellow needles, m.p. 167–168°. Recrystallization from methanol did not improve this m.p. The infrared spectrum (chf.) showed no hydroxyl or ordinary carbonyl bands, although there was an intense peak at 6.25 μ with shoulders at 6.09 and 6.13 μ. The ultraviolet spectrum (ethanol) had λ_{max} 234, 294 and 340 mμ (log ϵ 4.80, 3.57 and 4.00, respectively). The compound gave a dark-green ferric chloride test.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.01; H, 6.75.

Aromatization of a sample of XIa in the presence of 3 parts by weight of 10% palladium–charcoal in *p*-cymene (refluxed 2.5 hr.) gave a small amount of **2,3-dimethoxy-9-hydroxy-10-acetylphenanthrene**, m.p. 161–162° (from methanol). The infrared spectrum (chf.) was similar to but not identical with the spectrum of XIa. The ultraviolet spectrum (ethanol) had λ_{max} 235, 254, 272, 316, 333, 346 and 378 mμ (log ϵ 4.47, 4.57, 4.31, 3.84, 3.80, 3.81 and 3.74, respectively).

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.4. Found: C, 72.70; H, 5.7.

2,3-Dimethoxy-5-acetyl-6-hydroxy-8,9,10,11-tetrahydro-7H-cyclohepta[a]naphthalene (XIb).—Condensation of 9.9 g. of homoveratric anhydride and 5.8 g. of cycloheptanone in the presence of 50 ml. of boron-trifluoride-saturated glacial acetic acid, as described in the preceding experiment, and hydrolysis with 33 g. of sodium acetate and 20 g. of sodium bicarbonate in 300 ml. of water (warmed on a steam-cone for 20 minutes) gave, after cooling the mixture, semi-solid brown oil. This material was washed with 2 small portions of water (decanting) and was triturated with a small amount of methanol. There was obtained 0.6 g. of yellow crystals, m.p. 155–157°. Additional product (0.3 g.) was obtained when the original aqueous solution was allowed to stand for a week, bringing the total yield to 0.9 g. (11%). Recrystallization from methanol gave yellow needles, m.p. 157–158°. The infrared spectrum (chf.) was similar to that of XIa, and the ultraviolet spectrum had λ_{max} 235, 291 and 345 mμ (log ε 4.84, 3.56 and 4.02, respectively). The compound gave a dark green ferric chloride test.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.59; H, 7.06. Found: C, 72.64; H, 7.06.

2,3-Dimethoxy-9-hydroxy-10-(α-hydroxyethyl)-4b,5,6,7,-8,8a,9,10-octahydrophenanthrene (XIIa).—Compound XIa (0.3 g.) in 200 ml. of ethyl acetate with 1.5 g. of 10% palladium–charcoal was shaken under hydrogen (40 lb.) at 80° for 1.2 hr. Filtration of the catalyst and evaporation of the solvent gave viscous, pale yellow oil which crystallized rapidly in the presence of methanol. Recrystallization from cyclohexane–ethyl acetate gave 0.25 g. of colorless crystals, m.p. 167–170°. Further recrystallization gave pure material, m.p. 171–173°. The infrared spectrum (chf.) had a moderately strong doublet, 2.76 and 2.98 μ. The ultraviolet spectrum (ethanol) had λ_{max} 288 mμ (log ε 3.34) and an inflection point at 225 mμ (log ε 3.99).

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 70.56; H, 8.55. Found: C, 70.50; H, 8.23.

Similar hydrogenation of the boron complex, m.p. 239–241°, of XIa afforded a monohydroxy compound, probably **2,3-dimethoxy-9-hydroxy-10-ethyl-4b,5,6,7,8,8a,9,10-octahydrophenanthrene**, m.p. 151–152.5°, after recrystallization from cyclohexane–ether. The infrared spectrum (chf.) of this compound had a single, sharp peak at 2.73 μ, and the ultraviolet spectrum (ethanol) had λ_{max} 280 and 285 mμ (log ε 3.17 and 3.20, respectively).

Anal. Calcd. for $C_{18}H_{26}O_3$: C, 74.44; H, 9.03. Found: C, 74.72; H, 9.12.

2,3-Dimethoxy-5-(α-hydroxyethyl)-6-hydroxy-6,6a,7,8,9,10,11,11a-octahydro-5H-cyclohepta[a]naphthalene (XIIb).—Hydrogenation of 0.4 g. of XIb as described in the preceding experiment gave 0.35 g. of colorless crystals, m.p. 138–140°. Recrystallization from cyclohexane–ethyl acetate gave pure material, m.p. 142–144°. The infrared spectrum (chf.) had a doublet 2.76 and 2.99 μ, and the ultraviolet spectrum (ethanol) had λ_{max} 291 mμ (log ε 3.43) and a point of inflection at 227 mμ (log ε 3.98).

Anal. Calcd. for $C_{19}H_{28}O_4$: C, 71.22; H, 8.81. Found: C, 71.44; H, 8.75.

2-Ethylcyclohexanone.—A solution of 5 g. of 2-acetylcyclohexanone[22] in 250 ml. of ethyl acetate containing 4 g. of 10% palladium–charcoal was shaken under hydrogen (40 lb.) at 80° for an hour. Two moles of hydrogen were consumed in 0.5 hr., and then the reaction became very slow. Filtration of the catalyst and evaporation of the solvent gave nearly colorless oil. The infrared spectrum (chf.) had an intense peak at 5.87–5.89 μ and a very weak band at 2.90 μ (indicating presence of some hydroxylic material). The **2,4-dinitrophenylhydrazone** was prepared in *ca.* 80% yield from the crude product; recrystallization from ethanol gave orange needles, m.p. 160–161° (lit.[23] m.p. 159–161°).

Condensation of Homoveratric Anhydride with 2-Tetralone.—To a mixture of 7.4 g. of homoveratric anhydride and 4.2 g. of 2-tetralone was added 65 ml. of ice-cold 47% boron trifluoride etherate. The suspension was swirled in an ice-bath for 15 minutes until the anhydride dissolved and was kept in an ice-box for 2 days. Hydrolysis with a solution of 60 g. of sodium acetate in 350 ml. of water at 60–70° for 10 minutes gave oily material, which was extracted with ether–ethyl acetate. The organic solution was washed with successive portions of water, sodium bicarbonate solution (excess) and water and was dried over magnesium sulfate. The solvents were evaporated at 30°, and the residual oil (6.9 g.) was dissolved in 20 ml. of ether. Refrigeration of this solution overnight resulted in formation of 0.85 g. of gummy crystals. Trituration of the crystals with additional ether gave 0.5 g. of product, m.p. 189–192°. Recrystallization from methanol afforded colorless crystals, m.p. 194–195° dec. The infrared spectrum (chf.) showed a weak band at 2.82–2.86 μ and a moderately strong peak at 5.83 μ. The ultraviolet spectrum (ethanol) had λ_{max} 227, 275, 321 and 349 mμ (log ε 4.45, 4.61, 3.96 and 2.96, respectively).

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 74.05; H, 6.22. Found: C, 74.08; H, 5.90.

Efforts to dehydrate and acetylate this material as with Ia led to decomposition and formation of mixtures of products.

Acknowledgment.—I am indebted to Dr. William C. Alford and his staff for microanalytical data, and to Mr. H. Franklin Byers, Miss Catherine Monaghan and Miss Patricia Wagner for spectra.

Further Research on Biphenyl, Stilbene and Diphenylethane Derivatives—Potential Anticholesterinemic, Antirheumatic Drugs. VII

BY G. CAVALLINI, E. MASSARANI, D. NARDI AND R. D'AMBROSIO

RECEIVED SEPTEMBER 21, 1956

Derivatives of biphenyl, stilbene and diphenylethane have been prepared with various substituents in the 4-position: alkylacetic acids; oxyacetic acid; and propionic, butyric, acrylic, pyruvic, crotonic, β-hydroxypropionic and γ-ethyl-β-hydroxybutyric acid.

In a previous paper[1] we prepared derivatives of biphenyl, stilbene and diphenylethane with various groups in the 4-position

$$-CH_2COOH,\ -\underset{\displaystyle C_2H_5}{\overset{\displaystyle |}{CH}}-COOH,\ -CH_2-CO-COOH$$

Some of these substances showed a marked anticholesterinemic activity, the most active among them being the 4-biphenylylethylacetic acid[2] which has been used therapeutically with satisfactory results.[3,4]

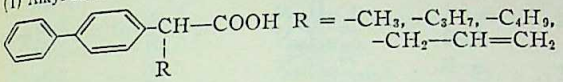
Digitized by Arya Samaj Foundation Chennai and eGangotri

With the hope of finding substances having both anticholesterinemic and antirheumatic activity, we have prepared additional derivatives of biphenyl (and in a few cases of stilbene and diphenylethane) with the following acid groups in the 4-position:

(1) Alkyl-substituted acetic acids



R = $-CH_3$, $-C_3H_7$, $-C_4H_9$, $-CH_2-CH=CH_2$

Diphenylethane, R = $-C_3H_7$

(2) Oxyacetic acid

Also stilbene and diphenylethane.

(3) 3 and 4 carbon acids

R = $-CH_2-CH_2-COOH$, $-CH_2-CH_2-CH_2-COOH$, $-CH=CH-COOH$, $-CH_2-CH=CH-COOH$, $-CH_2COCOOH$, $-CH(OH)-CH_2-COOH$, $-CH(C_2H_5)-CH(OH)-COOH$

Stilbene, R = $-CH=CH-COOH$

Diphenylethane, R = $-CH_2-CH_2-COOH$

4-Biphenylaldehyde, 4-biphenylylacetaldehydes and the 4-biphenylylalkylacetonitriles served as intermediates for the preparation of the acids. The 4-biphenylylalkylacetonitriles, obtained by alkylation[5] of 4-biphenylylacetonitrile, gave the corresponding acetic acids upon acid hydrolysis. Saponification of 4-biphenylylacetonitrile yielded 4-biphenylyloxyacetic acid; the oxyacetic acids of stilbene and diphenylethane were prepared in the same way. It was not possible to convert 4-biphenylyldiethylacetonitrile and 4-biphenylyl-*n*-octylacetonitrile to the corresponding acids as both the acid and alkaline hydrolyses were unsuccessful.

4-Biphenylaldehyde, which was obtained from 4-biphenylylmethyl chloride,[6] was used in the following preparations: (1) 2-phenyl-4-biphenylal-5-oxazolone which upon saponification yielded 4-biphenylylpyruvic acid; (2) 4-biphenylylacrylic acid by Knoevenagel's reaction[7]; the acrylic acid was reduced to the corresponding propionic acid; (3) 4-biphenylyl-β-hydroxypropionic acid which was obtained by the Reformatsky synthesis.[8]

4-Biphenylylacetaldehyde and the alkylacetaldehydes were prepared from the corresponding acid chlorides by Rosenmund's reaction.[9] The former was used for the synthesis of 4-biphenylylcrotonic acid which was subsequently reduced to the butyric acid.

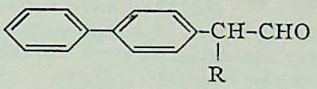
Experimental

The melting points are not corrected.

4-Biphenylaldehyde.—A mixture of 40.4 g. (0.2 mole) of 4-biphenylylmethyl chloride, 60.2 g. (0.44 mole) of hexamethylenetetramine and 90 ml. of 50% acetic acid was refluxed for 2 hours. It was then added to 200 ml. of water and extracted with ether. The organic layer was washed with saturated, aqueous sodium bicarbonate and with water, dried over sodium sulfate and concentrated. Distillation of the residue yielded 21 g. (60%) of 4-biphenylaldehyde b.p. 130° (0.5 mm.); m.p. 60°.[10]

4-Biphenylylacetaldehyde.—The following procedure was also used for the preparation of the 4-biphenylylalkylacetaldehydes. The data are reported in Table I. Thionyl chloride (59 g., 0.5 mole) was added dropwise to 10.56 g. (0.05 mole) of 4-biphenylylacetic acid. The mixture was stirred for one hour at room temperature and for one hour on a steam-bath. The thionyl chloride was then distilled at reduced pressure. The residue, dissolved in 100 ml. of dry toluene, was reduced by the procedure of Rosenmund.[9] The catalyst was filtered, and the solvent evaporated *in vacuo* at 40° under a stream of nitrogen. The residue yielded 4-biphenylylacetaldehyde which was characterized by its 2,4-dinitrophenylhydrazone.

TABLE I



R	Yield, %	M.p., °C.	2,4-Dinitrophenylhydrazone Solvent for cryst.[a]	Formula	N, % Calcd.	Found
–H	81	172	A	$C_{20}H_{16}O_4N_4$	14.88	14.94
$-CH_3$	78	177	A	$C_{21}H_{18}O_4N_4$	14.35	13.94
$-C_2H_5$	84	121–123	B	$C_{22}H_{20}O_4N_4$	13.85	13.94
$-C_3H_7$	82	117	A	$C_{23}H_{22}O_4N_4$	13.39	13.27

[a] A, acetic acid; B, ethanol.

4-Biphenylyl-*n*-propylacetonitrile.—The other 4-biphenylylalkylacetonitriles, which are reported in Table II, were prepared by this method.

A mixture of 19.30 g. (0.1 mole) of 4-biphenylylacetonitrile, 6 g. (0.15 mole) of sodium amide and 60 ml. of dry ether was refluxed for 1 hour. After the addition of 25.5 g. (0.15 mole) of propyl iodide dropwise with stirring, the reaction mixture was refluxed for 6 hours. Then it was cooled, cautiously diluted with water, acidified with dilute hydrochloric acid, and extracted with ether. The extract was washed with aqueous sodium thiosulfate. Drying and concentration gave an oil which upon distillation yielded 4-biphenylyl-*n*-propylacetonitrile.

4-Biphenylyl-*n*-propylacetic Acid.—This procedure is typical for the hydrolysis of the 4-biphenylylalkylacetonitriles to yield the corresponding acetic acids, which are listed in Table III. A mixture of 23.5 g. (0.1 mole) of 4-biphenylyl-*n*-propylacetonitrile, 103 g. (1 mole) of concentrated sulfuric acid, 100 ml. of water and 120 g. (2 mole) of acetic acid was refluxed for 36 hours and 1 liter of water added. The mixture was made alkaline with 40% NaOH, charcoal was added and the solution was filtered. Acidification with dilute hydrochloric acid gave a white precipitate, which was filtered, dried and recrystallized from ligroin.

Oxyacetic Acids and 4-Diphenylethane-*n*-propylacetic Acid.—A mixture of 26.3 g. (0.1 mole) of 4-diphenylethane-*n*-propylacetonitrile, 120 ml. of methanol and 120 ml. of 40% sodium hydroxide was refluxed until the evolution of ammonia was complete. After cooling and evaporation of solvent, water was added to the residue, which was extracted with ether. The aqueous layer was acidified with hydrochloric acid, cooled, filtered and crystallized from 70% acetic acid, ethanol or cyclohexane; yield 13.6 g. (48%), m.p. 95°.

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.81; H, 7.85. Found: C, 80.21; H, 7.73.

The oxyacetic acids of biphenyl, stilbene and diphenylethane were prepared by this method; see Table IV.

4-Biphenylylethylacetic Acid Ethyl Ester.—Thionyl chloride (11.9 g., 0.1 mole) was added dropwise to 2.40 g. (0.01 mole) of 4-biphenylylethylacetic acid. The mixture was stirred for 1 hour at room temperature and for 1 hour on a steam-bath. After distillation of the thionyl chloride at reduced pressure, 16 ml. of dry ethanol was added to the residue. The mixture was stirred for 1 hour at room temperature and for 2 hours over a steam-bath. Concentration gave an oil which, upon distillation, yielded 1.6 g. (64%) of

4-Biphenylyl-*n*-propylacetamide.—Thionyl chloride (11.9 g., 0.1 mole) was added dropwise to 2.54 g. (0.01 mole) of 4-biphenylyl-*n*-propylacetic acid. The mixture was stirred for 1 hour at room temperature and for 2 hours on a steam-bath. After distillation of the thionyl chloride at reduced pressure, 20 ml. of 15% ammonium hydroxide was added with shaking to the residue and vigorous stirring was continued for 3 hours at room temperature. The precipitate was filtered, washed with water and dried. Recrystallization from 70% acetone gave 2.4 g. (95%) of 4-biphenylyl-*n*-propylacetamide; m.p. 160°.

Anal. Calcd. for $C_{17}H_{19}ON$: N, 5.53. Found: N, 5.50.

4-Stilbenepyruvicacetamide was obtained by essentially the same procedure; m.p. 235°.

Anal. Calcd. for $C_{17}H_{15}O_2N$: N, 5.28. Found: N, 5.41.

2-Phenyl-4-(4′-biphenylal)-5-oxazolone.—A mixture of 3.64 g. (0.02 mole) of 4-biphenylaldehyde, 3.6 g. (0.02 mole) of hippuric acid, 3.2 g. (0.04 mole) of fused sodium acetate and 6.6 g. (0.6 mole) of acetic anhydride was stirred and heated for 4 hours on an oil-bath at 100°. After being cooled and standing overnight at room temperature, the mixture was filtered. The precipitate was washed with water and recrystallized from ethanol to give yellow crystals; yield 6 g. (92%); m.p. 182–183°.

Anal. Calcd. for $C_{22}H_{15}O_2N$: N, 4.30. Found: N, 4.29.

4-Biphenylylpyruvic Acid.—A mixture of 16.2 g. (0.05 [illegible] mole) of the above oxazolone and 1750 ml. of 6% aqueous sodium hydroxide was refluxed until the evolution of ammonia was complete. It was then cooled and filtered. The precipitate was suspended in water, boiled and acidified. The precipitate, which formed upon slow cooling, was crystallized from glacial acetic acid; yield 2 g. (17%); m.p. 220°.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.00; H, 5.03. Found: C, 74.52; H, 5.15.

***β*-4-Biphenylylacrylic Acid (I).**—A mixture of 3.64 g. (0.02 mole) of 4-biphenylaldehyde, 2.3 g. (0.022 mole) of malonic acid, 50 ml. of 95% ethanol and 0.5 ml. of pyridine was refluxed for 6 hours. After cooling the precipitate was filtered, washed with water and recrystallized from 95% ethanol. 4-Biphenylyl-γ-crotonic acid was prepared from the acetaldehyde by the same method. The data are listed in Table V.

4-Biphenylyl-*n*-propionic Acid (II).—4-Biphenylylacrylic acid (2.24 g., 0.01 mole), dissolved in 320 ml. of glacial acetic acid, was hydrogenated at normal pressure with 0.1 g. of a 10% Pd/C catalyst. Filtration followed by vacuum distillation gave a residue which was crystallized from 70% ethanol, see Table V.

4-Biphenylyl-β-hydroxypropionic Acid (III).—A Reformatsky reaction was carried out in the usual way with 3.64 g. (0.02 mole) of 4-biphenylaldehyde, 3.32 g. (0.02 mole) of ethyl bromoacetate, 1.3 g. (0.02 mole) of zinc dust in 50 ml. of benzene. After cooling the mixture was extracted with ether. The aqueous layer was acidified with hydrochloric acid and the resulting precipitate recrystallized from 50% acetic acid. 4-Biphenylyl-γ-ethyl-β-hydroxy-*n*-bu[illegible] same method; see Table V.

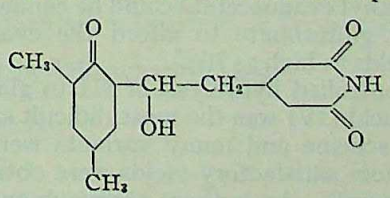
Actidione. I. The Synthesis of the Glutarimide Moiety

BY DONALD D. PHILLIPS,[1] MARIO A. ACITELLI[2] AND JERROLD MEINWALD

RECEIVED FEBRUARY 1, 1957

The synthesis of glutarimide-β-acetaldehyde (V) from acetone-dicarboxylic ester is described. The aldehyde is of interest as a possible intermediate in the total synthesis of actidione, an antifungal antibiotic produced by *Streptomyces griseus*.

The presence of an antifungal antibiotic in culture filtrates from streptomycin-producing strains of *Streptomyces griseus* was first reported in 1946.[3] The empirical formula $C_{27}H_{42}N_2O_7$ was originally assigned to the crystalline antibiotic[4] and the name "actidine" was proposed on the erroneous assumption that the compound was a diketone. The molecular formula was later corrected[5] to $C_{15}H_{23}NO_4$ and further investigations on the antibiotic indicated that it contained only one ketone group.[6] The total structure (I) for the antibiotic was established[7] in 1949, principally on the basis of the hydrolysis products obtained from I and the corresponding β-



I

diketone. To date, however, this assignment has not been verified by total synthesis.

Although the structure assigned to actidione (I) can hardly be in doubt, a total synthesis is of more than academic interest in view of the increasing importance of the antibiotic in plant disease control.[8]

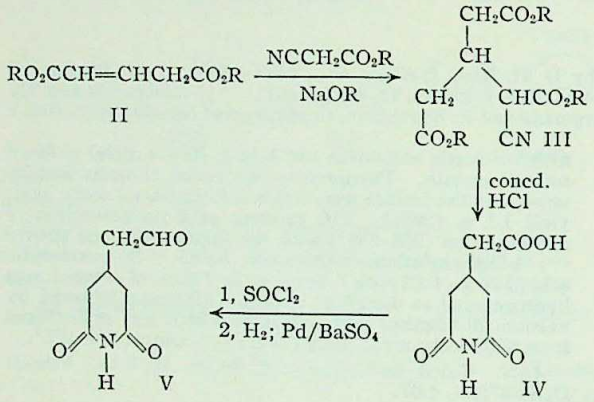
It has seen commercial application in the control of cherry leaf spot[9] and various turf diseases[10] and shows promise as a rodent repellent.[11] Moreover, its ability to prolong the life of leukemic mice[12] and its limited control of sarcoma 180[13] are of more than passing interest in cancer research.

We have approached the problem of total synthesis with the view that actidione (I) might be obtained from an aldol condensation between (+)-2,4-dimethylcyclohexanone and glutarimide-β-acetaldehyde (V). For this reason, we have synthesized the glutarimide moiety (V) and experiments designed to test our hypothesis are in progress.

The pertinent equations for the most satisfactory synthesis of the aldehyde are listed in Chart 1.

CHART 1



In the early stages of the problem, glutaconic ester (II) was prepared from chloroform and malonic ester,[14] but the yields were erratic and the reaction was difficult to control. A far superior method involved the catalytic reduction of acetone-dicarboxylic ester to dimethyl β-hydroxyglutarate which then could be dehydrated to II. This approach was particularly attractive in view of the recently announced commercial availability of dimethyl acetonedicarboxylate.[15] Although the corresponding hydroxy ester was surprisingly inert to a variety of dehydrating agents, good yields of glutaconic ester were obtained in the presence of phosphorus pentoxide. Under scrupulously anhydrous conditions, methyl cyanoacetate could be condensed with dimethyl glutaconate to afford the cyanotriester III in yields as high as 70%.

The controlled hydrolysis of III to glutarimide-β-acetic acid (IV) was the most difficult step in the reaction scheme and many variants were investigated before satisfactory yields were obtained (see Experimental). An indirect approach entailed the complete hydrolysis of III to methanetriacetic acid.

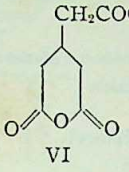
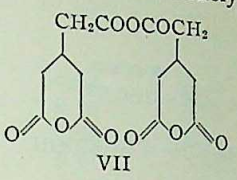
(15) We are grateful to the Chas. Pfizer Co. of Brooklyn, N. Y., for generous samples of this ester.

It was anticipated that the corresponding anhydride VI would yield IV (or its amide) on ammonolysis,



VI



VII

but the only anhydride that could be isolated from methanetriacetic acid was VII and ammonolysis experiments on VII were inconclusive. The Guareschi imide synthesis was equally unsuccessful as no crystalline product could be obtained from the reaction between chloroacetaldehyde and methyl cyanoacetate. Moreover, the recently reported[16] hydrolysis of cyano esters to glutarimides in basic media resulted in the formation of intractable oils when applied to III (R = CH_3 and C_2H_5).

The preparation of the acid chloride from glutarimide-β-acetic acid (IV) presented no difficulties and a beautifully crystalline product (m.p. 129–130°) was obtained readily. When subjected to the conditions of the Rosenmund reduction, this acid chloride afforded good yields of the desired aldehyde, m.p. 122–123°, although it was found necessary to omit completely the catalyst poison often suggested.

Acknowledgment.—The antifungal and antibiotic properties of glutarimide β-acetaldehyde (V) and acid (IV) are being tested by the Upjohn Laboratories, Kalamazoo, Mich., through the courtesy of Dr. Alan J. Lemin. We are also indebted to the Upjohn Laboratories for generous samples of actidione.

Experimental[17]

Trimethyl α-Cyanomethanetriacetate (III, R = CH_3).[14]—To a flame-dried flask was added 50 ml. of methanol and 79.2 g. (0.8 mole) of methyl cyanoacetate (both of which had been dried by distillation from magnesium methoxide) followed by 63.2 g. (0.4 mole) of freshly distilled dimethyl glutaconate.[18] To this mixture was added 18 drops of freshly prepared sodium methoxide solution (from 0.9 g. of sodium and 30 ml. of absolute methanol). The reaction mixture, adequately protected from moisture by phosphorus pentoxide tubes, was heated under reflux for 12 hours with the addition of 18 drops of sodium methoxide solution every two hours to ensure alkalinity.

The reaction was allowed to stand overnight at room temperature after which time it was quenched by the addition of a few drops of acetic acid. Solvent methanol was removed at the water-pump and the residue was fractionally distilled to give 62 g. (60%) of the cyano ester as a colorless, viscous oil, b.p. 162–165° (2.5 mm.), $n^{25}D$ 1.4521.

Anal. Calcd. for $C_{11}H_{15}O_6N$: N, 5.44. Found: N, 5.50.

Complete Hydrolysis of III.—A stirred mixture of 5.5 g. (0.02 mole) of trimethyl α-cyanomethanetriacetate (III) and 50 ml. of concentrated hydrochloric acid was heated for three hours on the steam-bath. The volatile components were removed by distillation *in vacuo* and the residue was

Digitized by Arya Samaj Foundation Chennai and eGangotri

taken up in 50 ml. of dry acetone. The ammonium chloride was removed by filtration and the acetone was evaporated to an oil. This oil was dissolved in ether and, on slow evaporation of the solvent, 1.9 g. (47%) of methanetriacetic acid precipitated, m.p. 115–118°. This material could not be recrystallized without large losses and was used directly in the next step.

(Glutaric Anhydride β-Acetic)-anhyride (VII).—Two grams of (0.02 mole) of acetic anhydride was added to 1.9 g. (0.01 mole) of methanetriacetic acid and the mixture was heated on the steam-bath for 15 minutes. Excess anhydride and acetic acid were removed by distillation *in vacuo* and the dark, residual oil was triturated with acetone. This induced the crystallization of needles that were recrystallized from acetone to give 0.6 g. of VII as colorless needles, m.p. 150–151°; λ_{max}^{KBr} 5.55, 5.60 and 5.70 μ.

Anal. Calcd. for $C_{14}H_{14}O_9$: C, 51.53; H, 4.32; neut. equiv., 54.4. Found: C, 51.45; H, 4.33; neut. equiv., 55.9.

Glutarimide-β-acetic Acid (IV).—A mixture of 30 g. (0.117 mole) of cyano ester III in 100 ml. of concentrated hydrochloric acid was stirred for one hour at room temperature. The reaction mixture was poured into 100 ml. of water and the resulting solution was evaporated on the steam-bath at a reduced pressure of approximately 50 mm. The yellow residual oil was taken up in 200 ml. of dry acetone leaving behind a small amount (*ca.* 10%) of ammonium chloride.

On concentration of the acetone to about 20 ml., colorless crystals were deposited. These were removed by filtration to yield 10 g. (50%) of the glutarimide, m.p. 168–170°. The analytical sample crystallized from acetone–hexane as colorless crystals, m.p. 172–173°, λ_{max}^{KBr} 5.82 and 6.00 μ.

Anal. Calcd. for $C_7H_9O_4N$: C, 49.12; H, 5.30; N, 8.18. Found: C, 49.15; H, 5.59; N, 7.89.

Yields in this reaction were subject to considerable variation because the hydrolysis conditions were difficult to duplicate, but usually they were in the range of 26–55%.

Glutarimide-β-acetyl Chloride. a. From the Sodium Salt of IV.—A solution containing 1.1 g. (0.008 mole) of glutarimide-β-acetic acid (IV) in 25 ml. of 95% alcohol was titrated to phenolphthalein with 1.0 *N* sodium hydroxide. The solvent was removed *in vacuo* and to the colorless solid was added 4.8 g. of thionyl chloride. The resulting slurry was heated on the steam-bath for 15 minutes and the excess thionyl chloride was removed by distillation under reduced pressure. The last traces were taken off by codistillation with dry benzene.

The dark red residue was taken up in warm benzene, filtered and the filtrate was concentrated to about 15 ml. On cooling there was deposited 0.5 g. (33%) of the acid chloride as colorless needles, m.p. 129–132°. A purified sample crystallized from acetone–hexane as colorless needles, m.p. 129–130°, λ_{max}^{KBr} 5.50 and 5.95 μ.

Anal. Calcd. for $C_7H_8O_3NCl$: C, 44.34; H, 4.25; Cl, 18.70. Found: C, 44.56; H, 4.39; Cl, 18.64.

The residue that did not dissolve in benzene was shown by infrared analysis to be a mixture of the acid and acid chloride. This mixture could be recycled so that the actual yield of acid chloride was probably higher than 33%.

b. From the Free Acid IV.—A slurry of 8.6 g. (0.05 mole) of the acid and 30 g. of thionyl chloride was heated under reflux for 30 minutes. The deep orange solution was cooled and the crystalline solid that precipitated was filtered rapidly, washed with dry acetone and stored immediately in a desiccator. The yield of impure acid chloride by this procedure was 6.3 g. (66%), m.p. 125–130°.

On some occasions the excess thionyl chloride was distilled under reduced pressure and the last traces were removed by codistillation with benzene. The orange residue then was triturated with cold acetone and dried. Yields of acid chloride, m.p. 126–131°, by this method were generally in the range of 50–55%. Repeated crystallizations of this impure material were seldom profitable and once-recrystallized acid chloride usually was employed in the Rosenmund reduction.

Glutarimide-β-acetaldehyde (V).—To a flask equipped with a gas inlet tube, stirrer and condenser were added 150 ml. of dry toluene, 3.4 g. (0.018 mole) of once-recrystallized glutarimide-β-acetyl chloride and 0.3 g. of 10% palladium-on-barium sulfate catalyst. The mixture was heated to reflux and hydrogen was passed through the system. The hydrochloric acid formed was titrated with standard alkali.

After three hours, 82% of the theoretical amount of acid had been titrated. The reaction was stopped and the hot toluene solution was filtered free of catalyst. On cooling, there was deposited long colorless needles of the aldehyde. These were removed and a second crop was obtained by concentrating the filtrate. In total, there was obtained 1.8 g. (64%) of the aldehyde, m.p. 121–123°. The analytical sample crystallized as colorless needles from acetone–hexane, m.p. 122–123°; λ_{max}^{KBr} 3.19, 3.73, 5.82 and 5.95 μ.

Anal. Calcd. for $C_7H_9O_3N$: C, 54.19; H, 5.84; N, 9.03. Found: C, 54.23; H, 5.47; N, 8.93.

The semicarbazone crystallized from dilute alcohol as colorless needles, m.p. 230–231°.

Anal. Calcd. for $C_8H_{12}O_3N_4$: N, 26.40. Found: N, 26.53.

When the catalyst was poisoned with quinoline and sulfur as suggested[19] in the literature, no aldehyde could be obtained in this reduction.

Terpenes. VII.[1] The Structures of the Dieucarvelones

BY G. BÜCHI AND W. S. SAARI

RECEIVED JANUARY 21, 1957

The structures of the isomeric dieucarvelones obtained earlier by Wallach have been reinvestigated. β-Dieucarvelone was shown to be a mixture of the α- and ε-isomers. The γ- and ϑ-isomers described by this author never could be isolated but two new isomers, ε and ζ, were found. Two substances reported by Rupe from the reaction of eucarvone with magnesium and methyl iodide were shown to be identical with α- and β-dieucarvelone. Chemical and spectroscopic findings are in agreement with structure III for these isomers. The conjugate bimolecular reduction of eucarvone is discussed.

In 1899, and again in 1914, Wallach[2] reported that the reduction of eucarvone (I), with zinc in basic solution gave a series of compounds, $C_{20}H_{30}O_2$, which he named the dieucarvelones. Wallach found that these isomers could be separated by recrystallization from an acetic acid–water mixture into an α-isomer, m.p. 177°; β-isomer, m.p. 143°; γ-isomer, m.p. 128°; and a ϑ-isomer, m.p. 111°.

Because the α- and β-isomers only slowly decolorized a solution of bromine in acetic acid *with* liberation of hydrobromic acid and because they were not

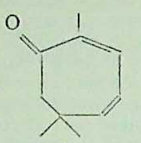
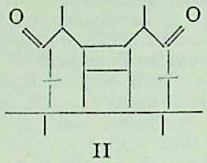
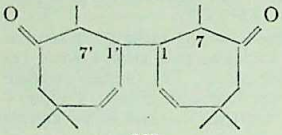
reducible over a palladium catalyst, he concluded that these compounds were saturated and proposed structure II for them. The γ-isomer, on the other



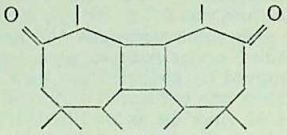
I



II



III



IV

hand, rapidly decolorized a solution of bromine in acetic acid with no liberation of hydrobromic acid. The unsaturated character of this isomer was furthermore ascertained by hydrogenation to a tetrahydro derivative over a palladium catalyst and structure III was proposed for the γ-isomer. The δ-isomer was isolated in such small yield that characterization was not possible.

In 1911, Rupe and Kerkovius[3] found that when eucarvone (I) was allowed to react with magnesium and methyl iodide two crystalline compounds for which they proposed structure IV ($C_{22}H_{36}O_2$) could be isolated in a total yield of 14%. They apparently did not realize that the melting points of their compounds and the corresponding oximes were identical with those of Wallach's α- and β-dieucarvelones.

The formation of both II and IV are mechanistically unsound in terms of present day theories and we therefore decided to reinvestigate these reactions. In this paper we describe work which shows that the dieucarvelones are most probably represented by III.

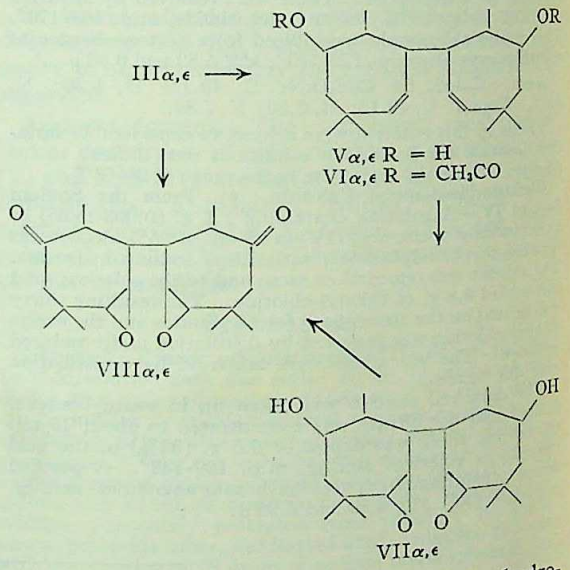
The α- and β-dieucarvelones were prepared easily by reduction of eucarvone with zinc dust in basic solution. Wallach's γ- and δ-isomers could never be isolated despite repeated recrystallization and chromatography of the crude reaction products, but two new isomers, ϵ- and ζ-dieucarvelone, were detected. Although the melting point of the ζ-isomer, 131°, is close to that of Wallach's γ-isomer, m.p. 128°, the two seem to differ markedly in their reactions with bromine in acetic acid solution.

When β-dieucarvelone, with a constant melting point of 142–144°, was chromatographed on active alumina, the α- and ϵ-isomers were obtained in yields of 23 and 77%, respectively. Both of these isomers were found to be stable to chromatography. Recombination of the α- and ϵ-isomers gave a mixture which was identical in all respects with the original β-dieucarvelone. Hence Wallach's β-dieucarvelone is not a pure compound but rather a mixture of the α- and ϵ-isomers. Confirmation was forthcoming from reduction of β-dieucarvelone with lithium aluminum hydride which yielded the α-glycol Vα in 23% yield and the ϵ-glycol Vϵ in 75% yield.

Repetition of Rupe and Kerkovius'[3] directions for the reaction of eucarvone with magnesium and methyl iodide gave two crystalline products in a total yield of 1% which appeared to be the compounds reported by them. These products were shown to be identical with α- and β-dieucarvelone by mixed melting point determinations.

Although none of the dieucarvelone isomers isolated decolorized a 5% solution of bromine in chloroform and all were saturated to tetranitromethane, we believe that they are in fact unsaturated since they all showed maxima in the infrared region at 3010, 1640 and 750 cm.$^{-1}$, characteristic of *cis*-disubstituted double bonds. Also the ultraviolet spectra of all the isomers exhibited strong end absorption at 210 mμ indicating unsaturation.

In order to further prove the unsaturated character of the dieucarvelone isomers, the α-glycol Vα obtained by a lithium aluminum hydride reduction of α-dieucarvelone (IIIα), was oxidized with perbenzoic acid. After seven days the α-glycol showed an uptake of peracid corresponding to 2.00 double bonds. Similarly the ϵ-glycol Vϵ derived from ϵ-dieucarvelone (IIIϵ) titrated for 1.96 double bonds after one day.



Furthermore we now have been able to hydrogenate the diacetate VIα, prepared from the α-glycol Vα, over Adams platinum catalyst in acetic acid solution to a tetrahydro derivative. The reduction is exceedingly slow and the fact that only this highly active catalyst is effective explains the negative results reported earlier by Wallach.[2] These findings as well as the inertness of α-dieucarvelone (IIIα) toward potassium permanganate (no reaction even in boiling pyridine) are only in agreement with the presence of two highly hindered double bonds in the molecule. It is significant that the three bands associated with the double bonds in the infrared spectra of the dieucarvelones are all present in every unsaturated derivative and disappear when any of the isomers, or their derivatives, are hydrogenated or converted to the epoxides. Contrary to Wallach's suggestion the dieucarvelones then must be bicyclic rather than tetracyclic.

Since α- and β-dieucarvelone can be recovered in

(3) H. Rupe and W. Kerkovius, *Ber.*, **44**, 2702 (1911). The analyses reported are also in agreement with $C_{11}H_{18}O$.

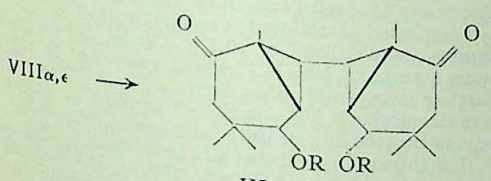
good yield from strenuous acid treatment, it is unlikely that they contain any three- or four-membered rings. This postulate is confirmed by the lack of significant absorption in the infrared in the regions usually associated with these groupings. Selenium dehydrogenation of the α-glycol Vα gave no aromatic compounds which could be detected spectroscopically and it is therefore unlikely that a six-membered ring is present in α-dieucarvelone. It is at any rate difficult to envision a change in the carbon skeleton of eucarvone under the conditions used in the preparation of III and structures containing two seven-membered rings seem much more plausible.

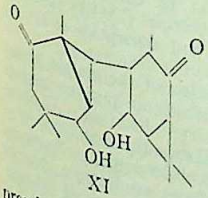
In agreement with structure III, α,α-dieucarvelone formed a hexadeutero derivative upon equilibration with alkaline deuterium oxide.

Oxidation of the α-diepoxyglycol VIIα with chromic acid in pyridine afforded α-diepoxydieucarvelone (VIIIα) which also could be obtained in good yield by epoxidation of α-dieucarvelone with trifluoroperacetic acid in the presence of a dibasic sodium hydrogenphosphate buffer. Similarly, ϵ-dieucarvelone (IIIϵ) yielded ϵ-diepoxydieucarvelone (VIIIϵ).

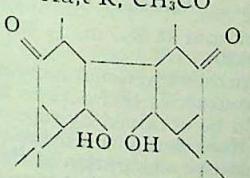
Treatment of α-diepoxydieucarvelone (VIIIα) with warm aqueous potassium hydroxide solution gave an isomeric compound which contained hydroxyl and carbonyl absorption in the infrared spectrum, a maximum in the ultraviolet spectrum at 216 mμ (ϵ 14,000) characteristic of cyclopropyl ketones,[4] was saturated to tetranitromethane and formed a diacetate (Xα). Only three structures (IX, XI and XII) fit these data. Since the dihydroxydiketone in question exchanged 3.76 hydrogens (after reconversion of –O–D to –O–H) upon equilibration with alkali in deuterium oxide, ex-



IXα,ϵ R, H
Xα,ϵ R, CH_3CO



XI

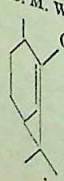


XII

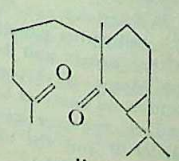
pression IXα must be the correct one.[5]

(4) R. H. Eastman and S. K. Freeman, THIS JOURNAL, **77**, 6642 (1955), and earlier references cited.

(5) Structures XI and XII have only three and two exchangeable hydrogens, respectively, because enols like i represent impossibly strained molecules. Similarly ii exchanged only five hydrogens (G. Büchi and D. M. White, THIS JOURNAL, **79**, in press (1957).



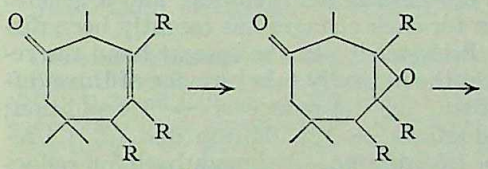
i



ii

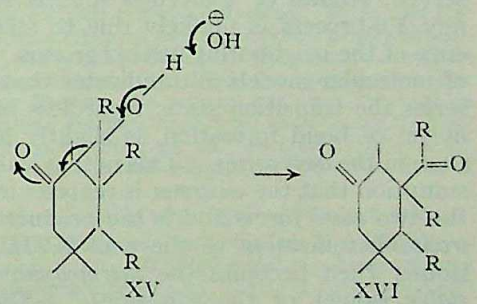
An analogous dihydroxydiketone (IXϵ) which exchanged 3.88 H on deuteration was prepared by the same sequence from ϵ-dieucarvelone (IIIϵ). The two compounds were clearly different.

The conversion of VIII to IX involves a transannular displacement reaction and is similar to the one observed by Barton and Lindsey[6] with an epoxycyclononanone derived from caryophyllene. Conversions of cycloheptanes to bicyclo[4,1,0]heptanes seem to occur generally with great ease and other reactions of this type recently have been discovered by Corey, *et al.*[7] The presence of a cyclopropane ring in IXα and IXϵ excludes partial structures XIII for these two dieucarvelones because the corresponding dihydroxydiketones would have to be represented by XV. Compounds of this type are known to be unstable to base and to undergo rapid retroaldol reactions[8] (*cf.* XV → XVI) a behavior not observed with IX. Furthermore the β,γ-unsaturated ketones XIII would be expected to rearrange at least partially to the corresponding α,β-unsaturated ketones in the presence of acids or bases but no such transformations have been observed in the present investigation.



XIII, R = second ring

XIV



XV XVI

A total of ten different isomers, namely, four *d,l*-pairs and two *meso* forms are possible from the parent structure III. Because α-dieucarvelone (IIIα) was not isomerized to any other isomer upon treatment with acid or base the methyl groups on C_7 and C_7' are already in the most stable configurations. The ϵ-isomer IIIϵ, on the other hand, was converted to an equilibrium mixture of the ϵ- and ζ-isomers on base-catalyzed isomerization. These facts clearly demonstrate that IIIα and IIIϵ cannot belong to the same (C_1, C_1', *syn* or *anti*) series and must have different configurations at C_1'. In agreement with this situation the α- and ϵ-isomers gave two different dihydroxydiketones (IXα and IXϵ).

Reduction of eucarvone (I) with zinc dust in the presence of ammonium chloride at 15° yielded only ϵ-dieucarvelone; under more strenuous conditions, however, a mixture of the ϵ- and α-isomers was

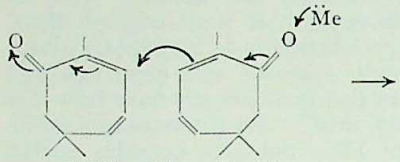
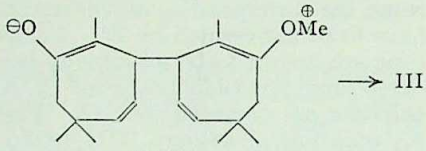
produced. This implies that the ϵ-isomer is formed through the transition state of lowest activation energy. We are inclined to believe that the formation of these "dimers" occurs *via* a concerted process involving reduction and Michael addition (*cf.* XVII → XVIII → III).



XVII Me = Zn, Mg



XVIII

There is ample precedent for such conjugate bimolecular reductions of α,β-unsaturated aldehydes[9] as well as α,β-unsaturated ketones[10] and a general mechanism for such changes has recently been discussed by Brewster.[11] In the case at hand the reaction could theoretically take any one of three different paths: (a) 1,4-reduction → 1,4-addition; (b) 1,6-reductions → 1,6-addition and (c) 1,4-reduction → 1,6-addition. Although both 1,6-reductions[12] and 1,6-Michael additions[13] have been observed, studies of molecular models suggest that any 1,6-process is unlikely due to steric interference of the neighboring methyl groups. Inspection of molecular models also indicates that in the *syn*-series the transition state, regardless of the mechanism of bond formation, is slightly less strained than in the *anti* series. This notion leads to the assumption that the ϵ-isomer is represented by one of the two *meso* forms and is the product of *rate controlled* ketonization of the enol XVIII.[14] The ζ-isomer then becomes the *thermodynamically most stable* isomer of the *syn*-series. α-Dieucarvelone thus is the most stable isomer in the *anti*-series. It must be pointed out though that an unambiguous assignment of configuration is by no means possible mainly because very little is known about the conformations of cycloheptenes. The configurational problem at hand is identical with the one of the isomeric perhydrodiphenic acids which has been solved so brilliantly by Linstead and Doering.[15] We have not yet had the courage to embark on a similar project to determine the configurations for the dieucarvelones.

Acknowledgment.—We are greatly indebted to Firmenich and Co., Geneva, for financial assistance and to the National Institutes of Health for a fellowship to W. S. S. Further, we should like to thank Mr. D. Shew for the preparation of dieucarvelone.

Experimental[16]

Eucarvone (I).—Eucarvone was prepared from carvone according to the directions of Corey and Burke[7] and was obtained as a yellow oil, b.p. 73–76° (5.0 mm.), $n^{25}D$ 1.5066 (lit.[7] $n^{21}D$ 1.5080), in a 45% yield.

Dieucarvelone Isomers.[2]—A solution of 68 g. (0.453 mole) of eucarvone in 700 ml. of 95% ethanol was added to a solution of 57 g. of potassium hydroxide in 250 ml. of water. After adding 57 g. (0.872 mole) of zinc dust, the mixture was heated under reflux for 3 hours with vigorous stirring and then allowed to stand at room temperature for 3.25 hours. One liter of ice-water was added and the precipitate filtered with suction. An additional liter of water was added to the filtrate and the solution extracted with ethyl ether which was then dried over anhydrous magnesium sulfate. After filtering, the solvents were removed *in vacuo* to give 2.6 g. (3.8%) of a yellow oil which could not be crystallized.

The filtered solids were extracted with chloroform and the solution dried over anhydrous sodium sulfate. After filtering, the solvent was removed *in vacuo* and the oily residue recrystallized from ethanol to give a total of 8.1 g. (12%) of α-dieucarvelone with a m.p. of 177–178° which was not raised upon further recrystallization. The sample did not decolorize a 5% solution of bromine in chloroform and was saturated to tetranitromethane in chloroform.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00; mol. wt., 302. Found: C, 79.42; H, 9.97; mol. wt., 300.

The infrared spectrum (KBr) contained maxima at 3008(w), 2955(s), 1699(s), 1640(w) and 752(s) cm.$^{-1}$. In chloroform, the carbonyl absorption was at 1692 cm.$^{-1}$.

The ultraviolet spectrum (EtOH) showed a maximum at 285 mμ (ϵ 115) with end absorption at 211 mμ (ϵ 1,700).

Continued fractional recrystallization of the mother liquors gave a total of 19.1 g. (28.3%) of β-dieucarvelone with a m.p. of 139–142° which was raised to 142–144° by further recrystallization from ethanol. The sample did not decolorize a 5% solution of bromine in chloroform and was saturated to tetranitromethane in chloroform.

The infrared spectrum (KBr) contained maxima at 2960(s) with a shoulder at 3020(w), 1691(s), 1647(w) and 752(m) cm.$^{-1}$. The carbonyl absorption in chloroform was at 1692 cm.$^{-1}$. The ultraviolet spectrum (EtOH) showed a maximum at 285 mμ (ϵ 68) with end absorption at 211 mμ (ϵ 2050).

Further fractional recrystallization of the mother liquors gave a series of fractions from which no pure compounds could be obtained by repeated recrystallization. All of the fractions were saturated to tetranitromethane and showed no significant absorption in the ultraviolet region. Fractional recrystallization of this mixture from an acetic acid–water mixture followed by repeated recrystallization of the fractions from ethanol gave no pure compounds. A total of 21.4 g. (31.5%) of this isomer mixture was obtained. Removal of the solvent *in vacuo* gave 12 g. (18%) of a yellow oil which would not crystallize even after chromatography on alumina, activity I.

Isolation of ϵ- and ζ-Dieucarvelone from the Zinc and Base Reduction of Eucarvone.—One gram of the dieucarvelone isomer mixture (m.p. 112–125°) mentioned above was

chromatographed in the usual manner on 100 g. of Merck acid-washed alumina, activity I. Elution with an 80% benzene–petroleum ether mixture gave a series of fractions one of which upon repeated recrystallization from ethanol gave γ-dieucarvelone, m.p. 131–132°, in a low yield. The infrared spectrum of this sample was identical with that of γ-dieucarvelone obtained by base isomerization of ϵ-dieucarvelone and there was no mixed melting point depression.

Several fractions were eluted with benzene which when recrystallized from ethanol gave α-dieucarvelone with a m.p. of 177–178°. No depression was observed upon mixed melting point with an authentic sample.

Elution with a 2–5% ethyl ether–benzene mixture gave a series of fractions which when recrystallized from ethanol gave ϵ-dieucarvelone with a m.p. of 151–152°. The infrared spectrum of this sample was identical with that of ϵ-dieucarvelone obtained from the chromatography of β-dieucarvelone and there was no mixed melting point depression.

Rupe and Kerkovius Grignard Reaction of Eucarvone (I).—To 1.1 g. (0.045 mole) of magnesium and a few drops of methyl iodide was added dropwise with stirring a solution of 6.0 g. (0.040 mole) of eucarvone and 6.4 g. (0.045 mole) of methyl iodide over a period of 2 hours. After the solution had been stirred at room temperature for 0.5 hour more, it was poured onto a mixture of 100 ml. of 10% sulfuric acid and ice. The reaction was extracted with ethyl ether which was then washed with water and dried over anhydrous magnesium sulfate. After filtering, the solvent was removed *in vacuo* and the oily residue chromatographed on 90 g. of alumina, activity I. Several of the fractions which were eluted with a 80% benzene–hexane mixture partially crystallized after standing overnight. These were combined and recrystallized from ethanol to give 0.04 g. (0.66%) of α-dieucarvelone with a m.p. of 178–179°. No depression was observed upon a mixed melting point with an authentic sample.

Later fractions of the recrystallization gave 0.02 g. (0.33%) of β-dieucarvelone with a m.p. of 142–143°. No depression was observed upon mixed melting point with an authentic sample.

Lithium Aluminum Hydride Reduction of α-Dieucarvelone (IIIα).—A solution of 1.7 g. (0.00563 mole) of α-dieucarvelone in 50 ml. of tetrahydrofuran was added over a period of 10 minutes to a slurry of 0.43 g. (0.0112 mole) of lithium aluminum hydride in 30 ml. of tetrahydrofuran with stirring. The mixture was then heated under reflux for 6 hours, cooled and the excess hydride decomposed with 15 ml. of ethyl acetate followed by 10 ml. of water. The reaction mixture was filtered and the residue washed with methylene chloride. The solvents were removed *in vacuo* and the crude product recrystallized from ethanol to give 0.775 g. (45%) of the α-glycol Vα with a m.p. of 246–248°. An analytical sample had a melting point of 249–249.4°. The infrared spectrum (KBr) contained bands at 3268(s), 2994(w), 2890(s), 1618(w) and 750(s) cm.$^{-1}$.

Anal. Calcd. for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18. Found: C, 78.07; H, 11.31.

A perbenzoic acid titration of the α-glycol Vα proceeded as follows: after 1 day, it titrated for 0.94 double bonds 2 days, 1.45; 3 days, 1.75; 4 days, 1.94; 7 days, 2.00 double bonds.

The α-Diepoxyglycol VIIα.—A solution of 0.1 g. (0.000328 mole) of the α-glycol Vα in 20 ml. of chloroform containing 0.178 g. (0.077 mole) of perbenzoic acid was allowed to stand at room temperature for seven days. The chloroform solution was then washed with a saturated ferrous sulfate solution, water, a saturated sodium bicarbonate solution, water and then dried over anhydrous sodium sulfate. After filtering, the solvent was removed *in vacuo* and the oily residue recrystallized from methanol to give 0.08 g. (73%) of the diepoxide with a m.p. of 172–174° dec. Recrystallization from methanol gave an analytical sample with a m.p. of 175.4–176.0° dec. which was saturated to bromine and tetranitromethane in chloroform. The infrared spectrum (KBr) contained maxima at 3500 to 3200(s), 2958(s), 1255(m), 1235(m), 943(m), 933(m), 890(m), 860(m), 820(m), 795(w) and 775(m) cm.$^{-1}$, the bands at 2994, 1618 and 750 cm.$^{-1}$ which were present in the spectrum of the α-glycol Vα having disappeared.

Anal. Calcd. for $C_{20}H_{34}O_4$: C, 70.97; H, 10.13. Found: C, 71.19; H, 10.02.

The α-Diacetate VIα.—A solution of 0.375 g. (0.00123 mole) of the α-glycol Vα in 20 ml. of pyridine and 5 ml. (0.005 mole) of acetic anhydride was allowed to stand at room temperature overnight. The solvents were removed *in vacuo* and the residue chromatographed on 20 g. of acid-washed alumina, activity I to II. Elution with a 50% benzene–petroleum ether mixture gave a white solid which was recrystallized from methanol to give 0.356 g. (70%) of the α-diacetate with a m.p. of 199–201°. Recrystallization from methanol gave an analytical sample with a m.p. of 202.4–203.0°. The infrared spectrum (KBr) contained maxima at 2933(w), 2857(s), 1718(s), 1634(w), 1232(s) and 755(m) cm.$^{-1}$.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81. Found: C, 73.58; H, 9.74.

Reduction of the α-Diacetate VIα.—When 0.051 g. (0.000135 mole) of the α-diacetate was reduced with hydrogen in 8 ml. of glacial acetic acid, using 5 mg. of platinum oxide as a catalyst, the reduction was complete after 8 hours with the uptake of hydrogen equivalent to 2.07 double bonds. Filtration, evaporation of the solvent and crystallization of the residue from methanol yielded 0.030 g. (60%) of the α-tetrahydrodiacetate with a m.p. of 197.8–198.5°. The product was saturated to bromine and tetranitromethane in chloroform. A strong depression was observed upon mixed melting point with the α-diacetate VIα. The infrared spectrum (KBr) contained maxima at 2940(s), 1728(s) and 1240(s) cm.$^{-1}$, the bands at 2933, 1634 and 755 cm.$^{-1}$ present in the spectrum of the α-diacetate having disappeared.

Anal. Calcd. for $C_{24}H_{42}O_4$: C, 73.05; H, 10.73. Found: C, 72.75; H, 10.56.

Deuterium Exchange of α-Dieucarvelone.—A solution of 0.100 g. (0.00032 mole) of α-dieucarvelone in 4 ml. of 95% EtOD–D_2O and 0.05 ml. of 20% NaOD–D_2O was heated under reflux in an atmosphere of nitrogen for 15 minutes. After cooling, the solvents were removed *in vacuo*. Four ml. of a 95% EtOD–D_2O mixture and 0.05 ml. of deuterium oxide were added to the residue and the solution was heated under reflux in an atmosphere of nitrogen for 15 minutes, cooled and the solvents removed *in vacuo*. After this last exchange had been repeated two more times, deuterium oxide was added to the solid residue and the mixture extracted with ethyl ether which was then dried over anhydrous sodium sulfate. After filtering, the solvent was then removed *in vacuo*, the residue recrystallized from a 95% EtOD–D_2O mixture and then sublimed at 120° (0.1 mm.) to give 51 mg. (51%) of the deuterated α-dieucarvelone with a m.p. of 174–174.5°.

Anal. Calcd. for $C_{20}H_{24}D_6O_2$: D, 20.0. Found: D, 20.2.

Attempted Acid-catalyzed Isomerization of α-Dieucarvelone.—A solution of 0.5 g. (0.00166 mole) of α-dieucarvelone in 35 ml. of absolute ethanol and 10 ml. of 20% (vol.) sulfuric acid was heated under reflux for 5 hours. Ice-water was added to the solution and the product extracted with ether after saturating with sodium chloride. The ether solution was dried over anhydrous magnesium sulfate, filtered free from drying agent and the solvent removed *in vacuo*. The residue was recrystallized from ethanol and gave 0.32 g. (64%) of α-dieucarvelone with a m.p. of 177.5–178°. No depression was observed upon mixed melting point with an authentic sample.

Attempted Acid-catalyzed Isomerization of β-Dieucarvelone.—An identical experiment carried out with the β-isomer led only to recovered starting material (74%).

Oxidation of the α-Diepoxyglycol VIIα.—To a solution of 0.040 g. (0.000118 mole) of the α-diepoxyglycol in 5 ml. of pyridine was added 0.070 g. (0.00070 mole) of chromium trioxide. After the mixture had remained at room temperature for 2 days, water was added and the ketone extracted with chloroform. After drying over anhydrous sodium sulfate, the solution was filtered and the solvent removed *in vacuo* to give a dark brown solid. Recrystallization from a chloroform–methanol mixture gave 0.027 g. (69%) of crude α-diepoxydieucarvelone (VIIIα) with a m.p. of 285–290° dec. Further recrystallization raised the melting point to 295–296° dec. The infrared spectrum was identical with that of α-diepoxydieucarvelone obtained from epoxidation of α-dieucarvelone and there was no mixed melting point depression.

α-Diepoxydieucarvelone (VIIIα).—To 0.15 ml. (0.0053 mole) of 90% hydrogen peroxide in 1 ml. of methylene chloride was added slowly 0.9 ml. (0.0063 mole) of trifluoro-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

acetic anhydride. The mixture was kept in an ice-bath and allowed to remain cool until 5 minutes after the addition of the anhydride was complete. This solution was then added dropwise with stirring to a solution of 0.5 g. (0.00166 mole) of α-dieucarvelone in 10 ml. of methylene chloride with 3 g. of dibasic sodium hydrogen phosphate present as a buffer. The solution warmed to reflux temperature during the addition and was then allowed to stand at room temperature for 15 hours with stirring. The solution was filtered, washed successively with a saturated solution of ferrous sulfate, water, a saturated sodium bicarbonate solution, water and then dried over anhydrous magnesium sulfate. After filtering, the solvent was removed *in vacuo* and the residue recrystallized from a chloroform–ethanol mixture to give 0.3 g. (52%) of α-diepoxydieucarvelone with a m.p. of 294–296° dec. Recrystallization from chloroform gave an analytical sample with a m.p. of 296.5–298.5° dec. which did not decolorize a 5% solution of bromine in chloroform and was saturated to tetranitromethane. The infrared spectrum (KBr) contained maxima at 2960(s), 1690(s), 1405(w), 1290(m), 1265(m), 1245(m), 1200(m), 945(m), 915(m), 890(w), 840(s), 815(s), 785(w) and 775(m) cm.$^{-1}$, the bands at 3012, 1639 and 750 cm.$^{-1}$ present in the infrared spectrum of α-dieucarvelone having disappeared.

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04. Found: C, 71.58; H, 9.14.

ε-Diepoxydieucarvelone (VIIIε).—This compound was prepared in 63% yield by the method described for the α-isomer. Recrystallization from ethanol gave an analytical sample with a m.p. of 176.5–177.5° which was saturated to bromine and tetranitromethane in chloroform. A strong depression was observed upon mixed melting point with α-diepoxydieucarvelone. The infrared spectrum (KBr) contained maxima at 2950(s), 1694(s), 1296(m), 1286(m), 1277(m), 1240(w), 1195(s), 940(m), 924(w), 902(w). 845(m), 820(m) and 809(m) cm.$^{-1}$, the bands at 3012, 1639 and 750 cm.$^{-1}$ present in the infrared spectrum of ε-dieucarvelone having disappeared. In chloroform solution the carbonyl absorption was at 1684 cm.$^{-1}$.

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.38; H, 9.04; mol. wt., 334. Found: C, 71.51, 71.63; H, 8.94, 9.09; mol. wt., 349.

Base Isomerization of α-Diepoxydieucarvelone (VIIIα).—A mixture of 0.33 g. (0.00099 mole) of α-diepoxydieucarvelone (VIIIα), 25 ml. of ethanol and 15 ml. of a 5% potassium hydroxide solution was heated under reflux with stirring. After 15 minutes solution was complete. The reaction mixture was then extracted with chloroform which was dried over anhydrous sodium sulfate. After filtering, the solvent was removed *in vacuo* and the residue recrystallized from chloroform to give 0.245 g. (74%) of the α-dihydroxydiketone IXα with a m.p. of 263–265°. Further recrystallization from chloroform gave an analytical sample with a m. p. of 265–266° which was saturated to tetranitromethane in chloroform and did not decolorize a 5% solution of bromine in chloroform.

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04. Found: C, 71.58; H, 8.82.

The infrared spectrum (KBr) contained maxima at 2540(s and broad), 2945(s), 1660(s and broad), 1430(m) and 1012 (m) cm.$^{-1}$. The ultraviolet spectrum (EtOH) showed maxima at 216 mμ (ε 14,000) and 282 mμ (ε 328).

The diacetate was prepared in the usual manner with acetic anhydride in pyridine. Recrystallization of the crude product from methanol gave an analytical sample with a m.p. of 275.5–277°. The infrared spectrum ($CHCl_3$) contained maxima at 2960(m), 1728(s), 1686(s), 1240 to 1210(s) and 1015(m) cm.$^{-1}$.

Anal. Calcd. for $C_{24}H_{34}O_6$: C, 68.86; H, 8.19. Found: C, 68.54; H, 8.17.

Deuterium Exchange of the α-Dihydroxydiketone (IXα).—A solution of 0.060 g. (0.00018 mole) of IXα, in 4 ml. of 95% EtOD–D_2O and 0.05 ml. of 20% NaOD–D_2O was heated under reflux in an atmosphere of nitrogen for 15 minutes. After cooling, the solvents were removed *in vacuo*. Four ml. of a 95% EtOD–D_2O mixture and 0.05 ml. of deuterium oxide were added to the residue and the solution was heated under reflux in an atmosphere of nitrogen for 15 minutes, cooled and the solvents removed *in vacuo*. After this last exchange had been repeated two more times, deuterium oxide was added and the solid recovered by suction and washed with 4 ml. of deuterium oxide. The residue was then dissolved in tetrahydrofuran and dried over anhydrous magnesium sulfate. After filtering, the solvent was removed *in vacuo* and the residue dissolved in methanol to exchange the hydroxyl deuteriums. The methanol was removed *in vacuo* and the crude product sublimed at 150° (0.1 mm.) to give 0.030 g. (50%) of the deuterated α-dihydroxydiketone with a m.p. of 262–263.5°. The infrared spectrum of the deuterated IXα showed no absorption in the –O–D region.

Anal. Calcd. for $C_{20}H_{26}D_4O_4$: D, 13.33. Found: D, 12.45.

Base Isomerization of ε-Diepoxydieucarvelone (VIIIε).—A mixture of 0.35 g. (0.00105 mole) of VIIIε and 40 ml. of a 5% potassium hydroxide solution was heated under reflux with stirring for 1.5 hours. After cooling, the solution was saturated with sodium chloride and extracted with chloroform which was then dried over anhydrous magnesium sulfate. Removal of the filtered solvent *in vacuo* and recrystallization of the residue from an ethanol–benzene mixture gave 0.245 g. (70%) of the ε-dihydroxydiketone IXε with a m.p. of 235–238°. Recrystallization from an ethanol–benzene mixture gave an analytical sample with a m.p. of 239–240.5° which was saturated to tetranitromethane and did not decolorize a 5% solution of bromine in chloroform.

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04. Found: C, 71.52; H, 9.02.

The infrared spectrum (KBr) contained maxima at 3500(s and broad), 2945(s), 1682(s and broad), 1648(s), 1432(m) and 1005(m) cm.$^{-1}$. The ultraviolet spectrum (EtOH) showed maxima at 210 mμ (ε 11,200) and 280 mμ (ε 178).

The diacetate was prepared in the usual manner with acetic anhydride in pyridine. Recrystallization of the crude product from ethanol gave an analytical sample with a m.p. of 216.5–217.5°. The infrared spectrum ($CHCl_3$) contained maxima at 2980(m), 1275(s), 1686(s), 1250 to 1220(s) and 1013(m) cm.$^{-1}$.

Deuterium Exchange of the ε-Dihydroxydiketone IXε.—Using the method described above for the α-dihydroxydiketone IXα the deuterated ε-dihydroxydiketone, m.p. 237–239°, was obtained in 45% yield. The infrared spectrum of the deuterated IXε showed no absorption in the O–D region.

Anal. Calcd. for $C_{20}H_{26}D_4O_4$: D, 13.33. Found: D, 12.95.

Chromatography of β-Dieucarvelone. ε-Dieucarvelone (IIIε).—The chromatography of 60 mg. of β-dieucarvelone, with a constant melting point of 142–144°, on 6 g. of Merck acid-washed alumina, activity I, was carried out in the usual manner. Elution with benzene gave 14 mg. of a solid which when recrystallized from ethanol gave α-dieucarvelone with a m.p. of 177.0–177.8°. No depression was observed upon mixed melting with an authentic sample. A strong depression was observed upon mixed melting with β-dieucarvelone.

Elution of the column with a 5% ethyl ether–benzene mixture gave 45 mg. of a solid which when recrystallized from ethanol gave ε-dieucarvelone with a m.p. of 153.0–153.5°. The melting point was not raised upon further recrystallization. ε-Dieucarvelone did not decolorize a 5% solution of bromine in chloroform and was saturated to tetranitromethane in chloroform. No depression was observed upon mixed melting with β-dieucarvelone.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00; mol. wt., 302. Found: C, 79.64; H, 10.07; mol. wt., 288.

The infrared spectrum (KBr) showed maxima at 2980(s) with a shoulder at 3017(m), 1692(s), 1645(w) and 755(w) cm.$^{-1}$. The ultraviolet spectrum (EtOH) shows a maximum at 285 mμ (ε 68) with end absorption at 210 mμ (ε 1,260).

A mixture of equal amounts of α- and ε-dieucarvelone was recrystallized from methanol. Pure α-dieucarvelone was obtained from the first fractions. The later fractions gave β-dieucarvelone with a constant melting point of 141–143°. The infrared spectrum of this sample was identical with that of β-dieucarvelone isolated from the zinc dust–base reduction of eucarvone and no mixed melting point depression was obtained.

Trifluoroperacetic Acid Reaction of β-Dieucarvelone.—The oxidation was performed as described for α-dieucarvelone (VIIIα). The product was recrystallized from a chloroform–methanol mixture to give 0.25 g. (7.5%) of α

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized By Arya Samaj Foundation Chennai and eGangotri

diepoxydieucarvelone (VIIIα), with a m.p. 260–270° dec. The melting point was raised to 296–298° dec. by further recrystallization from chloroform. The infrared spectrum was identical with that of an authentic sample of VIIIα and no mixed melting point depression was observed.

Solvent was removed from the mother liquors and the oily residue recrystallized from ethanol to give 1.9 g. (57%) of ϵ-diepoxydieucarvelone (VIIIϵ) with a meltiug point of 167–171°. The melting point was raised to 176–177° by further recrystallization from ethanol. The infrared spectrum was identical with that of an authentic sample of VIIIϵ and no mixed melting point depression was observed.

Lithium Aluminum Hydride Reduction of β-Dieucarvelone.—A solution of 4.0 g. (0.0132 mole) of β-dieucarvelone in 100 ml. of tetrahydrofuran was added over a period of 20 minutes to a slurry of 0.86 g. (0.023 mole) of lithium aluminum hydride in 70 ml. of tetrahydrofuran with stirring. The mixture was then heated under reflux for 5 hours, cooled and the excess hydride decomposed with 10 ml. of ethyl acetate followed by 20 ml. of water. The reaction mixture was filtered and the residue placed in a Soxhlet extractor and extracted with chloroform. The solvents were removed *in vacuo* and the crude product recrystallized from methanol to give 0.9 g. (22.5%) of the α-glycol Vα with a m.p. of 248–249°. The infrared spectrum of this sample was identical with that of an authentic sample of the α-glycol and there was no depression upon mixed melting point.

Concentration of the mother liquors gave 3.0 g. (75%) of the ϵ-glycol Vϵ with a m.p. of 182–184°. Recrystallization from methanol gave an analytical sample with a m.p. of 182.6–183.8°. The infrared spectrum (KBr) contained bands at 3390(s), 3000(m), 2950(s), 1640(w), and 752(s) cm.$^{-1}$.

Anal. Calcd. for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18. Found: C, 78.33; H, 11.19.

A perbenzoic acid titration of the ϵ-glycol Vϵ proceeded as follows: after 10 hours, the glycol titrated for 1.38 double bonds; 24 hours, 1.96 double bonds.

Attempted Base Isomerization of α-Dieucarvelone.—A solution of 0.69 g. (0.00229) mole of α-dieucarvelone and 0.3 g. of sodium in 100 ml. of absolute ethyl alcohol was allowed to stand at room temperature for 48 hours. A saturated sodium chloride solution was added and the mixture extracted with chloroform which was then dried over anhydrous magnesium sulfate. After filtering, the solvents were removed *in vacuo* and the solid residue recrystallized from ethanol. The first fractions, 0.500 g., had a melting point of 174–175° which was not lowered when melted with an authentic sample of α-dieucarvelone. The later fractions had a lower melting point and were chromatographed on 5 g. of alumina, activity I. A series of fractions was obtained (0.073 g.) which when recrystallized from ethanol had a m.p. of 177–178° which was not lowered when melted with an authentic sample of α-dieucarvelone. A total of 0.573 g. (83%) of α-dieucarvelone was recovered from the reaction mixture.

Base Isomerization of ϵ-Dieucarvelone (IIIϵ).—A solution of 0.700 g. (0.00232 mole) of ϵ-dieucarvelone and 0.15 g. of sodium in 50 ml. of absolute ethyl alcohol was allowed to stand at room temperature for 48 hours. A saturated sodium chloride solution was added and the mixture extracted with chloroform which was then dried over anhydrous magnesium sulfate. After filtering, the solvents were removed *in vacuo* and the solid residue chromatographed on 70 g. of Merck acid-washed alumina, activity I. Elution with benzene followed by a 10% chloroform–benzene mixture gave 0.377 g. (54%) of ζ-dieucarvelone which when recrystallized from ethanol gave an analytical sample with a m.p. of 131.0–132.0° which did not decolorize a 5% solution of bromine in chloroform and was saturated to tetranitromethane in chloroform.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00; mol. wt., 302. Found: C, 79.05: H, 9.86; mol. wt., 280.

The infrared spectrum (KBr) contained maxima at 3020 (m), 2930(s), 1700(s), 1640(w) and 755(m) cm.$^{-1}$. The ultraviolet spectrum (EtOH) showed a maximum at 290 mμ (ϵ 53) with end absorption at 210 mμ (ϵ 1,780).

Elution of the column with chloroform gave 0.285 g. (41%) of ϵ-dieucarvelone which when recrystallized from ethanol had a m.p. of 150–152°. Further recrystallization raised the melting point to 151.5–152.5° which was not lowered when melted with an authentic sample.

Zinc Reduction of Eucarvone (I).—A solution of 0.2 g. (0.00133 mole) of eucarvone and 1 g. of ammonium chloride in 10 ml. of an ethanol–water mixture was cooled to 10–15° with an ice-bath. Two grams of zinc dust was added and the slurry stirred vigorously at this temperature for 45 minutes. The mixture was then filtered and the filtrate extracted with ethyl ether which was dried over anhydrous magnesium sulfate. After filtering, the oily residue was recrystallized from methanol to give 0.025 g. (12.5%) of ϵ-dieucarvelone with a m.p. of 150.5–152.0°. The infrared spectrum of this sample was identical with that of an authentic sample and no mixed melting point depression was observed. Only uncrystallizable oils could be obtained from the mother liquors.

Terpenoids. XXVIII.[1] The Triterpene Composition of the Genus Myrtillocactus[2]

BY CARL DJERASSI, S. BURSTEIN, H. ESTRADA, A. J. LEMIN,[3a] A. E. LIPPMAN,[3b] A. MANJARREZ AND H. G. MONSIMER

RECEIVED JANUARY 23, 1957

All known species of the genus *Myrtillocactus* have been examined. While no alkaloids were encountered, seven triterpenes have been isolated of which only two have been found outside the cactus family. Cochalic acid, chichipegenin and myrtillogenic acid seem to be particularly characteristic of this genus and attention is called to possible taxonomic implications of these results.

The main purpose of our chemical investigations of giant cacti has been the isolation and structure proof of new alkaloids and triterpenes.[4] It was felt desirable to study, as far as possible, all species of a given genus which contained alkaloids or triterpenes since such results could be of biogenetic and taxonomic interest. Some fruitful conclusions already have been reached from examinations of the genera *Lemaireocereus*,[4,5] *Machaerocereus*,[6] and *Lophocereus*[7] and we should now like to report on a

Digitized by Arya Samaj Foundation Chennai and eGangotri

detailed investigation of the genus *Myrtillocactus*.

Britton and Rose[8] have assigned four species—*M. geometrizans*, *M. cochal*, *M. schenckii* and *M. eichlamii*—to this genus, which is indigenous to Mexico and Guatemala. *Myrtillocactus grandiareolatus* is usually considered a synonym[9] for *M. geometrizans*, but our chemical results indicate a distinct difference. Through the coöperation of Mr. Howard E. Gates (Corona, California), Don Mariano Pacheco (Guatemala, C.A.) and Dr. Alberto Sandoval (Instituto de Quimica, Mexico, D.F.) it has been possible to secure specimens of all five species, which were investigated in the customary manner[4] for alkaloids and triterpenoid glycosides. All of these plants were rich in glycosides but did not contain any alkaloids, in agreement with earlier results among the *Cactaceae*[4] as well as other plant families[10] that glycosides and alkaloids usually do not occur in the same plant. In three instances, the non-glycosidic, neutral fraction was saponified[11] and was found to contain small amounts of triterpenes which were present in esterified form.

Myrtillocactus cochal (Baja California, Mexico) proved to be particularly rich in triterpenes. Acid hydrolysis of the glycosides yielded a neutral and an acidic fraction. The former consisted of essentially one triterpene which could be purified by direct crystallization and was found to be a new triterpene tetrol ($C_{30}H_{50}O_4$). With one exception (*M. schenckii*) this tetrol has proved to be the principal triterpene of all *Myrtillocactus* species and it has been encountered subsequently in only one species of another genus, namely, *Lemaireocereus chichipe*. We have named the substance chichipegenin and its structure elucidation[12] is being undertaken jointly with Dr. Alberto Sandoval and collaborators. The acidic portion consisted chiefly of one acid, cochalic acid, the structure (Ia) of which recently has been established.[13] Methylation of the mother liquors and chromatography gave in addition to methyl cochalate the methyl ester of a new trihydroxy triterpene acid which has now been named myrtillogenic acid and whose structure has been shown[1] to be IIa. Saponification of the oily, neutral, non-glycosidic constituents of this cactus furnished a small amount of longispinogenin (IIIa).[14] The co-occurrence of cochalic acid (Ia) and longispinogenin (IIIa), two triterpenes which differ only in the oxidation state of C-28, suggested that myrtillogenic acid (IIa) and the new tetrol chichipegenin might bear the same relationship to each other. This possibility was eliminated, however, when it was found that the lithium aluminum hydride reduction product (IVa) of myrtillogenic acid (II) was different from chichipegenin.

Myrtillocactus geometrizans (Central Mexico) exhibited qualitatively the same triterpene composition as *M. cochal* thus confirming the close botanical relationship of these two species. The common structural feature among its three triterpenes of known structure—cochalic acid (Ia), myrtillogenic acid (IIa) and longispinogenin (IIIa)—is the fact that they are oxygenated at positions 3, 16 and 28. Whether this also applies to the main constituent, chichipegenin, will have to be determined by degradation experiments which are now in progress.[12]

Myrtillocactus eichlamii is the only species of this genus which grows in Guatemala and it also contained chichipegenin, cochalic acid (Ia), myrtillogenic acid (IIa) and longispinogenin (IIIa), the latter being present in the non-glycosidic portion. In addition, there was encountered oleanolic acid (Va) (from the glycosidic fraction) and maniladiol (VI) (present in esterified form). The isolation of the latter is of interest since it has so far been found only in *manila elemi* resin[15] and in the cactus *Escontria chiotilla*.[5] Structurally, it fits nicely into the cactus triterpene pattern[4] according to which oxygenation is observed only in rings D and E aside from C-3.

The remaining two Mexican species *M. grandiareolatus* and *M. schenckii* yielded only two triterpenes.[16] The principal constituent of the former was the above-mentioned chichipegenin accompanied by some oleanolic acid (Va) while the latter contained oleanolic acid (Va) and stellatogenin (VIIa).[17]

From these studies it can be concluded that chichipegenin is the most characteristic triterpene (followed by cochalic and myrtillogenic acids) of this genus since it has been isolated in large amounts from four species. The only species which did not contain it, *M. schenckii*, yielded triterpenes which are characteristic[4] of the genus *Lemaireocereus*, while the only species outside the genus *Myrtillocactus* where chichipegenin has been encountered has been *Lemaireocereus chichipe*.[12] It would appear that a botanical reinvestigation of these two species is in order and in view of the considerable taxonomic difficulties among the *Cactaceae* chemical criteria (such as triterpene content) might be used to good advantage.

Britton and Rose[4] have pointed out that botanically the genus *Myrtillocactus* has no close relatives and it has been placed next to *Lophocereus* only because plants of both genera show several flowers at each areole. Chemically these two genera are completely distinct[4] since all *Lophocereus* species are rich in alkaloids but do not contain any triterpenoid glycosides in marked contrast to the above described *Myrtillocactus* species.

Experimental[18]

Isolation of Triterpenes from *M. cochal*.[19]—Dried and ground plant (1.6 kg.) from 21 kg. of fresh cactus (furnished by Mr. Howard E. Gates, Corona, California) was extracted continuously for 4 days with ethanol in a Soxhlet extractor and the solvent removed to yield 475 g. of extract. This was washed thoroughly with ether to remove non-glycosidic material (see below) and then hydrolyzed by heating under reflux for 4 hours with 450 cc. of concd. hydrochloric acid and 800 cc. of ethanol. After reducing the volume to one-half, much water was added and the precipitate was collected and dried. Continuous extraction of this solid with ether in a Soxhlet apparatus (4 days) and cooling of the ether solution furnished 25.5 g. of crude **chichipegenin**, m.p. 278–285°, raised to 320–325° after two recrystallizations from ethanol. The ether filtrate was washed thoroughly with 5% potassium hydroxide solution (see below for isolation of acids), water, dried and evaporated, leaving 34 g. of neutral semi-solid. Extraction of this fraction with benzene left 14 g. of insoluble residue which after recrystallization from methanol–acetone yielded an additional 12 g. of chichipegenin (m.p. 304–310°). Chromatography of the benzene solution on 400 g. of acetic acid-deactivated alumina and elution with ether gave 2.0 g. of chichipegenin to raise the total yield to 39.5 g. (2.47% based on dry plant). The analytical sample was obtained from methanol–acetone and exhibited m.p. 322–325°, $[\alpha]D$ +60° (methanol).

Anal. Calcd. for $C_{30}H_{50}O_4$: C, 75.90; H, 10.62. Found: C, 75.56; H, 10.93.

Acetylation of a sample with acetic anhydride–pyridine at room temperature overnight followed by recrystallization from methanol–chloroform led to **chichipegenin tetraacetate**, m.p. 278–280, $[\alpha]D$ +30°.

Anal. Calcd. for $C_{38}H_{58}O_8$: C, 70.99; H, 9.09. Found: C, 70.78; H, 9.17.

The above alkali washes were combined and acidified. Extraction with ether gave *ca.* 40 g. of acidic residue, which upon crystallization from acetone yielded 15 g. of **cochalic acid** (Ia), m.p. 300–302°.[13] The filtrate was evaporated, methylated overnight with excess diazomethane in methanol solution and then chromatographed on 800 g. of alumina deactivated with 10 cc. of 10% acetic acid. Elution with 8:2 benzene–ether provided 5.0 g. of crude methyl cochalate (Ib) (m.p. 175–180°)[13] raising the total yield of this triterpene to 1.25%.

Washing of the column with ether gave 3.1 g. (0.19%) of **methyl myrtillogenate** (IIb), m.p. 232–236°. Recrystallization from methanol–acetone provided the analytical sample, m.p. 248–250°, $[\alpha]D$ +87°.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03. Found: C, 74.24; H, 9.98.

Acetylation with acetic anhydride–pyridine and recrystallization from methanol gave the corresponding **triacetate**, m.p. 147–149°, $[\alpha]D$ +76°.

Anal. Calcd. for $C_{37}H_{56}O_8$: C, 70.67; H, 8.98. Found: C, 70.56; H, 9.11.

The ether washings of the original ethanolic cactus extract were evaporated and the dark green oil (25 g.) was heated under reflux overnight with 25 g. of potassium hydroxide and 250 cc. of methanol. Concentration, dilution with water and extraction with ether furnished 6.5 g. of a semi-solid which was chromatographed on 80 g. of acetic acid-deactivated alumina. All crystalline eluates were combined and recrystallized from acetone to give 2.5 g. (0.157%) of **longispinogenin** (IIIa), m.p. 241–245°. Purification was best accomplished *via* its **triacetate** (m.p. 219–222°, $[\alpha]D$ +69°) which was shown to be identical with an authentic sample[14] by mixture melting point determination and infrared comparison.

Isolation of Triterpenes from *M. geometrizans*.[20]—The isolation was carried out exactly as above and the results differed only quantitatively from those observed with *M. cochal:* chichipegenin (0.62%), methyl cochalate (Ib) (0.25%), methyl myrtillogenate (IIb) (0.14%) and longispinogenin (IIIa) (0.0025%).

Isolation of Triterpenes from *M. eichlamii*.—The cactus was collected by Don Mariano Pacheco near Guatemala City and sun dried before being shipped to Detroit. From 1720 g. of dried, ground cactus, there was obtained 430 g. of ethanol extract which upon thorough washing with ether led to 319 g. of solid, tan-colored glycoside and 77 g. of neutral, non-glycosidic material.

Acid cleavage of the glycosides yielded 0.90% of chichipegenin, while chromatography of the methylated acid fraction gave 0.16% of **methyl oleanolate** (Ib) (m.p. 199°, $[\alpha]D$ +72°), 0.037% of **methyl cochalate** (Ib) and 0.028% of **methyl myrtillogenate** (IIb).

Saponification of the non-glycosidic fraction followed by chromatography of the neutral fraction gave some **β-sitosterol** (m.p. 138–140°, $[\alpha]D$ −37°; **acetate**, m.p. 125–128°, $[\alpha]D$ −44°), 0.14% of **maniladiol** (VI) (m.p. 215–217°, $[\alpha]D$ +67°, identified by direct comparison with a sample prepared[14] from gummosogenin) and 0.83% of **longispinogenin** (IIIa).

Isolation of Triterpenes from *M. grandiareolatus*.—This

(18) Melting points are uncorrected. Unless noted otherwise, rotations were measured in chloroform solution. We are indebted to Mrs. Theodora Phillips for the infrared spectra and to Dr. A. Bernhardt (Mülheim, Germany) for the microanalyses.

(19) A preliminary investigation was carried out by Dr. G. H. Thomas (see ref. 13).

cactus was collected near Zapotitlán on the road from Tehuacán Puebla to Huajuapan de León and from the glycosidic fraction there was obtained nearly 1% of chichipegenin and 0.2% of methyl oleanolate (Vb).

Isolation of Triterpenes from *M. schenckii*.—A 1.54-kg. sample (dry) of cactus collected near Diaz Ordaz, Oaxaca, yielded only 55 g. of glycosidic material after alcohol extraction and ether washing. Acid hydrolysis and chromatography of the neutral fraction gave 0.052% of stellatogenin (VIIa)[17] (m.p. 311–314°, $[\alpha]_D$ +40°; acetate VIIb, m.p. 323–326°, $[\alpha]_D$ +49°), identified by infrared comparison with an authentic sample,[6] while methylation of the acids and chromatography led to 0.136% of methyl oleanolate (Vb) (m.p. 197–199°).

Lithium Aluminum Hydride Reduction of Triacetyl Methyl Myrtillogenate.—Methyl myrtillogenate (IIb) triacetate (196 mg.) was heated under reflux for 12 hours with 1 g. of lithium aluminum hydride in 100 cc. of ether and was then processed in the manner described earlier[21] for oleanolic acid lactone. The crude Δ^{12}-oleanen-3β,16β,28,29-tetrol (IVa) (155 mg., m.p. 275–280°) was recrystallized from methanol to yield an analytical specimen, m.p. 280–283°, $[\alpha]_D$ +101° (methanol), no infrared absorption in the carbonyl region.

Anal. Calcd. for $C_{30}H_{50}O_4$: C, 75.90; H, 10.62. Found: C, 76.00; H, 10.52.

Acetylation with acetic anhydride–pyridine and purification by alumina chromatography (elution with benzene) followed by recrystallization from methanol furnished Δ^{12}-oleanen-3β,16β,28,29-tetrol tetraacetate (IVb), m.p. 182–183°, $[\alpha]_D$ +71°.

Anal. Calcd. for $C_{38}H_{58}O_8$: C, 70.99; H, 9.09. Found: C, 71.23; H, 9.47.

The difference in physical constants precluded identity with chichipegenin (and its acetate) and the infrared spectra were also different.

Terpenoids. XXIX.[1] Iresin (Part 2).[2] A New Fundamental Sesquiterpene Skeleton[3,4]

BY CARL DJERASSI AND WERNER RITTEL[5]

RECEIVED FEBRUARY 14, 1957

By means of various degradations, it has been shown that iresin possesses structure XXV (or the variant XXXII) based on a skeleton (XIII or XIV) which is unique among sesquiterpenes. Since this skeleton is always found in rings A, B and C of the higher (di- and tri)-terpenes, iresin represents an important link in the presently accepted biogenetic pattern of the lower and higher terpenes.

Recently,[2] there has been described the isolation and characterization of a novel sesquiterpene ($C_{15}H_{22}O_4$) which was named iresin. We should now like to record the salient experiments which led to the elucidation of the skeletal structure of this substance and which suggest that iresin occupies a unique position in terpene chemistry. Future papers will deal with various transformations of the functional groups of iresin and with its stereochemistry.

The nature of the four oxygen atoms already has been elucidated in the first paper[2] of this series and they were shown to be present as two reactive hydroxyl groups and as an α,β-unsaturated, five-membered lactone ring. The latter could, *a priori*, be of two types—the double bond being exocyclic (I) or endocyclic (II) with respect to the lactone ring—and it seemed important to differentiate between these two possibilities before initiating more drastic degradations.

Since α,β-unsaturated lactones of type II are known[6] to be convertible by base to the corresponding keto acids III, iresin was subjected to such treatment and was recovered unchanged (after acidification) even when heated with potassium *t*-butoxide. We conclude that the unsaturated lactone system of iresin is of type I and direct chemical proof for this supposition was afforded by ozonization experiments described below. The only double bond present in iresin is that conjugated with the

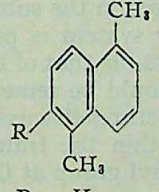
lactone system and it can be reduced readily.[2,7] The resulting dihydroiresin (IV) was found[2] to be unstable to base and after acidification yielded an isomer, isodihydroiresin. Simple opening of the lactone ring and closure with another, suitably located hydroxyl group was excluded,[2] since iresin[8] and dihydroiresin afforded the same tetrol upon lithium aluminum hydride reduction while a different tetrol was obtained from isodihydroiresin. It follows that base treatment of dihydroiresin either resulted in inversion of the enolizable α-position or that inversion accompanied by lactonization with another hydroxyl group had occurred. An unambiguous differentiation between these two alternatives was accomplished as follows.

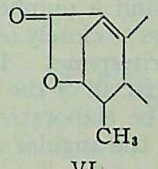
The two hydroxyl groups of iresin are not located on adjacent carbon atoms since the substance is unaffected[2] by glycol-cleaving reagents such as lead tetraacetate. On the other hand, it was now found that iresin condensed readily with benzaldehyde or acetaldehyde in the presence of zinc chloride[9] to yield highly crystalline benzylidene (XXX) or acetylidene (XXI) derivatives from which iresin could be regenerated after acid treatment. This observation not only indicated that iresin possessed a 1,3-glycol system but it also presented a means of protecting the two hydroxyl groups in an alkaline medium. Hydrogenation of benzylidene–iresin (XXX) led to benzylidene–dihydroiresin (XXXI) and alkaline treatment afforded benzylidene–isodihydroiresin, alternatively prepared from isodihydroiresin and benzaldehyde. This circle demonstrates that the two hydroxyl groups cannot be implicated in the dihydroiresin → isodihydroiresin change and that the reaction simply involves inversion at the adjacent enolizable center[10] to the more stable isomer.[11]

The gross structural features of sesquiterpenes usually can be detected[12] by dehydrogenation and identification of the resulting aromatic products. When iresin was heated with palladized charcoal catalyst near 300°, two crystalline dehydrogenation products were obtained. These were identified as 1,5-dimethylnaphthalene (Va)[13] and 1,5-dimethyl-2-naphthol (Vb)[14] and it should be noted that while both substances had been described in the literature,[13,14] neither one had ever been encountered as a characteristic sesquiterpene dehydrogenation product.[12] This constituted the first indication that iresin might represent a novel sesquiterpene type, a supposition which was shown in the sequel to be correct.

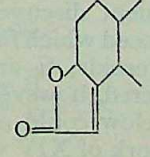
The two naphthalene derivatives (Va, Vb) account for 12 out of the 15 carbon atoms of iresin. Since angular or *gem*-substituents as well as actual or potential carboxyl groups are lost during dehydrogenations,[12] it can be assumed that the loss of three carbon atoms involved the carboxyl group of the lactone ring as well as one (ethyl or oxygenated ethyl) or two (methyl or oxygenated methyl) angular (or *gem*) alkyl groups. Obviously the more significant dehydrogenation product was the naphthol Vb since the surviving oxygen atom automatically labeled one of the three hydroxylic functions of iresin. *A priori*, the phenol could have arisen from either the two alcoholic substituents of iresin or from the hydroxyl group incorporated in the lactone ring. The latter possibility, however, could be ruled out since an α,β-unsaturated five-membered lactone moiety involving that oxygen atom (and furnishing Vb upon dehydrogenation) would lead to partial structures VI or VII. The former would violate Bredt's rule while the latter does not follow the earlier mentioned prerequisite (*cf.* I) that the double bond be exocyclic to the lactone ring.



Va, R = H
b, R = OH
c, R = C_6H_5COO



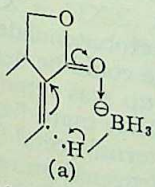
VI



VII

It follows, therefore, that the phenolic hydroxyl group of 1,5-dimethyl-2-naphthol (Vb) originated from one of the two alcoholic groups, which are very easily acylated and saponified.[2] Since this chemical behavior excludes tertiary hydroxyl functions and since they must be part of a 1,3-glycol system (condensation with aldehydes), partial structures VIII and IX (R = H or alkyl) are the only permissible ones insofar as the two hydroxyl groups are concerned. The survival of an alcohol under the drastic dehydrogenation conditions is reminiscent of the 3-hydroxy-4,4-dimethyl system of the pentacyclic triterpenes (*e.g.*, β-amyrin (X)), since dehydrogenation[15] of such compounds leads in part to phenolic products (*e.g.*, XI, XII) in which the orig-

(7) Unsaturated butenolides usually are not attacked by sodium borohydride (*cf.* R. Richter, O. Schindler and T. Reichstein, *Helv. Chim. Acta*, **37**, 76 (1954), and references cited) but iresin was found to be converted by this reagent in very good yield to dihydroiresin (XXIX) (see Experimental). While examples of the reduction of α,β-unsaturated ketones by means of sodium borohydride to the saturated alcohols are known (*e.g.*, F. Sondheimer, M. Velasco, E. Batres and G. Rosenkranz, *Chemistry & Industry*, 1482 (1954)), the sole reduction of the double bond appears unusual (*cf.* H. Schechter, D. E. Ley and E. B. Roberson, THIS JOURNAL, **78**, 4984 (1956)) and may possibly proceed through a cyclic intermediate (*cf.* R. E. Lutz and J. S. Gillespie, *ibid.*, **72**, 2002 (1950)) which would be favored by the *cisoid* unsaturated carbonyl system (a).



(a)

(8) In this case the double bond was also reduced.

(9) Cf. K. Freudenberg, H. Toepffer and C. C. Andersen, *Ber.*, **61**, 1758 (1928).

(10) As is to be expected on mechanistic grounds, inversion appears to occur prior to opening of the lactone ring since some isodihydroiresin can be extracted from the alkaline solution without acidification.

(11) The stereochemistry of these compounds will be discussed in a subsequent paper.

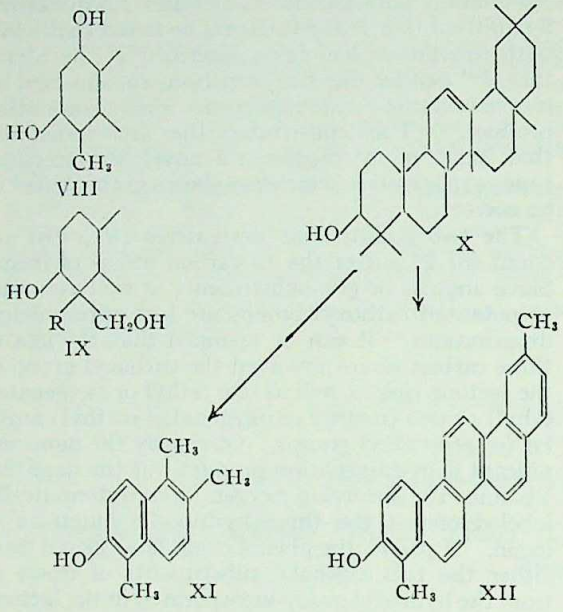
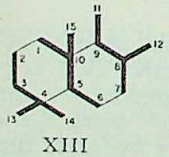
Digitized by Arya Samaj Foundation Chennai and eGangotri

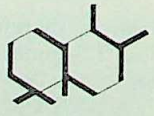
inal alcoholic group is retained. Such an analogy would tend to support partial structure IX (R = alkyl) for iresin and direct chemical proof will be described below.



On the assumption that iresin obeys the isoprene rule, only two carbon skeletons need to be considered. The first one (XIII) (1x-y2, 2x-y3)[16] follows both the isoprene and farnesol rules (head-to-tail attachments of isoprene units) and is thus suggestive of rings A, B and C of the di- and triterpenes, while structure XIV (1x-x2, 2y-y3)[16] involves an irregular attachment of isoprene units. For the sake of brevity, only XIII will be used in the subsequent discussion and a numbering system is proposed which follows as closely as possible that of the steroids, di- and triterpenes. It should be remembered, however, that all of the structures discussed below could also be elaborated within the framework of XIV with the angular methyl group at C-5 instead of C-10.

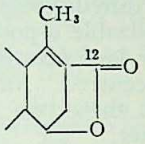


XIII

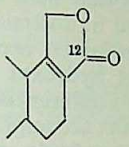


XIV

If a skeleton based on XIII or XIV is provisionally accepted for iresin, then the attachment of the lactone ring follows rigorously. The carboxyl carbon atom of the lactone ring is lost during dehydrogenation to 1,5-dimethylnaphthalene (V) and hence can only be represented by C-12, C-13 (or C-14) or C-15. Since iresin possesses a double bond which is in conjugation with the potential carboxyl group, only C-12 is left for consideration. This, *ipso facto*, also locates the hydroxyl group involved in lactone formation since of the three possible attachments of a five-membered, α,β-unsaturated lactone moiety originating at C-12 (of XIII or XIV), XV violates Bredt's rule and XVI possesses a double bond endocyclic to the lactone ring (II rather than the required I). This leaves XVII (or the variant with the angular methyl group at C-5) as the only reasonable expression for iresin, the remaining hydroxyl group occupying either position 1 (*cf.* VIII) or 13 (or 14) (*cf.* IX). Experimental proof for this structural proposal was provided by various oxidations.



XV



XVI

The key experiment proved to be the ozonolysis of iresin, which was expected to lead to rupture of the double bond and the introduction of two extra carbonyl groups ($C_{15}H_{22}O_4 \rightarrow C_{15}H_{22}O_6$). In point of fact, only one oxygen atom was added and the two hydroxyl groups originally present in iresin had disappeared. The ozonization product ($C_{15}H_{20}O_5$) gave a color with ferric chloride solution and exhibited an ultraviolet absorption maximum at 240 mμ (as compared to 224 mμ for iresin) which was shifted to 274 mμ in alkaline solution. Acetylation produced a monoacetate (subsequently shown to be XIXb) which had an ultraviolet absorption maximum at 218 mμ and which could be saponified to the original compound. These spectral properties are in excellent agreement with those predicted for an α-ketobutenolide[17] (XVIIIa) (and its enol acetate XVIIIb), which would be formed by ozonolysis of XVII. This would also explain the disappearance of the two hydroxyl groups in the ozonization product since if structure XVII (hydroxyl group at C-1 or C-13) were indeed correct, then the intermediate aldehyde XVIIIa would be perfectly located for internal acetal closure. On that basis, the final product should be represented by XIXa or XXa, depending upon the location of the second hydroxyl group (VIII or IX) in iresin and either structure is strain-free as well as fully compatible with the analytical, spectroscopic and chemical data. Complete confirmation for these views was provided by the observation that ozonolysis[18] of acetylidene iresin (XXI or XXIII)—the two hydroxyl groups now being blocked—afforded a crystalline product (XXII or XXIV) in which the presence of an α-ketobutenolide system as well as that of an aldehyde could be demonstrated. When the protecting group was removed by acid treatment, the intermediate immediately cyclized to the above described internal acetal (XIX or XX).

While the dehydrogenation results (formation of 1,5-dimethyl-2-naphthol (Vb)) favor locating the second hydroxyl group at C-13 or C-14 (IX) and consequently structures XIX, XXI and XXII, more conclusive evidence had to be provided concerning this important constitutional point.

Chromium trioxide oxidation of iresin in pyridine

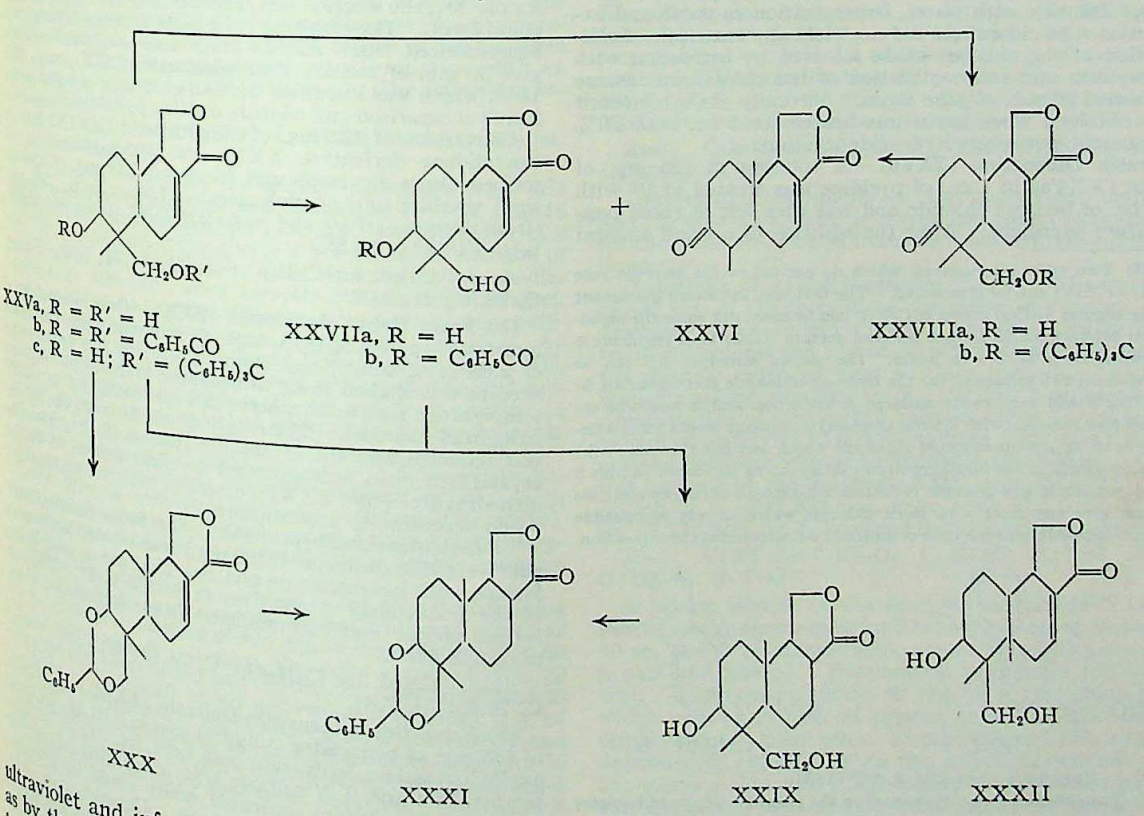
solution[19] led to two products which could be separated chromatographically. The analysis of the less polar substance indicated the loss of CH_4O, which would only be compatible with a 13-nor-3-keto structure (XXVI). The presence of the unchanged α,β-unsaturated butenolide system and of an isolated keto group was demonstrated by the nor-ketone (XXVI) can be rationalized only *via* an intermediate β-keto aldehyde or β-keto acid and consequently requires the presence of a primary hydroxyl group in iresin (XXVa), thus eliminating the alternate formulation with a hydroxyl group at C-1 (VIII). The more polar product, although not giving a Tollens reaction, was shown to be the hydroxy-aldehyde XXVIIa rather than the corresponding hydroxy-ketone (XXVIIIa). The substance did not give formaldehyde upon base treatment, as would be expected[21] from the hydroxy ketone XXVIIIa upon retroaldolization, and did not form a trityl ether. On the other hand, it did yield a crystalline benzoate (XXVIIb) as well as a 2,4-dinitrophenylhydrazone, the ultraviolet absorption maximum of which was typical[20] ($\lambda_{max}^{CHCl_3}$ 354 mμ) of an aldehyde and produced dihydroiresin (XXIX) upon reduction with sodium borohydride.[7,8]

A related approach by another series of transformations[22] led to the same conclusion and involved conversion of iresin (XXVa) to its trityl ether XXVc followed by chromium trioxide–pyridine oxidation[19] to the keto-alcohol trityl ether XXVIIIb. Acid cleavage of the trityl ether was accompanied by reverse aldol condensation with formation of formaldehyde (isolated as the dimedone derivative) and the nor-ketone (XXVI).



ultraviolet and infrared spectroscopic data as well as by the formation of a yellow 2,4-dinitrophenylhydrazone ($\lambda_{max}^{CHCl_3}$ 364 mμ[20]). The formation of a

The above-described degradations are only compatible with structures XXV or XXXII for iresin, the single uncertainty being the location of the

(22) These three experiments were carried out by Dr. F. W. Donovan (see ref. 3) and will be published in part 3 of this series, together with other reactions of the glycol system of iresin.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

angular methyl group[23] which could be at C-10 (XXV) or at C-5 (XXXII). Experiments are under way to settle this point but from a biogenetic standpoint, either structure would be acceptable since XXXII would almost certainly have arisen by methyl migration of a plant precursor based on structure XXV. It should be noted that iresin is the first sesquiterpene which follows an isoprene pattern found so far only among the higher terpenes (di- and triterpenes). In fact, the conspicuous absence of such a skeleton in the sesquiterpene series (prior to the isolation of iresin) led Ruzicka[24] to the plausible assumption that "this appears to indicate that the biogenesis of the steroids, diterpenes and triterpenes differs in some fundamental detail from that of the monoterpenes and sesquiterpenes." The present demonstration that iresin possesses such a structure makes this assumption unnecessary and to that extent iresin can be considered a missing link in terpene biogenesis.[25] Its importance in the terpene series has encouraged us to study its chemistry in detail and future papers will deal with additional transformations as well as with its relative[26] and absolute configuration.

Experimental[27]

Stability of Iresin toward Alkali.—A solution of 100 mg. of iresin and 0.45 g. of potassium in 20 cc. of dry *t*-butyl alcohol was heated under reflux for 16 hr. in an atmosphere of nitrogen. Dilution with water, concentration *in vacuo* and extraction with chloroform did not yield any material. Acidification of the aqueous phase followed by extraction with chloroform and recrystallization of the chloroform residue furnished 86 mg. of pure iresin. Virtually the same result was obtained when iresin was heated for 5 hr. with 20% methanolic potassium hydroxide solution.

Iresin Dibenzoate (XXVb).—A solution of 100 mg. of iresin (XXVa) in 1 cc. of pyridine was treated at 0° with 0.5 cc. of benzoyl chloride and was then left at room temperature overnight. After the addition of a small amount of methanol, the reaction mixture was worked up in the usual fashion and the dibenzoate (190 mg.) was recrystallized from acetone–ether, methanol and methanol–ether to give colorless prisms, m.p. 209.5–210.5°, $[\alpha]^{22}D$ −52° (*c* 1.07).

Anal. Calcd. for $C_{29}H_{30}O_6$: C, 73.40; H, 6.37. Found: C, 73.47; H, 6.36.

Benzylideneiresin (XXX).—A mixture of 50 mg. of iresin, 2 cc. of freshly distilled benzaldehyde and 80 mg. of powdered, freshly fused zinc chloride[9] was shaken at room temperature for 14 hours. The excess benzaldehyde was removed at 60° and 0.01 mm., and the residue was taken up in chloroform and washed well with sodium bicarbonate and water. The solid residue (66 mg.) was recrystallized successively from chloroform–petroleum ether and from acetone–ether to yield colorless needles, m.p. 242–244°, $[\alpha]D$ +70° (*c* 1.11).

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.39. Found: C, 74.48; H, 7.52.

Cleavage of the benzylidene derivative was accomplished by heating under reflux 30 mg. of the substance with 20 cc. each of methanol and of 0.1 *N* sulfuric acid. All volatile material was removed *in vacuo* and the product was isolated by means of chloroform. Recrystallization from acetone–ether furnished 16 mg. of leaflets of iresin (m.p. 133–135°), identified by infrared comparison.

Benzylidenedihydroiresin (XXXI). (a) **From Dihydroiresin (XXIX).**—The required dihydroiresin (XXIX) could be prepared by hydrogenation[2] as well as by sodium borohydride[7] reduction of iresin in the following manner.

A solution of 40 mg. of iresin, 8 mg. of sodium borohydride and 6 cc. of 95% ethanol was kept for 6 hr. at room temperature and then acidified with dilute sulfuric acid to *p*H 3. After addition of 10 cc. of water and heating to 60° for one hr., the solution was concentrated and extracted with chloroform. The resulting crystalline residue (38 mg.) was recrystallized from acetone–ether and methanol–ether to give 30 mg. of needles of **dihydroiresin (XXIX)**, m.p. 142–145°, which was identified with an authentic sample[2] by infrared comparison and mixture melting point determination.

Conversion of 125 mg. of dihydroiresin (XXIX) into its benzylidene derivative XXXI was accomplished as described above for iresin and furnished 123 mg. of the desired product as two polymorphic forms, m.p. 188–191° (from acetone–ether) and m.p. 204–206° (from methanol), $[\alpha]D$ +19.5° (*c* 1.15).

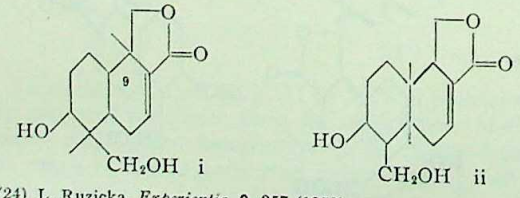
Anal. Calcd. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92. Found: C, 73.64; H, 8.09.

(b) **From Benzylideneiresin (XXX).**—One equivalent of hydrogen was taken up within 40 minutes when a solution of 2.66 g. of benzylideneiresin (XXX) in 250 cc. of ethyl acetate was shaken in an atmosphere of hydrogen at room temperature and atmospheric pressure with 1.5 g. of 5% palladized charcoal. The catalyst was filtered, the solvent was removed and the crystalline residue (2.51 g.) was recrystallized from acetone–ether to yield prisms of benzylidenedihydroiresin (XXXI), identical with the material prepared according to procedure (a).

Benzylideneisodihydroiresin. (a) **From Isodihydroiresin.**[18]—Isodihydroiresin[2,28] (60 mg.) was treated in the usual fashion with benzaldehyde and zinc chloride to give 51 mg. of the benzylidene derivative, m.p. 236–239°. The analytical sample was recrystallized from methanol–acetone, m.p. 238–240°.

Anal. Calcd. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92. Found: C, 74.30; H, 7.88.

(b) **From Benzylidenedihydroiresin (XXXI).**—A solution of 185 mg. of benzylidenedihydroiresin in 8 cc. of 5% methanolic potassium hydroxide was kept for 24 hr. at room temperature and 2 *N* sulfuric acid was added followed by water. A precipitate separated which could be extracted only with difficulty with chloroform. Concentration of the washed and dried chloroform extract yielded colorless needles (153 mg.) which were filtered. This rather insoluble material gave an acid reaction toward litmus and its solubility increased during recrystallization attempts. It appears,



(23) Two other alternatives, which do not follow the isoprene rule (XIII or XIV) can be eliminated. The first one, involving placement of the angular methyl group at C-9 (i) can be ruled out since the ozonization product XIXa formed an enol acetate XIXb thus requiring a hydrogen atom at C-9 in iresin. The second structure (ii) can be excluded on two grounds: (a) the hydroxy-aldehyde corresponding to XXVIIa would very easily undergo dehydration and it would be expected that reaction with 2,4-dinitrophenylhydrazine would yield a derivative of an α,β-unsaturated aldehyde which was not the case. (b) In experiments in the isodihydroiresin series (to be published in part 3 of this series), it was possible to isolate a 3-keto-13-aldehyde and this did not give any color with ferric chloride which is only compatible with a β-ketoaldehyde which is completely substituted at the α-position.

(24) L. Ruzicka, *Experientia*, **9**, 357 (1953).

(25) The substance may be formed in the plant by a type of farnesol (or its equivalent) cyclization for which there exists experimental precedent (for leading references see G. Stork and A. W. Burgstahler, THIS JOURNAL, **77**, 5068 (1955)).

(26) In this connection it may be pertinent to mention that the formation of the cyclic acetal XIX is of considerable significance since this requires that the C-3 hydroxyl group, the carbon atom bearing the primary hydroxyl function and the 5–6 bond must all be *cis*.

(27) Melting points are uncorrected. Unless noted otherwise, rotations were determined in chloroform solution in 1 dcm. tubes. The microanalyses were carried out by Geller Laboratories (Hackensack, N. J.) and by Mr. Joseph F. Alicino (Metuchen, N. J.).

(28) Mr. Sumner Burstein has observed that when the alkaline isomerization of dihydoiresin is conducted in the earlier described manner (ref. 2) approximately 10–15% of isodihydroiresin can be extracted from the alkaline solution prior to acidification (*cf.* ref. 10).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

therefore, that this was the open hydroxy acid which relactonized slowly. Crystallization from ethanol–ether furnished two fractions, a low melting material (50 mg., m.p. 183–200°) probably representing impure starting material, and 40 mg. of a more soluble substance. After one more recrystallization, this latter substance melted at 235–238°, undepressed upon admixture with benzylideneisodihydroiresin prepared according to (a). The infrared spectra of the two samples were identical.

Dehydrogenation of Iresin.—An intimate mixture of 1.04 g. of iresin and 2.0 g. of 5% palladized charcoal was heated for 2 hr. at 280–300° in an atmosphere of nitrogen. After cooling, the reaction mixture was extracted first with hot petroleum ether and then with ether and each extract was washed with sodium carbonate solution and with 20% sodium hydroxide solution. From the petroleum ether fraction there was obtained 118 mg. of neutral oil, no carbonate-soluble material and 45 mg. of phenolic solid (after acidification and ether extraction of the sodium hydroxide washings) with m.p. 150–164°. Similar examination of the ether fraction produced 90 mg. of hydrocarbon and 150 mg. of phenolic solid, m.p. 158–165°.

The two phenolic fractions were pooled, recrystallized twice from chloroform and then sublimed at 125° and 14 mm., whereupon a m.p. of 163.5–164.5° was observed. Identity was established by mixture melting point determination and infrared comparison with a specimen (m.p. 164–165°) of **1,5-dimethyl-2-naphthol (Vb)**[14] which was prepared by saponification of a sample of authentic benzoate Vc kindly furnished by Prof. O. Jeger, E.T.H., Zurich.

Anal. Calcd. for $C_{12}H_{12}O$: C, 83.69; H, 7.02. Found: C, 83.74, 83.63; H, 7.00, 7.01.

A 31-mg. sample of the phenol Vb was benzoylated in the manner described above for iresin dibenzoate (XXXVb) and purified by chromatography on neutral alumina.[29] The crystals (20 mg.) eluted with hexane–benzene (4:1) were recrystallized from methanol to afford prisms of the **benzoate Vc**, m.p. 152–153°, undepressed upon admixture with an authentic specimen[14] of the same m.p. The infrared spectra were identical.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84. Found: C, 82.29; H, 5.99.

The neutral oils from the original petroleum ether and ether extracts were pooled and distilled at 80–100° and 16 mm. The colorless distillate (122 mg.) was dissolved in 2 cc. of ethanol and treated with a hot ethanolic solution of 150 mg. of trinitrobenzene. The resulting yellow needles melted at 120–150° after recrystallization from ethanol, but could not be purified effectively by further recrystallization and the complex was decomposed, therefore, by passing a hot pentane solution of it through alumina. The regenerated hydrocarbon was partially crystalline and several recrystallizations from methanol and from pentane at −80° gave 6 mg. of colorless leaflets of **1,5-dimethylnaphthalene (Va)**, m.p. 77–79°. The undepressed (78–81°) mixture melting point with authentic[13] 1,5-dimethylnaphthalene (m.p. 81–81.5°), kindly provided by Dr. A. S. Bailey (Dyson Perrins Laboratory, Oxford University), and the coincidence of the infrared and ultraviolet absorption spectra established the identity of the dehydrogenation product.

Ozonolysis of Iresin.—A stream of dry oxygen containing 1.5% of ozone (flow rate *ca.* 180 cc./minute) was passed at −80° through a solution of 490 mg. of iresin dissolved in 60 cc. of ethyl acetate. A faint blue color appeared after 20 minutes and ozonization was continued for an additional 10 minutes. The excess ozone was removed *in vacuo*, 2 g. of 5% palladium–calcium carbonate catalyst was added and the mixture was shaken in an atmosphere of hydrogen for 15 minutes whereupon no more hydrogen was consumed and a starch–iodide test was found to be negative. The catalyst was filtered, the ethyl acetate solution was washed with sodium carbonate solution, dried, evaporated and crystallized (acetone–ether) yielding 160 mg. (31%)[30] of solid, m.p. 210–220°. Recrystallization from acetone–ether and from methanol–ether furnished colorless prisms of the **acetal XIXa** showing the following properties: m.p. 230–233°, $[\alpha]D$ −26° (*c* 0.56); $\lambda_{max}^{CHCl_3}$ 2.82, 3.00, 5.69 and 5.95 μ; λ_{max}^{EtOH} 240 mμ, log ϵ 3.90; $\lambda_{max}^{0.01\ N\ KOH}$ 274 mμ, log ϵ 4.03; bluish-gray color with alcoholic ferric chloride solution, negative Tollens (room temperature) and Schiff reactions.

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19; mol. wt., 280. Found: C, 64.08, 64.22; H, 7.38, 7.06; neut. equiv. (titration with 0.1 *N* sodium hydroxide), 263.

Acetylation with acetic anhydride–pyridine and recrystallization from acetone–ether and from methanol–ether gave needles of the **enol acetate XIXb**, m.p. 149–151°, $[\alpha]D$ −20° (*c* 0.53), λ_{max}^{EtOH} 218 mμ, log ϵ 4.02, no free hydroxyl absorption in the infrared.

Anal. Calcd. for $C_{17}H_{22}O_6$: C, 63.34; H, 6.88; acetyl, 13.35. Found: C, 63.46; H, 6.72; acetyl, 13.75.

A 40-mg. sample of the above enol acetate dissolved in 5 cc. of 80% aqueous methanol containing 50 mg. of potassium bicarbonate was kept at room temperature for 4 days. The methanol was removed under reduced pressure and the remaining aqueous phase was extracted with chloroform. Evaporation of the washed and dried chloroform extract left 36 mg. of crystals which melted at 232–234° after recrystallization from methanol–ether and were shown to be identical with the acetal XIXa by the usual criteria.

Acetylideneiresin (XXI).—A mixture of 2.66 g. of iresin, 100 cc. of acetaldehyde and 2.5 g. of freshly fused zinc chloride was set aside at room temperature overnight. During this time, large, well-formed prisms separated which were filtered (1.74 g., m.p. 272–275°) and washed with ether. The filtrate was evaporated to dryness, the residue was taken up in ethyl acetate, washed, dried, evaporated and recrystallized to yield an additional 0.5 g. of satisfactory material. Recrystallization from methanol, chloroform–ethyl acetate and from acetone afforded large prisms, m.p. 283° (with variable, earlier sintering), $[\alpha]D$ + 64° (*c* 1.0).

Anal. Calcd. for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27. Found: C, 69.96; H, 8.25.

The relative insolubility of the acetylidene derivative and the ease with which it crystallizes would recommend it for the isolation of iresin from crude concentrates or mother liquors.

Ozonolysis of Acetylideneiresin (XXI).[18]—The ozonolysis of 825 mg. of the acetylidene derivative was carried out as described above for iresin itself except that a mixture of 50 cc. of chloroform and 250 cc. of ethyl acetate was used and the reaction extended over a 1.5-hr. period. The crude, semi-crystalline product (m.p. 140–210°) obtained upon concentration of the reaction mixture (after filtration of the palladium catalyst) was recrystallized from ethyl acetate–acetone and from acetone–methanol to give 275 mg. of colorless crystals of the **aldehyde XXII**, m.p. 222–225°, λ_{max}^{Nujol} 5.72–5.75 μ, λ_{max}^{EtOH} 233 mμ, log ϵ 3.92; $\lambda_{max}^{0.01\ N\ KOH}$ 272 mμ, log ϵ 3.72; positive Tollens and ferric chloride reactions.

Anal. Calcd. for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46. Found: C, 62.76; H, 7.47.

A 53-mg. sample of the acetylidenealdehyde XXII was heated on the steam-bath for 3 hr. with 30 cc. of dioxane and 10 cc. of 0.2 *N* sulfuric acid, neutralized with barium carbonate and filtered. Evaporation to dryness and isolation with chloroform furnished 50 mg. of a crystalline residue which yielded 22 mg. of prisms, m.p. 230–234° after recrystallization from ethyl acetate–ether. The m.p. was depressed to 195–210° when this substance was mixed with the starting aldehyde XXII but remained unchanged when the compound was mixed with the cyclic acetal XIXa. Infrared spectral examination confirmed the identity.

Chromium Trioxide–Pyridine Oxidation of Iresin.—Iresin (3.8 g.) was added at 0° to the complex[19] derived from 4.0 g. of chromium trioxide and 100 cc. of pyridine and the mixture was kept at room temperature for 6 hr. whereupon 15 cc. of methanol was added. After 3 hr., the mixture was evaporated to dryness at 40° and 1 mm. and the dark red residue was extracted with ethyl acetate. The latter was

(29) All of the alumina used in this work was freed of alkali and reactivated (*cf.* J. v. Euw, A. Lardon and T. Reichstein, *Helv. Chim. Acta*, **27**, 1292 (1944)) in the following manner. Commercially available alumina (Alcoa, grade F-20), which showed a strongly alkaline reaction, was heated under reflux for 24 hr. with ethyl acetate, filtered and dried at 110°. The alumina was then washed continuously (Soxhlet extractor) for 48 hr. with hot water and then for 24 hr. with methanol. After drying at 110°, the alumina was reactivated at 180–190° for 30 minutes whereupon it exhibited activity I–II (H. Brockmann and H. Schodder, *Ber.*, **74**, 73 (1941)) and was found to be neutral.

(30) On a larger scale (*e.g.*, 2.90 g. of iresin), the yield was reduced to 22%.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

washed with dilute sulfuric acid, 10% sodium bicarbonate solution, water, dried and evaporated. The resulting gum (2.76 g.) was chromatographed on 85 g. of alumina[29] and led to two crystalline products.

Elution with benzene produced 350 mg. of solid (m.p. 127–137°) which was recrystallized successively from methanol, benzene–ether and ethanol to give colorless plates of the **13-nor-3-ketone XXVI**, m.p. 146–148°, $[\alpha]D$ +74° (*c* 0.43); λ_{max}^{EtOH} 224 mμ, log ε 4.11; $\lambda_{max}^{CHCl_3}$ 5.65 (lactone), 5.82 (ketone) and 5.90 μ (double bond[2]).

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74. Found: C, 71.71, 71.87; H, 7.74, 7.76.

The 2,4-dinitrophenylhydrazone of the nor-ketone XXVI, prepared by the acetic acid method,[31] was purified by chromatography on alumina and eluted with benzene–chloroform (1:1). Recrystallization from acetic acid and from ethanol gave fine yellow needles, m.p. 188–191°, $[\alpha]D$ +178° (*c* 0.80); $\lambda_{max}^{CHCl_3}$ 364 mμ,[20] log ε 4.34; $\lambda_{max}^{CHCl_3}$ 3.00 (NH), 5.67 (lactone) and 5.90 μ (double bond[2]).

Anal. Calcd. for $C_{20}H_{22}N_4O_6$: C, 57.96; H, 5.35; N, 13.52. Found: C, 57.93; H, 5.34; N, 13.48.

The later benzene and benzene–chloroform (9:1) eluates from the original chromatogram furnished 725 mg. of crystals (m.p. 150–160°) which were subjected to recrystallization from acetone–ether, methanol and finally acetone. The resulting small prisms of the **hydroxy-aldehyde XVIIa** exhibited m.p. 164–166°, $[\alpha]D$ +39° (*c* 0.79); λ_{max}^{EtOH} 224 mμ, log ε 3.90; $\lambda_{max}^{CHCl_3}$ 2.82, 5.65, 5.82 and 5.90 μ, did not give a Tollens reaction at room temperature and did not form a trityl ether under conditions where iresin readily forms a monotrityl ether (XXVc).[22] No formaldehyde was produced under the basic conditions employed successfully with icterogenin,[21] thus excluding structure XXVIIIa.

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63. Found: C, 67.74; H, 7.73.

A small sample (21 mg.) of the hydroxy-aldehyde XXVIIa was treated with 4 mg. of sodium borohydride[7] in ethanol solution and was then processed as described above in the reduction of iresin. Recrystallization from acetone–ether led to 16 mg. of dihydroiresin (XXIX),[2] m.p. 142–146°, diacetate,[2] m.p. 208–210°.

The presence of the alcoholic function in the hydroxy-aldehyde XXVIIa was demonstrated by the formation of the **benzoate XXVIIb**, which was recrystallized from methanol and from acetone–ether, m.p. 193–195°, $[\alpha]^{16}D$ −45° (*c* 0.96).

Anal. Calcd. for $C_{22}H_{24}O_5$: C, 71.72; H, 6.57. Found: C, 71.95; H, 6.53.

The hydroxy aldehyde was converted into the **2,4-dinitrophenylhydrazone** by the acetic acid procedure[31] and crystallized from ethanol as orange-yellow prisms, m.p. 274–278° dec., $[\alpha]D$ +19° (*c* 0.95), $\lambda_{max}^{CHCl_3}$ 354 mμ,[20] log ε 4.12, $\lambda_{max}^{CHCl_3}$ 3.00, 5.67 and 5.90 μ.

Anal. Calcd. for $C_{21}H_{24}N_4O_7$: C, 56.74; H, 5.44; N, 12.61. Found: C, 56.76; H, 5.59; N, 12.86.

Constitution of Samidin, Dihydrosamidin and Visnadin[1]

BY ERIC SMITH, NORMAN HOSANSKY, W. G. BYWATER AND EUGENE E. VAN TAMELEN

RECEIVED OCTOBER 22, 1956

Analytical and degradative evidence have been obtained which indicate the structure XIII for samidin (R = —CH=C-$(CH_3)_2$), dihydrosamidin (R = —$CH_2CH(CH_3)_2$) and visnadin (R = $CH(CH_3)CH_2CH_3$), potent vasodilatory agents isolated from the "visnagan" fraction of *Ammi visnaga*.

Ammi visnaga L. (bishop's weed), a plant indigenous to the Mediterranean regions, has been used in Egypt for centuries as a home remedy and spasmolytic. That the seeds contain biologically active substances other than the chromones khellin and visnagin[2] has been shown by Samaan,[3] whose "visnagan" fraction (the oil remaining after removal of all crystalline material) evidenced considerable vasodilatory activity. Visnagan was subsequently investigated by Cavallito and Rockwell,[4] who obtained, through chromatography on silica, a glassy solid to which the formula $C_{22}H_{26}O_7$ was ascribed. In repeating the chromatographic procedure, Smith, Pucci and Bywater[5] were able to secure two crystalline substances, designated as RI-778 (visamminol)[6] and RI-832. More recently,[5b] refined chromatographic techniques allowed isolation from the visnagan fraction of six crystalline components, of which RI-860, the so-called "yellow body," and visamminol did not possess biological activity in the test employed. The three remaining substances, all colorless and optically active, were strongly vasodilatory and consequently chemical investigations were initiated.

Elemental analyses indicated the molecular formula $C_{21}H_{22}O_7$ for substance RI-870 (m.p. 134–5°), which has been given the name *samidin*. RI-832 (m.p. 85–8°), called *visnadin*, and dihydro-RI-870 (m.p. 111–13°) are isomers possessing the formula $C_{21}H_{24}O_7$. The relationship between samidin and dihydro-RI-870 is more than empirical: the former substance absorbed one mole of hydrogen over platinum, giving rise to the latter. Therefore, dihydro-RI-870 may be properly designated *dihydrosamidin*.

The ultraviolet absorption spectra of all three substances (Table I) coincide at the maximum 323–324 mμ and at the minimum 264 mμ and are otherwise similar except that samidin absorbs strongly at lower wave lengths.

Comparison of ultraviolet curves with those of authentic chromones and coumarins provided at the outset strong evidence for the presence of a 7-oxygenated coumarin chromophore, an assignment

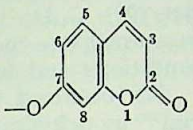
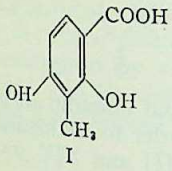
Dihydroxanthotoxin	330	4.01	274	3.45

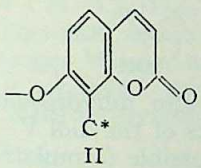
supported by the alkaline fusion results described below.[7]



Maintenance of a samidin-alkali melt at 230° for 30 minutes led to the formation of a substance $C_8H_8O_4$, m.p. 213–214° dec., which, yielding 2-methylresorcinol on thermal decarboxylation, subsequently was identified by infrared spectral comparison as 3-methyl-β-resorcylic acid (I).[8] Since samidin itself is not an acid, the carboxyl group present in the methylresorcylic acid must be masked, and, by incorporating the lactone moiety known to be present, the only logical[9] skeleton which emerges is II, where the starred carbon represents the actual or potential methyl group of the basic fusion product.



I



II

In order to continue the structural argument, it is necessary to describe certain hydrolysis operations and the study of the resulting products. In titration experiments, two equivalents of alkali were consumed by each of the coumarins at room temperature, whereas at reflux, three equivalents were used up. Apparently one equivalent is required for opening of the lactone ring; the remaining two serve to liberate volatile carboxylic acids, all of which were isolated and identified At the higher temperature, samidin surrenders senecioic acid, whereas *l*-methylethylacetic acid and isovaleric acid are obtained from visnadin and dihydrosamidin, respectively. In addition, one mole of acetic acid accompanies, in each case, the five-carbon acid. These findings, it may be mentioned in passing, define the structural difference between samidin and dihydrosamidin.

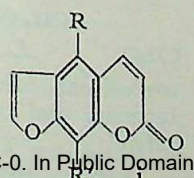
It seemed most likely, in light of the above results, that the trio of new natural products were diesters, and isolation of a glycol with the anticipated composition $C_{14}H_{14}O_5$ was indicated as a logical move. When a solution of samidin or visnadin in *ethanolic* potassium hydroxide was refluxed, an optically active substance III formed which gave, however, an analysis corresponding to the formula $C_{16}H_{18}O_5$. This same product resulted from the action of ethanolic hydrochloric acid on the parent material. Moreover, when the basic hydrolysis was carried out in *methanolic* base, a different product IV, having the composition $C_{15}H_{16}O_5$, was obtained; *and it became clear that solvent had been incorporated into the system during the saponification step.* Neither samidin nor visnadin shows the presence of alkoxyl in the Zeisel determination, and the fact that III and IV possess one ethoxyl and one methoxyl, respectively, confirms this interpretation.

The desired C_{14}-diol (V) was obtained in two ways. Either aqueous alkaline hydrolysis of samidin or ether cleavage of III with concentrated hydriodic acid afforded the crystalline, optically active product, the glycol nature of which was confirmed by the preparation of a diacetate. The hydriodic acid step is very facile in that it is completed in a matter of minutes at room temperature, and the preparation of the diol by this means is preferable to the direct, aqueous alkaline hydrolysis.

The ultraviolet spectra of all these transformation products were similar to those of the parent coumarins, indicating that the chromophores had been unmodified in any major respect during the hydrolysis steps.

Sufficient evidence for a unique structure assignment was provided by a more detailed chemical investigation of the ethanolysis product III, which appears to be identical with the "ethylkhellactone" obtained by Spaeth, *et al.*,[10a] through alkaline hydrolysis of crude *Ammi visnaga* extracts. The analogous "methylkhellactone" and "khellactone" (diol V) were studied more recently by Schmid, *et al.*[10b] Although the latter group of investigators did not advance definite structures for the naturally occurring parent coumarins, they did establish the same structures independently deduced by us for the products III, IV, V and XI. Presented below are our experimental findings and an abbreviated version of the arguments which led to the structural assignments.

First of all, none of the coumarins secured in the entirety of this investigation gave a coloration with ferric chloride and consequently none is phenolic. Substance III was expected to be the monoether of a glycol, and this presumption was confirmed by the preparation of a monoacetate. Since the fifth oxygen in III did not reveal itself by any detectable reactivity and since the parent coumarins bear no small alkyl group attached to oxygen, the members of this group must be *cyclic ethers*, a conclusion which, in view of the apparent absence of an excess of double bonds over those in the coumarin ring



1

(7) The observation that each of the three substances dissolves on warming in alcoholic alkaline solution with the formation of a deep yellow color is in keeping with the coumarin formulation (E. Spaeth and H. Schmid, *Ber.*, **73B**, 1309 (1940)).

(8) The authors are indebted to Dr. J. W. Hinman, The Upjohn Co., for supplying the 3-methyl-β-resorcylic acid and 2-methylresorcinol.

(9) Xanthotoxin (i, R = H, R′ = OCH_3), on basic fusion, affords pyrogallol-4-carboxylic acid (H. Thoms, *Ber.*, **44**, 332 (1911)); bergapten (I, R = OCH_3; R′ = H) is reported to yield phloroglucinol (C. Pomeranz, *Monatsh.*, **12**, 379 (1891)).

(10) (a) E. Spaeth, W. Gruber and O. Matzke, *Canadian J. Chem.*, **31**, 715 (1953); (b) W. Benzce, O. Halpern and H. Schmid, *Experientia*, **12**, 137 (1956); (c) a similar finding was reported by Schmid, *et al.* (ref. 10b).

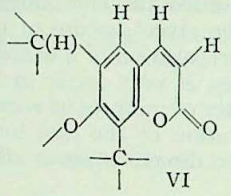
(*vide infra*), agrees with the demands of the molecular formulas. Finally, none of these substances gives indication of aldehydic or ketonic properties, hence they are probably not hemiacetals or hemiketals.

The nature of three additional carbon atoms became apparent when it was observed that alkaline permanganate oxidation of ether III yielded acetone—a $(CH_3)_2C-O-$ grouping is necessarily present.[10c]

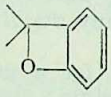
Hydrogenation of III by means of palladium-on-charcoal in glacial acetic acid led to the *dihydro product*, the ultraviolet spectrum of which indicated saturation of the 3,4-double bond of the coumarin ring. The new substance was oxidized with fuming nitric acid; succinic acid was identified as one of the products, a finding which indicates lack of substitution at the 3- and 4-positions of the parent ring system.[11]

By utilizing these results we see that partial structure II may now be expanded to VI, which is potentially tricyclic.[12]



VI

Now, any four-membered ether of the type VII is untenable because, being a benzyl ether, ring cleav-

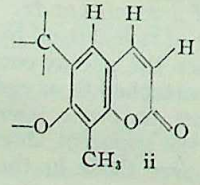


VII

age by hydrogen iodide during the conversion of III to V would be expected; on this basis the diol should be phenolic, but it is not. Also, 3-hydroxy-2,3-dihydrobenzofurans may be excluded from consideration, since they have been reported[13] to dehydrate spontaneously and give the benzofuran. Finally, by taking into account the observation that the diol consumes in an acidic medium just one mole of periodate[10c] without liberation of volatile aldehydes, we find that only one formulation, namely, IX, serves suitably as the structure of the diol.

(11) The spectral character of the natural coumarins offered no evidence for oxygenation at either of these positions, and it is apparent that hydroxyl attachment is excluded. Because of the number of oxygens which must therefore be placed on the few carbon atoms remaining after allowance is made for those in the coumarin ring and those in the $(CH_3)_2C-O-$ portion, the two methylene groups of the succinic acid *cannot* arise from any portion of the molecule other than the 3- and 4-positions of dihydro-III.

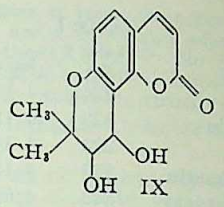
(12) Partial structure ii, which is the one following most naturally



ii

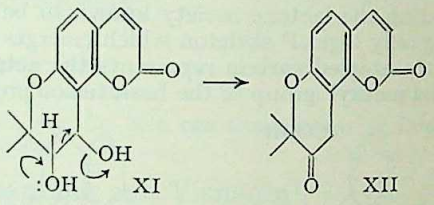
from the basic fusion results, can be dismissed at this stage in that it is not possible to develop from it a structure for diol V which has no more than one hydroxyl or ethereal oxygen per carbon atom.

(13) R. Stoermer and W. Koenig, *Ber.*, **39**, 1496 (1906).



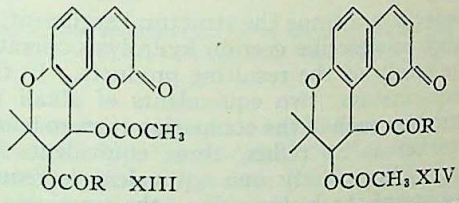
IX

Spaeth, Gruber and Matzke[10a] reported that the monoethyl ether III yielded, through the action of phosphorus pentoxide or hydrogen bromide in acetic acid, a substance (X), $C_{14}H_{12}O_4$, which was optically inactive, consumed two moles of hydrogen under catalytic conditions and formed a *p*-nitrophenylhydrazone. We obtained what appears to be the same material[10c] by dehydrating the diol V in hydrobromic–acetic acid and noted in addition that compound X gives no aldehyde or phenol color tests and displays an ultraviolet absorption which is very similar to that of its precursor. These observations provide support for the proposal IX, in that XII, a completely satisfactory expression for ketone X, arises logically from the diol structure by the process (XI → XII).[14]



XI XII

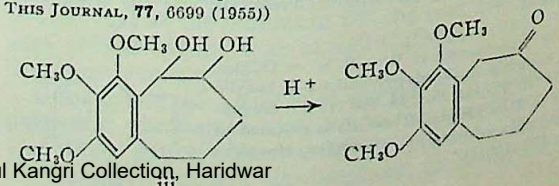
Samidin, dihydrosamidin and visnadin are mixed diesters of the diol V. In order to distinguish the two possible formulations XIII and XIV, we con-



XIII XIV

sider now the selective solvolysis of a representative, samidin. When subjected to the action of excess potassium hydroxide in ethanol *at room temperature*, this substance was converted to a new product (XV), $C_{21}H_{24}O_6$, which must have arisen through loss of acetic acid and incorporation of solvent into the molecule. The general nature of the change was confirmed by Zeisel determination (one $-OC_2H_5$), the apparent absence of alcoholic hydroxyl in XV and the liberation of senecioic acid on refluxing XV with alcoholic alkali. The incorporation of ethoxyl during hydrolysis becomes clear with the development of the diester structures pictured above. It is well recognized that certain *benzyl esters* suffer O-alkyl cleavage in either basic or

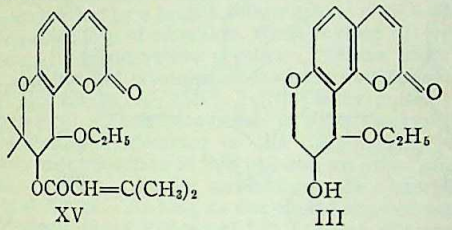
(14) Glycol iii rearranges to the β-benzsuberone (G. N. Walker, THIS JOURNAL, **77**, 6699 (1955))



CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

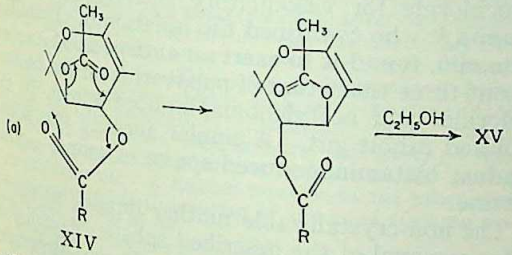
Digitized by Arya Samaj Foundation Chennai and eGangotri

acidic alcohol solution. Although not observed with esters of benzyl alcohol itself, such cleavage is facilitated by alkyl substitution on the benzyl carbon, attachment of the benzyl oxygen to a ring (*e.g.*, α-tetralol) and the presence of *o*- or *p*-electron-donating groups on the aromatic ring.[15] All three of these features are present in the structural type under consideration. *If* the loss of acetoxyl involves *simple* replacement by ethoxyl, structure XIII (R = CH=C(CH$_3$)$_2$) must represent samidin, and dihydrosamidin and visnadin may be assigned the structure XIII (R = CH(CH$_3$)C$_2$H$_5$), respectively. The partial solvolysis product XV of samidin and the monoether III may then be represented by the formulas

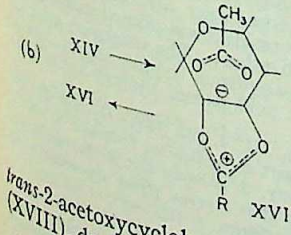


XV III

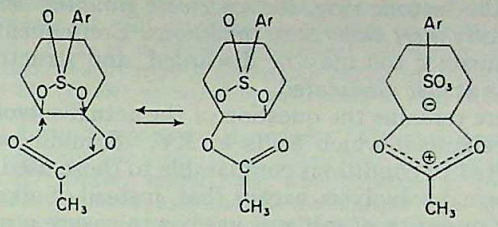
However, before considering the structural question settled, we must examine the possibility that the monoester XV might have come, not from XIII, but—by way of over-all acyl migration—from the alternate structure XIV (R = CH=C(CH$_3$)$_2$) for the parent natural product. There are several distinct mechanisms by which such a change might be realized. In the first (a), a concerted, twofold migration is envisioned which leads to inversion at



both asymmetric centers and interchange of the acetyl and the senecioyl groups. Mechanism b, in which starting diester XIV is transformed to the ion pair XVII and then collapses to the isomeric diester, is similar to (a) and may be indistinguishable from it. In connection with the possible contributions of *either* mechanism a or b, it is pertinent that a closely similar case has been investigated in some detail. Winstein and Heck,[16] studying *d*-

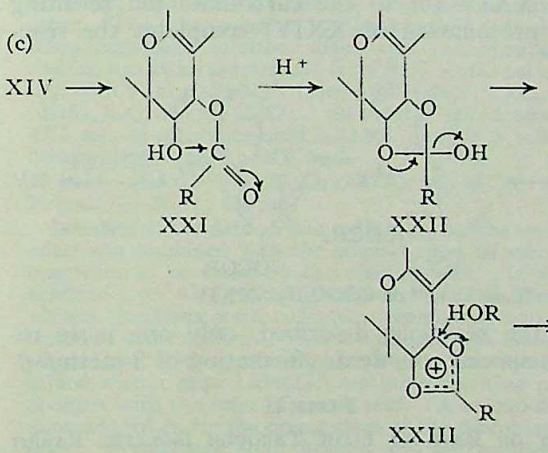


trans-2-acetoxycyclohexyl *p*-toluenesulfonate (XVIII), demonstrated the absence of any internal rearrangement phenomenon during solvolysis, thereby vitiating the case for the process (XIX → XVIII) or (XVIII ⇄ XX); the absence of this type of change[17] was considered as due to "the



special nature of the neighboring acetoxy group."[16] Application of these findings to the case under consideration seems direct and convincing; we therefore consider mechanisms a and b inoperative.

Still a third route can be envisioned for the hypothetical change XIV → XV. In (c), a selective removal of acetyl from XIV yields initially the monoester XXI which then cyclizes, as the first stage in an acyl migration, to XXII. The latter intermediate could advance to the isomeric mono-



ester, which in itself would be incapable of yielding an ether, or it could undergo alcoholysis, possibly *via* the mesomeric cation XXIII, and finally afford structure XV. The solvolysis rate data on samidin can be marshalled so as to exclude convincingly path c. Bearing in mind that the ester group in XV and the acetate substituent in XIV would possess the same steric environment, one concludes that the rate difference in hydrolysis of both ester functions should approximate that between simple esters of acetic acid and senecioic acid. Although this specific information apparently has not been recorded, rough calculations, using accessible rate data,[18] show that ethyl acetate and ethyl crotonate differ in basic hydrolysis rate by a factor of only about ten.

The difference between the cases XIV and XV should be of the same order of magnitude. However, this expectation is contrary to fact, in that samidin, in the presence of excess alcoholic alkali, consumes

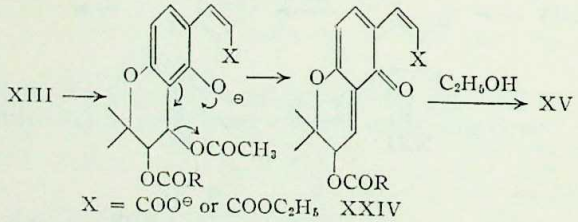
at room temperature almost two moles of base in six minutes without further uptake after 4 hr. These are the conditions used to prepare XV; therefore, the two moles are used to discharge acetoxyl and to open the lactone ring, *the senecioate grouping being essentially inert under these conditions*. Consequently mechanism c too may be discarded, and structure XIII is at last vindicated.

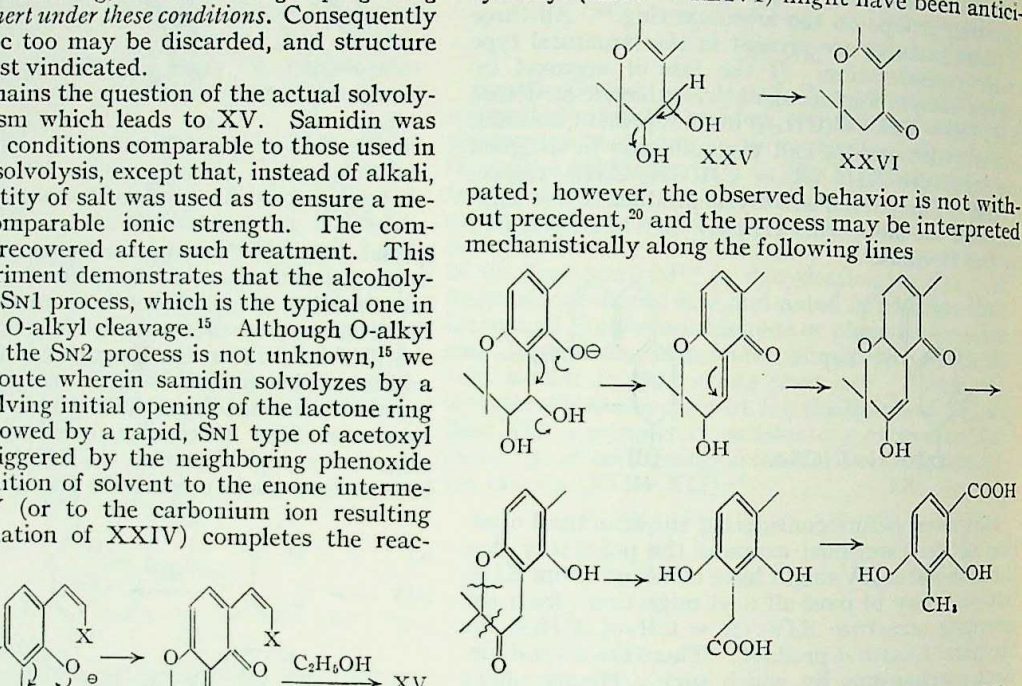
There remains the question of the actual solvolysis mechanism which leads to XV. Samidin was subjected to conditions comparable to those used in the normal solvolysis, except that, instead of alkali, such a quantity of salt was used as to ensure a medium of comparable ionic strength. The compound was recovered after such treatment. This simple experiment demonstrates that the alcoholysis is not an SN1 process, which is the typical one in benzyl ester O-alkyl cleavage.[15] Although O-alkyl cleavage by the SN2 process is not unknown,[15] we prefer the route wherein samidin solvolyzes by a process involving initial opening of the lactone ring by base, followed by a rapid, SN1 type of acetoxyl expulsion triggered by the neighboring phenoxide anion. Addition of solvent to the enone intermediate XXIV (or to the carbonium ion resulting from protonation of XXIV) completes the reaction.[19]



X = $COO^{\ominus}$ or $COOC_2H_5$ XXIV

Of the reactions described, only one more requires special comment: formation of 3-methyl-β-resorcylic acid in the basic fusion of samidin, an unusual result in that *a partially oxidized carbon atom is converted to methyl*.

Base-catalyzed dehydration with β-elimination of hydroxyl (XXV → XXVI) might have been anticipated; however, the observed behavior is not without precedent,[20] and the process may be interpreted mechanistically along the following lines



Pharmacology.—Visnadin and dihydrosamidin were compared with khellin and papaverine hydrochloride for vasodilatory activity (Table II). Gomes,[21] who confirmed the isolation of crystalline visnadin, found it to exert an antispasmodic action about three times that of papaverine on the barium chloride- and acetylcholine-induced spasm of the isolated rabbit gut. A similar activity was found against histamine-induced spasm of guinea pig intestine.

The non-crystallizable mother liquors remaining after removal of the described substances still contained considerable activity. Their ultraviolet spectra, which were identical with those of the compounds described above, show that this activity probably was derived from material of similar chemical structure. These mother liquors are being investigated further.

TABLE II

EFFECT ON RATE OF FLOW THROUGH ISOLATED RABBIT HEART[a]

Compound	Concentration	Rate of flow Control, ml./2 min.	Sample ml./2 min.	Increase, %	Relative potency
Khellin	1:60,000	26.5	37	40	1

Experimental[22]

Purification of Visnagan.—About 10 lb. of visnagan prepared according to Samaan[3] was mixed with 6 gal. of pentane and this solution extracted repeatedly with 80% alcohol, using 6, 2 and 2 gallons, respectively. The alcoholic layers were separated, washed once with pentane and concentrated *in vacuo*. The residue was diluted with 2 gal. of water and extracted with ether. The combined ether extracts were dried over anhydrous sodium sulfate, filtered and gaseous hydrochloric acid passed through the solution

(19) The arguments leading to structure XIII render untenable the structures of samidin, dihydrosamidin and visnadin proposed earlier by E. Smith, N. Hosansky and W. G. Bywater.[5b] The stereochemistry of XIII is not known but is arbitrarily designated on account of its kinship to *trans* (*e.g.*, XVI).

under cooling as long as oxonium salts precipitated. The ether solution was filtered, washed acid-free with sodium carbonate solution, then washed with water, dried over anhydrous sodium sulfate and concentrated; 160 g. of clear brown oil remained. This fraction had an optical activity of +22°.

Chromatography of Visnagan.—Seven pounds of the refined oil was diluted with 5 lb. of ether and mixed into 7 lb. of Filter-cel. The mix was air-dried, put through a screen and then added to a column containing 127 lb. of silica (J. F. Smith) which had previously been covered with pentane. The column was developed and cut, according to the following scheme: (1) Fifteen gallons of pentane which eluted 690 g. of oil not further investigated; (2) fifty gallons of an ether-pentane mixture containing 10 to 20% ether. This eluted 59 g. of a non-crystalline oil with an optical activity of +55°. The oil, rubbed up with alcohol, gave 24 g. (RI-860) of crystals which, after repeated recrystallizations from alcohol, melted at 285–287°, $[\alpha]_D$ +69°. This fraction was followed by a bright yellow eluate which on concentration gave 113 g. of oil which, when rubbed up with ether, gave 10 g. of bright yellow crystals ("yellow body") melting, after repeated crystallizations from methanol, at 176–178°, λ_{max} 293 mμ (E^1_1 1580). (3) Thirty gallons of ether pentane (1:3). The eluate began to show the typical ultraviolet absorption spectrum of the dihydrofurocoumarins; an absorption minimum at 268 mμ and an absorption maximum at 320 mμ. At the same time, the absorption was taken at 220 mμ. As long as the eluate showed an absorption ratio of 322 mμ:222 mμ of 1–1.7:1 and 322 mμ:262 mμ of 2–4:1, it was collected for the preparation of *visnadin*. A total throughput of 75 gal. was collected, concentrated to 5 gal. and allowed to crystallize for a week in the ice-box. There were thus obtained 236 g. of crude visnadin, melting at 75–78° and having an optical activity of +12°, and 190 g. of oil with an optical activity of +10°. (4) The next fraction was collected until the ratio 322 mμ:220 mμ had risen to about 6:1. This fraction eluted *samidin*. It required about 30 gal. of ether–pentane (1:3) and 40 gal. of ether–pentane (3:7). The combined eluates were concentrated to 6 gal. and allowed to crystallize; 320 g. of crude samidin, with a melting point 127–135° and an optical activity of +20°, and 220 g. of a non-crystallizable oil were recovered from this fraction. (5) At this point the ultraviolet absorption spectrum of the eluate showed a distinct shift of the minimum from 262 to 270 mμ and of the maximum from 320 to 300 mμ. Further elution with ether–pentane (1:1) resulted in the isolation of *visamminol*. Fifty gallons of eluate was needed for total removal and gave, on concentrating to 5 gal., 215 g. of visamminol and 200 g. of non-crystallizable oil. A further increase in the ether concentration resulted in the elution of 110 g. of *visnagin* and an additional 270 g. of oil.

Visnadin.—The crude fraction (236 g.) was dissolved in 500 ml. of ether, charcoaled, 600 ml. of hexane was added; the solution was concentrated to 600 ml. and allowed to crystallize. The 200 g. of visnadin so obtained was once more crystallized and gave 160 g. of white needles, m.p. 84–86°, $[\alpha]_D$ +9° (*c* 2.0) and +38° (*c* 1.0 in dioxane). In a volatile acid determination, 46.0 mg. yielded an amount of acid equivalent to 11.29 ml. of 0.02 *N* sodium hydroxide; calcd. for two acids, 11.75 ml.

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.95; H, 6.23. Found: C, 65.04; H, 6.19.

Dihydrosamidin.—The mother liquors of the visnadin recrystallizations were concentrated to half-volume and an additional small amount of impure visnadin was isolated. They were then taken down to dryness and rubbed up with 20 ml. of ether and allowed to crystallize in the ice-box; 6 g. of crystals was obtained which, when recrystallized from 90% methanol, gave 5 g. of pyramids, m.p. 117–119°, $[\alpha]_D$ +19° (*c* 1.0) and +63° (*c* 1.0 in dioxane). On volatile acid determination, 84.8 mg. used 22.08 ml. of 0.02 *N* sodium hydroxide; calcd. for two acids 21.86 ml.

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.95; H, 6.23. Found: C, 64.91; H, 6.09.

Samidin.—The 320 g. of crude samidin was repeatedly crystallized from alcohol to give 250 g. of pure material as cubes, m.p. 135–137°, $[\alpha]_D$ +26° (*c* 1.0) and +100° (*c* 1.0 in dioxane). In a volatile acid determination, 40.6 mg. used 9.99 ml. of 0.02 *N* sodium hydroxide; calcd. for two acids 10.51 ml.

Anal. Calcd. for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74. Found: C, 65.21; H, 5.53.

Hydrogenation of Samidin.—Twenty grams of samidin was dissolved in 200 ml. of alcohol and hydrogenated with 200 mg. of platinum oxide. After 1 mole of hydrogen was consumed, the hydrogenation was interrupted, the catalyst filtered off, and the alcoholic solution concentrated to 20 ml., 12 g. of substance crystallized out which, on recrystallization from 90% methanol, melted at 115–117°, $[\alpha]_D$ +16° (*c* 1.0); no mixed m.p. depression with natural dihydrosamidin.

Room Temperature Hydrolysis. Titration Experiments.—Samidin (59.8 mg., 0.154 mmole) and visnadin (45.6 mg., 0.117 mmole), respectively, were dissolved in 10.0 ml. of 0.25 *N* sodium hydroxide in alcohol and after time, *t*, at room temperature a 1.0-ml. aliquot was removed, diluted with 10 ml. of CO_2-free water and titrated with 0.025 *N* sulfuric acid, using phenolphthalein as indicator. A blank consisting of the alcoholic alkaline solution was titrated at the same time. After t = 6, 80 and 230 min., the moles of alkali consumed were for samidin 1.73, 2.23 and 2.19, and for visnadin 1.78, 2.10 and 2.11. The remainder of the solutions were then refluxed for 1 hr., cooled and again titrated as above. The total mole uptake for samidin was 3.06, for visnadin 3.25.

Samidin (5 g.) was dissolved in 45 ml. of ethanol and 45 ml. of 1 *N* sodium hydroxide in ethanol was added. The solution was allowed to stand at room temperature and its rotation taken every 10 min. The rotation increased for about 45 min., after which the solution was diluted with 1 l. of water, acidified with sulfuric acid and extracted with ether. The ether solution was backwashed with dilute sodium carbonate solution, dried and concentrated. The residue was twice crystallized from 80% methanol and gave 3 g. of XV, m.p. 91–93°, $[\alpha]_D$ +99° (*c* 0.9); λ_{max} 326 mμ (4.16), $\lambda_{min.}$ 264 mμ (3.42). On volatile acid determination 47.7 mg. of substance used 5.92 ml. of 0.02 *N* sodium hydroxide; calcd. for 1 acid 6.4 ml.

Anal. Calcd. for $C_{21}H_{24}O_6$ (372.4): C, 67.73; H, 6.50. Found: C, 67.81; H, 6.51.

Isolation of the Acid.—The sodium carbonate wash of the ether was combined with the original aqueous solution and concentrated *in vacuo* on the alkaline side. It was then acidified with 5 *N* sulfuric acid and steam distilled. Ten 100-ml. fractions were collected, neutralized and concentrated *in vacuo* to 50 ml. A 5-ml. aliquot was taken for the preparation of the *p*-phenylphenylacyl ester which was obtained with a m.p. 110–111°, no mixed melting point depression with the ester of acetic acid. A second 5-ml. aliquot was taken for the preparation of the *p*-bromophenacyl ester. Crystallized from hexane and recrystallized from aqueous alcohol, the ester melted at 84–86° and showed no mixed m.p. depression with authentic ester prepared from acetic acid.

Hot Ethanolic Alkaline Hydrolysis.—Twenty-five grams of samidin in ethanol was refluxed with 165 ml. of 2 *N* alcoholic sodium hydroxide for 1.5 hr. The orange colored solution was cooled, diluted with water, concentrated *in vacuo* to remove alcohol, acidified with concentrated sulfuric acid and extracted with ether. The ether was backwashed with sodium bicarbonate solution, dried and concentrated. Pentane was added to the concentrated solution to slight turbidity, whereupon crystallization occurred. The 7.4 g. (40% of theory) of III so obtained was repeatedly recrystallized from an ether–pentane mixture; m.p. 161–162°; $[\alpha]_D$ −59° (*c* 0.9), λ_{max} 325 mμ (4.15), $\lambda_{min.}$ 266 mμ (3.18). The same compound was obtained when either XV or visnadin or dihydrosamidin was used as starting material.

Anal. Calcd. for $C_{16}H_{18}O_5$ (290.3): C, 66.19; H, 6.25; OC_2H_5, 15.52. Found: C, 66.20; H, 6.11; OC_2H_5, 16.00.

Isolation of Acid.—The sodium bicarbonate wash of the ether solution was combined with the original water solution and concentrated on the alkaline side *in vacuo*, acidified and extracted thoroughly with ether. The ether was concentrated, after drying, to give a yellow, oily residue which distilled at 20 mm. at 160–180°. The distillate crystallized and was redistilled at atmospheric pressure. The fraction coming over at 190–193° was recrystallized from water; m.p. 68–69° (lit.[23] for senecioic acid 68–70°).

The *p*-toluidide was prepared over the acid chloride; m.p. 107–108° (lit.[23] 106–107°). *Anal.* Calcd. for C_{12}-

$H_{15}ON$: C, 76.15; H, 7.99; N, 7.40. Found: C, 76.20; H, 7.88; N, 7.26.

The *p*-phenylphenacyl ester was prepared in the usual way; m.p. 144.5–146°. *Anal.* Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.17. Found: C, 77.54; H, 5.76.

On hydrogenation with platinum oxide, the acid consumed 1 mole equivalent of hydrogen. The *p*-phenylphenacyl ester of the hydrogenated acid had a m.p. 76–77°; no depression on admixture with the ester of isovaleric acid. *Anal.* Calcd. for $C_{19}H_{20}O_3$: C, 76.98; H, 6.87. Found: C, 77.00; H, 6.49.

The acid isolated in the same manner from visnadin gave a *p*-phenylphenacyl ester melting at 69–70° (lit. for 1-α-methylbutyric acid, 70–71°)[24] and a *p*-bromphenacyl ester, m.p. 54–55° (lit.[24] 55°).

Acetate of III.—On acetylation with acetic acid anhydride in pyridine, 392 mg. of III gave, after crystallization from aqueous methanol, 385 mg. of monoacetate, m.p. 170–172°, $[\alpha]_D$ −40.8° (*c* 0.6%), λ_{max} 325 mμ (4.16), $\lambda_{min.}$ 264 mμ (3.22).

Anal. Calcd. for $C_{18}H_{20}O_6$ (332.3): C, 65.05; H, 6.07. Found: C, 65.23; H, 6.03; mol. wt. by Rast, 332.

Oxidation of III.—III (1.16 g.) was dissolved with slight warming in 1% sodium hydroxide solution. To the cooled solution a saturated solution of permanganate was added until the violet color persisted. After acidification the solution was steam distilled and the distillate precipitated with *p*-nitrophenylhydrazine. The hydrazone obtained (240 mg.) melted, after recrystallization, at 147–149°; no depression on admixture with *p*-nitrophenylhydrazone prepared from acetone.

Hydrogenation and Oxidation of III.—III (4 g.) was hydrogenated in 40 ml. of glacial acetic acid with 400 ml. of palladium-on-charcoal. The uptake was very slow, one mole equivalent being taken up after 9 hr. The catalyst was filtered off, the filtrate diluted with water and extracted with ether. The ether was backwashed with sodium carbonate solution, dried and concentrated. The residue was crystallized twice from ethyl acetate–hexane (1:2) to give 3.56 g. of the reduced product, m.p. 125–127°, $[\alpha]_D$ −11°, dissolving colorless in alcoholic alkali; λ_{max} 287 mμ (3.36), $\lambda_{min.}$ 261 mμ (2.81).

One gram of this substance was dissolved in ice-cold fuming nitric acid (d. 1.4) and allowed to stand at room temperature for 12 hr. The yellow solution was then heated on the steam-bath for 8 hr. and taken down to dryness. The residue was dissolved in dilute ammonia, the *p*H adjusted to 5.5 and the oxalic acid precipitated from the boiling hot solution with calcium chloride. The precipitate was filtered off and the filtrate concentrated *in vacuo*, acidified and extracted in a liquid–liquid extractor with ether. The ether deposited crystals on concentrating, which were collected and then sublimed *in vacuo*. The sublimate melted at 187–188° and did not give a m.p. depression on admixture with succinic acid; 25.6 mg. of substance used 21.2 ml. of 0.02 *N* sodium hydroxide; calcd. for succinic acid, 21.6 ml.

Hot Methanolic Alkaline Hydrolysis.—Twenty grams of samidin in 85 ml. of methanol was refluxed with 85 ml. of 2 *N* methanolic sodium hydroxide for 1.5 hr. The solution was then concentrated *in vacuo*, diluted with water, acidified and extracted with ether. The ether was backwashed with dilute sodium carbonate solution, water, dried and concentrated. The residue was crystallized from ether–pentane to give 6.48 g. (44%) of IV, m.p. 158–159°, $[\alpha]_D$ +14° (*c* 1.04), λ_{max} 328 mμ (4.18), $\lambda_{min.}$ 267 mμ (3.21).

Anal. Calcd. for $C_{15}H_{16}O_5$ (276.3): C, 65.19; H, 5.84; OCH_3, 11.23. Found: C, 65.46; H, 5.76; OCH_3, 11.17.

On acetylation, 400 mg. of IV gave, after recrystallization from methanol, 318 mg. of the monoacetate, m.p. 147–149°, $[\alpha]_D$ +18.4° (*c* 1.29), λ_{max} 324 mμ (4.17), $\lambda_{min.}$ 265 mμ (3.19).

Anal. Calcd. for $C_{17}H_{18}O_6$ (318.31): C, 64.14; H, 5.70. Found: C, 64.12; H, 5.83.

The same alcohol and acetate were obtained when the hydrolysis was conducted with methanolic hydrochloric acid.

Preparation of Diol V.—Eight hundred and eighty-four mg. of III was dissolved in 5 ml. of hydriodic acid (d. 1.70). After about 20 min., crystalline material began to separate out and was collected after standing 1 hr. After several crystallizations from acetone, 400 mg. of V was obtained, m.p. 180–182°, $[\alpha]_D$ +13° (*c* 0.7), λ_{max} 328 mμ (4.17), $\lambda_{min.}$ 265 mμ (3.16).

Anal. Calcd. for $C_{14}H_{14}O_5$ (262.3): C, 64.11; H, 5.38. Found: C, 64.16; H, 5.37.

V, acetylated in the usual way, gave after recrystallization from methanol, the diacetate, m.p. 161–163°, $[\alpha]_D$ −27° (*c* 0.69), λ_{max} 323 mμ (4.14), $\lambda_{min.}$ 263 mμ (3.21).

Anal. Calcd. for $C_{18}H_{18}O_7$ (346.3): C, 62.42; H, 5.24. Found: C, 62.54; H, 5.07; mol. wt., 344.8 (Rast).

The same substance was obtained when samidin was refluxed with aqueous sodium hydroxide. From 20 g., 7.7 g. of oil was recovered, which was chromatographed over alumina. The eluate obtained by developing with ether crystallized to give, after repeated crystallization from methanol, 2 g. of V, m.p. 183–184°, $[\alpha]_D$ +11°, no mixed m.p. depression with V prepared from III.

Anal. Found: C, 64.07; H, 5.40.

Dehydration of V.—V (200 mg.) was refluxed with 0.5 ml. of acetic acid and 0.5 ml. of concd. hydrobromic acid for 15 min. The solution was cooled, diluted with water and extracted into ether. The ether, after washing with sodium bicarbonate and water, was dried, evaporated to dryness and the residue crystallized from ethyl acetate. The product XII, after several crystallizations, melted at 156–157°, $[\alpha]_D$ 0 (*c* 2.0), λ_{max} 321 mμ (4.11), $\lambda_{min.}$ 263 mμ (3.45).

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.86; H, 4.95. Found: C, 68.54; H, 4.95.

Alkaline Fusion of Samidin.—Three and two-tenths grams of samidin was added in small portions to a sodium hydroxide–potassium hydroxide melt kept at 150–160°. The temperature was then raised slowly to 230° and kept at that temperature until the melt cleared. After cooling, the melt was dissolved in water, filtered, chilled in ice and acidified with concentrated hydrochloric acid. Insoluble flocculent material was filtered off and the filtrate extracted with ether. The ether gave, on concentration, 1.5 g. of amorphous residue.

This material was chromatographed on 20 g. of silica with benzene. The first benzene eluates gave, on concentration, 910 mg. of crystalline material, m.p. 213–214° with evolution of gas, λ_{max} 262 mμ (4.14), λ 297 mμ (3.65). Its infrared spectrum was indistinguishable from that of 3-methyl-β-resorcylic acid.

Anal. Calcd. for $C_8H_8O_4$ (168.1): C, 57.14; H, 4.80. Found: C, 56.92; H, 5.11; mol. wt. (Rast), 163.3.

Preparation of 2-Methylresorcinol.—One hundred and sixteen mg. of the acid was melted in a sealed tube at 220° and kept at that temperature until gas evolution stopped. The cooled contents were dissolved in benzene and chromatographed on silica. From the first benzene eluates 76 mg. of crystals was isolated, sublimed in high vacuum at 60–70° to give pure material melting at 117–119°. Its infrared spectrum was identical with that of authentic 2-methylresorcinol.

Anal. Calcd. for $C_7H_8O_2$ (124.1): C, 67.73; H, 6.50. Found: C, 68.00; H, 6.42; mol. wt. (Rast), 131.

Periodate Oxidation of V.—Twelve and nine-tenths mg. (0.049 mmole) of diol V was dissolved in 5.0 ml. of 0.098 molar periodic acid in 80% methanol (distilled from zinc–sodium hydroxide). The analysis was standard, excess arsenite being titrated by 0.00946 molar iodine.

Time, hr.	HIO_4 consumed, mole
0.17	0.35
0.50	0.40
2.50	0.65
12.50	1.00
17.00	0.98
21.00	1.00

Dimedon was employed to detect any volatile aldehyde. However, apart from a small amount of amorphous material, no derivative was obtained.[25]

The Preparation of Glycamines[1]

BY FRED KAGAN, M. A. REBENSTORF AND RICHARD V. HEINZELMAN

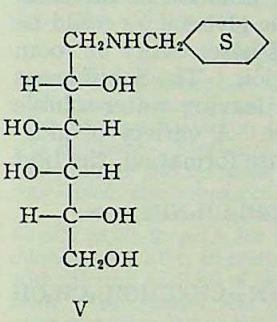
RECEIVED FEBRUARY 8, 1957

Large quantities of pure glycamines were conveniently prepared by the reductive alkylation of ammonia or by the hydrogenolysis of N-benzylglycamines. To ensure high quality products, purification of the glycamines from either process should be carried out through their Schiff bases.

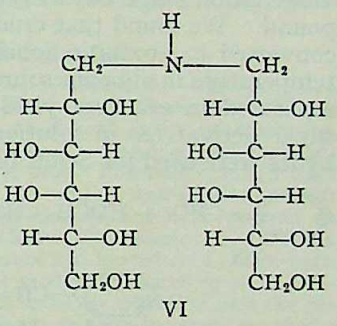
Although 1-amino-1-deoxy sugars, the glycamines, have been known for over fifty years, a good preparative method which is practical for the synthesis of large quantities of high purity material is not available. The need for large quantities of galactamine of greater than 95% purity as a resolving agent in a synthesis of pantothenic acid[2] prompted us to reinvestigate the preparation of this class of compounds.

Glycamines previously have been prepared by the chemical reduction of sugar oximes,[3-5] by electrolytic, chemical and catalytic reduction of glycosylamines[5] and by the reductive alkylation of ammonia with a sugar.[6-8] The chemical and electrolytic reduction methods were of little interest because they were not readily adaptable to large-scale operations. The Flint and Salzburg[7] method yielded impure sirups unsuitable for our purposes. Wayne and Adkins[8] prepared glucamine in low yield by the reduction of glucose in methanolic ammonia. Holly and co-workers[9] synthesized glycamines of approximately 80% purity by the reductive alkylation of liquid ammonia with sugars. None of these methods was suitable for the large-scale production of pure sugar amines.

One route to glycamines which we investigated involved the hydrogenolysis of an N-benzylglycamine. For example, N-benzylgalactamine (III), prepared in 64% yield by the reductive alkylation of benzylamine with galactose, gave galactamine (IV) in 77% yield when hydrogenolyzed in the presence of palladium-on-charcoal. An attempt to simplify the process by carrying out the two hydrogenations consecutively in the same vessel without isolating the intermediate N-benzylgalactamine yielded an impure product, a major constituent of which proved to be cyclohexylmethylgalactamine (V). Structure assignment was made on

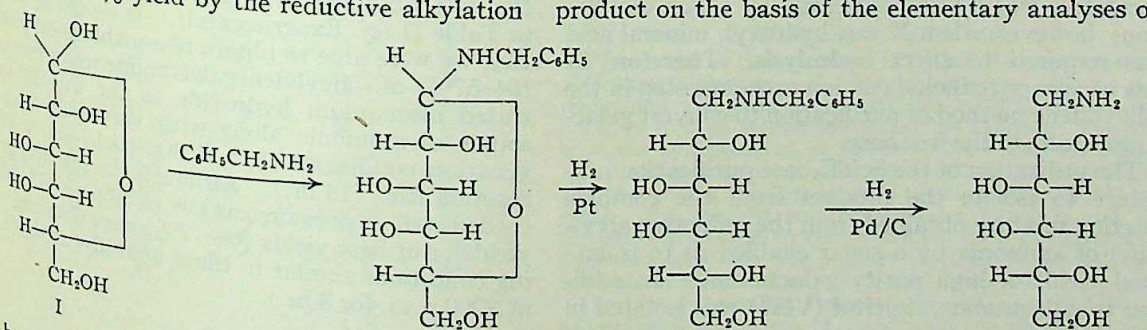


V



VI

the basis of elementary analysis (6 more hydrogens than N-benzylgalactamine), the absence of characteristic phenyl absorption in the ultraviolet and by the neutral equivalent. One attempt to carry out the reductive alkylation and hydrogenolysis steps simultaneously in the presence of a mixed catalyst (platinum and palladium-on-charcoal) yielded another new sugar amine, didulcitylamine (VI). The structure VI has been assigned tentatively to the product on the basis of the elementary analyses of both the free base and the hydrochloride and on the basis of the neutral equivalent.



I II III IV

In several experiments, the glycamines obtained by the hydrogenolysis procedure were difficult to purify. It seems likely that didulcitylamine and cyclohexylmethylgalactamine, were the main contaminants. To ensure a high quality product, it is recommended that the crude hydrogenolysis mixture be purified through either the benzylidene or salicylidene derivative as described below.

Although the hydrogenolysis of an N-benzylglycamine was a satisfactory low pressure laboratory procedure for the preparation of glycamines, cata-

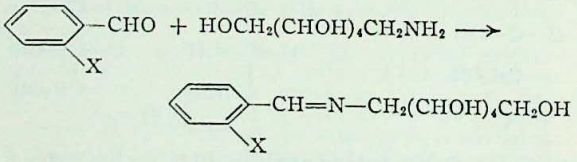
lyst costs and the multiplicity of steps made it unattractive for large-scale preparative work.

Roux[2] has reported the preparation of benzylideneglucamine and its hydrolysis by steam distillation. He suggested that this procedure could be used for the purification of glucamine; however, no experimental details were given. Wayne and Adkins[3] prepared benzylideneglucamine by heating glucamine with benzaldehyde at 180–190° They obtained a dark reaction mixture from which the benzylidene derivative was isolated by fractional crystallization. The low over-all yield of glucamine in this case may have been due in part to the vigorous conditions used in the isolation of the product. These investigators stated that in their opinion the difficulty in obtaining glucamine was not in the hydrogenation stage but in the isolation of the compound. We found that crude glycamines could be converted to aromatic Schiff bases easily at room temperature in aqueous solution. The Schiff bases separated in excellent yield leaving water-soluble sugar derivatives in solution. A variety of aldehydes were used for Schiff base formation, the best



being salicylaldehyde, benzaldehyde, cinnamaldehyde, furfural, 2-hydroxy-3-methoxybenzaldehyde and anisaldehyde. Vanillin and 2,4-dihydroxybenzaldehyde condensed sluggishly with galactamine and yielded only small amounts of Schiff bases. The ease of hydrolysis of the Schiff bases depended to a great extent upon the nature of the substituent X. When X was hydrogen, the benzylidene derivative was hydrolyzed easily by steam distillation; however, when X was hydroxyl, mineral acid was required to effect hydrolysis. Therefore, it was necessary to include an ion exchange step in the salicylidene method of purification to convert galactamine salts to the free base.

The utilization of the Schiff-base purification procedure to isolate the product from the complex reaction mixture obtained from the reductive alkylation of ammonia by a sugar enabled us to isolate good yields of high purity galactamine. In addition to galactamine, dulcitol (VIII) was isolated in up to 12% yield by ion exchange treatment of crude reaction mixtures. It is of interest that even in the presence of a large excess of liquid ammonia a significant portion of the original sugar remained in the aldehyde form and was reduced to dulcitol during the hydrogenation. Didulcitylamine (VI) was also isolated; however, the yields were generally less than 10% when liquid ammonia was used as solvent during the hydrogenation. When concentrated aqueous ammonia was used as solvent, the yield of VI was variable, being as high as 20% in one case. Compound VII, 1,2-dideoxydiaminodulcitol was not isolated as such; however, its presence in some of our products was inferred from potentiometric titration data. In addition to the inflections for galactamine (pK_a' in water, 9.4) and didulcitylamine (pK_a' in water, 8.9), a basic group (in small amounts) with a pK_a' of 5.9 was identified. The pK_a' of this group is typical of what one would expect from the neutralization of the second amino group in VIII; however, in addition to the titration behavior, we have further justification for assigning the vicinal diamine structure to VII. Careful purification of the salicylidenegalactamine obtained from crude hydrogenation mixtures yielded a salicylidene derivative, m.p. 126–128°, in very low yield (<3%). This material was hydrolyzed to an amine hydrochloride whose infrared spectrum was identical to that of ethylenediamine dihydrochloride. This material could have formed by cleavage of the carbon chain after the formation of a vicinal diamine or by cleavage to ethanolamine followed by conversion to ethylenediamine. In view of the titration data, which indicated the presence of a diamine, we prefer the former hypothesis.

We investigated many sets of conditions for the reductive alkylation of ammonia with a sugar. Since most of our work was done with galactamine, the data obtained with this sugar are summarized in Table II (*cf.* Experimental). It should be noted that we were able to obtain reasonably good yields (54–57%) of salicylidenegalactamine using concentrated ammonium hydroxide as the solvent and source of ammonia along with very mild hydrogenation conditions (55° at 200 p.s.i.) and a long reaction time (16 hr.). Although the reaction proceeded well at pressures as low as 50 p.s.i. (48–52% yields), our best yields (66–77%) were obtained using conditions similar to those of Holly, *et al.*[8] (85° at 2000 p.s.i. for 3 hr.).

Solvent: [a] Liquid ammonia containing 3% by weight of water. [b] 28–30% ammonium hydroxide. [c] S = salicylidenegalactamine; B = benzylidenegalactamine. Under comparable conditions, the yield of benzylidenegalactamine was consistently about 5% less than that of the salicylidene derivative. [d] Constant.

Experimental[10]

N-Benzylgalactamine (III).—Galactose (50 g., 278 millimoles), benzylamine (30 g., 280 millimoles) and 15 ml. of water were heated on a steam-bath at 60° until solution was complete. Methanol (50 ml.) was added and the reaction mixture was set aside to cool. Platinum oxide (3.2 g.) was added, the volume of the solution was adjusted to 500 ml. with methanol and the mixture was hydrogenated at 40–50° at 50–20 p.s.i. for 15 hr. The reaction mixture was diluted with 1.5 l. of methanol and heated on a steam-bath with stirring until all of the product appeared to be in solution. The catalyst was removed by filtration and the filtrate was allowed to cool slowly to room temperature as the product separated from solution. N-Benzylgalactamine (48 g., 64%, m.p. 151–157°) was obtained in three crops. An analytical sample was prepared by recrystallization from methanol, m.p. 157–159°, $[\alpha]_D$ −6°.

Anal. Calcd. for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16. Found: C, 57.23; H, 7.59; N, 5.05.

N-Benzylglucamine.—The procedure for the preparation of N-benzylglucamine was similar to that for N-benzylgalactamine. The yield of crude product, m.p. 132–135°, was 67.5%. Recrystallization from ethanol to a constant melting point, 138–139°, produced an analytical sample.

Anal. Calcd. for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16. Found: C, 57.59; H, 8.03; N, 5.00.

Preparation of Galactamine (IV). (a) Hydrogenolysis of N-Benzylgalactamine.—N-Benzylgalactamine (30 g., 111 millimoles) was suspended in 250 ml. of 95% ethanol and 5.0 g. of 10% palladium-on-charcoal was added. The mixture was hydrogenated at 50° and 50–30 p.s.i. for 1.5 hr. The reaction mixture was diluted to 500 ml. with methanol and heated on a steam-bath until the supernatant liquid was clear. The catalyst was removed by filtration and the filtrate was allowed to cool overnight in a refrigerator at approximately 3°. The product (14.1 g., 77% yield) was removed by filtration, m.p. 143–145°, $[\alpha]_D$ −1°.

(b) Liquid Ammonia Process.—D(−)-Galactose (150 g., 833 millimoles), 400 ml. of liquid ammonia and 4 teaspoonfuls of Raney nickel were hydrogenated in a stainless steel autoclave equipped with a mechanical stirrer at 1800 p.s.i. at 85° for 4 hr. The contents of the reactor were removed with hot water and the purple reaction mixture was filtered to remove the catalyst The filtrate was concentrated under reduced pressure until the odor of ammonia was no longer apparent. The concentrate was diluted to 750 ml. with water, transferred to a 3-necked, creased flask equipped with a mechanical stirrer and a nitrogen inlet. Salicylaldehyde (103 g., 833 millimoles) was added with stirring and the mixture was stirred vigorously for 10 minutes while being cooled in an ice-bath. The yellow solid which precipitated was removed by filtration, washed on the filter by slurrying with water and dried in a vacuum oven at 50° to yield 192 g. of salicylidenegalactamine (81% yield), m.p. 189–195°.

The crude salicylidene derivative (159 g.) was suspended

(10) All melting points were taken in capillaries and are uncorrected. Rotations were measured in water at 23° at a concentration of 1–4% in a 2-decimeter tube.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in 400 ml. of ether, and the mixture was stirred vigorously for 5 minutes. The salicylidene derivative was washed onto a filter with an additional 250 ml. of ether and air-dried under a heat lamp to yield 146 g. (74% over-all) of purified material, m.p. 196–198°. A nicely crystalline solid (2.5 g.), m.p. 123–125.5°, was isolated from the ether solution by concentrating and cooling. This material proved to be N,N′-bis-salicylideneethylenediamine (*cf.* below for proof of structure).

An analytical sample of salicylidenegalactamine was prepared by recrystallization from methanol, m.p. 200–202°.

Anal. Calcd. for $C_{13}H_{19}NO_6$: C, 54.73; H, 6.71; N, 4.91. Found: C, 54.94; H, 7.09; N, 4.75.

The purified salicylidenegalactamine (145.5 g., 0.51 mole), m.p. 196–198°, was suspended in a solution of 1 l. of water and 90 ml. of concentrated hydrochloric acid, and the mixture was heated on a steam-bath for 15 minutes with vigorous stirring. After being cooled to room temperature the reaction mixture was extracted three times with 125-ml. portions of methylene chloride to remove salicylaldehyde. The aqueous phase was concentrated to dryness, the residual galactamine hydrochloride was dissolved in 2 l. of water and the solution was passed through a bed of IR-410 anion exchange resin ($1^5/_8'' \times 31''$) (OH^- cycle). The column was rinsed with water until the *p*H of the effluent was 7–8. The effluent was concentrated under reduced pressure (20 mm.) to a volume of 200 ml., 800 ml. of ethanol was added and the solution was cooled at 3° overnight. The galactamine which crystallized was removed by filtration (78 g., 85% over-all from salicylidenegalactamine), m.p. 145–148°, $[\alpha]D$ −1°. The over-all yield of galactamine from galactose was 63%.

Anal. Calcd. for $C_6H_{15}NO_5$: C, 39.77; H, 8.34; N, 7.73; Van Slyke N, 7.73; neut. equiv., 181. Found: C, 39.43; H, 8.65; N, 7.29; Van Slyke N, 8.0; neut. equiv., 183.

The Isolation of Galactamine through the Benzylidene Derivative.—The procedure for the preparation of benzylidenegalactamine was similar to that used for the salicylidene derivative. From a hydrogenation mixture which yielded 66% of pure salicylidenegalactamine, we obtained a 61% yield of benzylidenegalactamine, m.p. 192–193° (analytical sample, m.p. 191.5–193°). The benzylidenegalactamine was hydrolyzed by steam distillation in a nitrogen atmosphere to yield galactamine in 91% yield (based on the benzylidene derivative), m.p. 146–148°, $[\alpha]D$ −1°.

Anal. Calcd. for $C_6H_{15}NO_5$: Van Slyke N, 7.7; neut. equiv., 181. Found: Van Slyke N, 7.72; neut. equiv., 182.

Hydrogenolysis of N-Benzylglucamine. The Preparation of Glucamine.—The procedure in this preparation was similar to that employed for the hydrogenolysis of N-benzylgalactamine. The yield was 62% of material melting at 124.5–130°. Recrystallization of the crude product from absolute ethanol showed that a considerable amount of a high melting impurity was present which proved very difficult to separate by fractional crystallization. The Schiff base procedure was not developed at the time this experiment was done.

Proof of Structure of N,N′-Bis-salicylidenegalactamine.—The ether-soluble salicylidene derivative isolated above had a melting point after recrystallization from ethanol of 126–128°. The literature melting point of N,N′-bis-salicylidenegalactamine is 125–126°.[11]

Anal. Calcd. for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44. Found: C, 72.10; H, 6.42; N, 10.94; ash, 0.24.

A sample of the salicylidene derivative was hydrolyzed with dilute hydrochloric acid to yield salicylaldehyde and an amine hydrochloride melting over 250°. The infrared spectrum of the latter was identical to that of an authentic sample of ethylenediamine dihydrochloride.

Isolation of Cyclohexylmethylgalactamine (V) from a Preparation of Galactamine by Hydrogenolysis of N-Benzylgalactamine.—Galactose (54 g., 300 millimoles), benzylamine (32.1 g., 300 millimoles) and 16.5 ml. of water were heated at 60° for 20 minutes, and the reaction mixture was stored at room temperature overnight. The resulting viscous solution was diluted with 360 ml. of methanol and hydrogenated in a stainless steel autoclave in the presence of 3.5 g. of platinum oxide for 5 hr. at 50° and 30 p.s.i. The hydrogen in the reactor was displaced with nitrogen, the head was removed and 15 g. of 10% palladium-on-charcoal, slurried in 150 ml. of 95% ethanol, was added. Hydrogenation was continued at 50° and 30 p.s.i. for 3 hr. The product was washed from the autoclave with 250 ml. of water and the resulting suspension was heated to 60°, filtered, and the filtrate was concentrated under reduced pressure until a solid began to separate. After cooling to 3°, a white solid was isolated (6.1 g., 11.3%), m.p. 148–152°. The mother liquor was concentrated to an oil which crystallized when triturated with methanol yielding 35 g. (65%) of a white solid, m.p. 120–127°, $[\alpha]D$ +2°, neut. equiv., 244.

The first crop of crystals was recrystallized from water yielding a 38% recovery of a new sugar amine, m.p. 132–135°. Recrystallization of this material four times from water yielded an analytical sample of N-cyclohexylmethylgalactamine, m.p. 135–136°, $[\alpha]D$ −6°. The ultraviolet spectrum showed no evidence for the presence of a phenyl group.

Anal. Calcd. for $C_{13}H_{27}NO_5$: C, 56.29; H, 9.81; N, 5.05; neut. equiv., 277. Found: C, 56.45; H, 9.68; N, 4.95; neut. equiv., 279.

D(−)-Didulcitylamine (VI).—A mixture of galactose (54 g., 300 millimoles), benzylamine (33 g., 308 millimoles) and water (16.5 ml.) was heated on a steam-bath at 60° with occasional swirling until homogeneous. The reaction mixture was diluted with alcohol (54 ml.) and set aside for 17 hr. Further dilution with 500 ml. of alcohol was followed by the addition of 3.5 g. of platinum oxide and 15 g. of 10% palladium-on-charcoal. The mixture was then hydrogenated at 50° and 10 p.s.i for 6 hr. The reaction mixture was heated to 65°, filtered and diluted to 1 l. with water. The white solid that separated was removed by filtration (10.3 g., 20%), m.p. 195–197°. A second crop was obtained by concentrating under reduced pressure to a white paste-like mass which was diluted to 500 ml. with methanol and filtered. The solid which was obtained (21.0 g., 40%) melted at 169–173°. A third crop of solid was obtained after storage of the filtrate at 3° for 5 days (8.6 g., 16.7%), m.p. 93–100°.

Recrystallization of the first crop of solid three times from water yielded an analytical sample of D-(−)-didulcitylamine, m.p. 202–204°, $[\alpha]D$ −9°.

Anal. Calcd. for $C_{12}H_{27}NO_{10}$: C, 41.73; H, 7.88; N, 4.06; neut. equiv., 345. Found: C, 42.00; H, 7.71; N, 4.08; neut. equiv., 352.

A crystalline hydrochloride salt of this amine melted at 240–241°.

Anal. Calcd. for $C_{12}H_{28}ClNO_{10}$: C, 37.75; H, 7.39; N, 3.67; Cl, 9.29. Found: C, 38.05; H, 7.34; N, 3.95; Cl, 9.24.

Acknowledgments.—The authors are grateful to Dr. E. R. Garrett for potentiometric titration data, to Dr. J. L. Johnson and Mrs. G. S. Fonken for infrared spectra and to Mr. W. A. Struck and his associates for optical rotations and microanalyses.

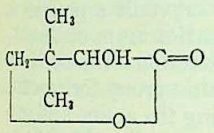
A Novel Resolution of Pantolactone—The Synthesis of D(+)-Calcium Pantothenate[1]

BY FRED KAGAN, RICHARD V. HEINZELMAN, DAVID I. WEISBLAT AND WARD GREINER

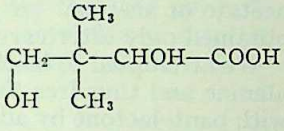
RECEIVED FEBRUARY 8, 1957

D(−)-Galactamine, a novel resolving agent, was used to resolve pantolactone, a key intermediate in the synthesis of D(+)-calcium pantothenate. Pantolactone reacted with D(−)-galactamine to yield a pair of diastereoisomeric N-D-dulcityl-2,4-dihydroxy-3,3-dimethylbutyramides. Fractional crystallization yielded (+)-N-D-dulcityl-D-2,4-dihydroxy-3,3-dimethylbutyramide in 70% yield (98% optical purity) and the (−)-diastereoisomer in 80% yield (93–98% optical purity). D(−)-Pantolactone and D(−)-galactamine were recovered from the (+)-diastereoisomer in 94 and 96% yields, respectively, by acid hydrolysis. The calcium salt of β-alanine was coupled with D(−)-pantolactone in methyl Cellosolve at 25–30° to yield crystalline D(+)-calcium pantothenate in 94% yield based on pantolactone.

Pantolactone (I), a key intermediate in the synthesis of pantothenic acid, previously has been resolved by conversion to diastereoisomeric salts of the corresponding 2,4-dihydroxy acid (II)[2–6] by



I



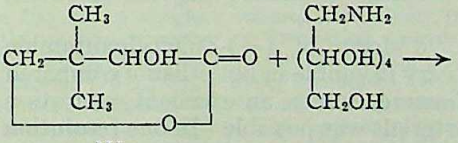
II

conversion of the secondary hydroxyl group to a half-ester followed by salt formation[7–9] and through the formation of molecular complexes with brucine.[7]

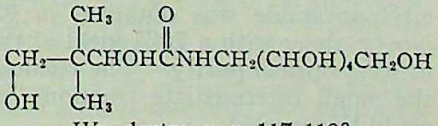
With the exception of the pyridinium diacetyl tartrate resolution,[7] each of the above schemes utilized a relatively expensive alkaloid[2–4,7–9] or a synthetic material which itself had to be resolved before use.[5,6] Our initial objective was to find an optically active base useful in the resolution of pantolactone and sufficiently inexpensive so that its near quantitative recovery would not be a critical factor in the successful operation of a commercial process. To achieve such an objective, one must necessarily prepare the resolving agent from inexpensive, naturally occurring, optically active materials. Since certain sugars are the least expensive of the pure optically active organic compounds available to the chemist, it seemed desirable to use a sugar or one of its derivatives for resolution work. The benzimidazole base formed by D-*gluco*-D-*gulo*-heptonolactone and *o*-phenylenediamine has been used successfully to resolve tartaric acid[10]; however, no report has yet appeared on the use of a simple basic sugar derivative such as a glycamine as a resolving agent. Since the glycamines appeared to meet our requirements for a readily available, inexpensive resolving agent, we undertook a program aimed at determining their applicability to the resolution of pantolactone.

Glucamine, potentially the least expensive of the glycamines, was prepared by the hydrogenolysis of N-benzylglucamine.[11] Galactamine was prepared by the method of Flint and Salzberg[12] as modified by Holly and co-workers.[13] The crude product obtained by the latter method was not suitable for resolution work. It was purified through the salicylidene or benzylidene derivatives to yield a material which was essentially pure galactamine.[11]

Glucamine failed to form crystalline derivatives with pantolactone; however, galactamine condensed smoothly with the lactone to form crystalline diastereoisomeric forms of N-D-dulcityl-2,4-dihydroxy-3,3-dimethylbutyramide (IV), hereafter referred to as dulcitylpantamide. The reaction occurred readily in refluxing ethanol or by fusion at 100–125°. N-Substituted glycamines such as N-methylglucamine and N-benzylglucamine failed to react with pantolactone in refluxing ethanol, refluxing pyridine or by fusion.



III



IVa, dextro, m.p. 117–118°
b, levo, m.p. 122–123°

In contrast with glucamine, galactamine proved to be a very satisfactory resolving agent. Early experiments in which this agent was used to resolve pantolactone yielded dextrorotatory dulcitylpantaamide (IVa), m.p. 117–118°, and the levo diastereoisomer IVb, m.p. 122–123°. Solubility studies in ethanol at 25° indicated that the dextro diastereoisomer was about 30% more soluble than the levo form. During resolution, the first compound to crystallize from the reaction mixture was the unexpected, more soluble dextro compound. As the initial dextro enriched crops crystallized from solution, the composition of the mother liquor became

predominantly levo until a 5–10% enrichment was reached. At this point, levo isomer was deposited until the composition of the mother liquor again approached that of a racemate. This behavior was then repeated in a cyclic fashion. Since an appreciable displacement of the composition of the mother liquor from that of a racemate was impossible, and, furthermore, since optical purity appeared to be inversely related to the size of the crops which were isolated, this method of resolution of pantolactone was tedious.

In one of the galactamine resolution experiments a new material was obtained which melted 40° higher than either of the previously isolated dulcitylpantamides (IVa and IVb). Potentiometric titration showed that the compound was not a dulcitylammonium salt of 2,4-dihydroxy-3,3-dimethylbutyric acid. Since acid hydrolysis yielded galactamine hydrochloride and L(+)-pantolactone, it appeared that the new material was a polymorphic form of *l*-dulcitylpantamide. A mixed melting point between the previously isolated *l*-dulcitylpantamide (m.p. 122–123°, IVb) and the new material (m.p. 162.5–165°, IVc) was not depressed, and the specific rotations of the two materials in water were identical. The new polymorph, synthesized from D(−)-galactamine and L(+)-pantolactone by the methods which had previously yielded the low melting material, was designated the "β"-form of (−)-dulcitylpantamide. In resolution work in these laboratories, the "α"-form (IVb) had been used for several years with no apparent instability. Samples stored at room temperature in screw-cap vials remained unchanged; however, attempts to recrystallize existing samples of "α"-(−)-dulcitylpantamide have thus far yielded only the "β"-form (IVc).

Since the "β"-form of (−)-dulcitylpantamide proved to be very insoluble in hot ethanol compared to the (+)-diastereoisomer, an excellent separation of the two materials was possible. In one resolution of 100 g. of pantolactone, an 80% yield of (−)-dulcitylpantamide was obtained in 93–98% optical purity along with a 70% yield of the D(+)-isomer in 96% optical purity. The residual material and the small intermediate fractions of lesser purity could be recycled.

(+)-Dulcitylpantamide was hydrolyzed with dilute hydrochloric acid to give a 94% yield of D-(−)-pantolactone based on the starting amide and a practically quantitative yield of galactamine hydrochloride. The latter was converted to the free base by passage of an aqueous solution through a bed of anion exchange resin. The over-all yield of recovered galactamine was 96% from (+)-dulcitylpantamide. This material was suitable for further resolution work with no additional purification.

The biologically inactive L(+)-pantolactone was easily racemized by the procedure of Stiller and co-workers,[14] by fusing with trisodium phosphate at 160° or by merely heating to 195° in the presence of soft glass. The soft-glass method is similar to that of Klein and Kapp[15] in which they used alkali metal silicates as their catalyst. Both trisodium phosphate and the soft-glass procedures convert L(+)-pantolactone to the racemic form in over 95% yield.

The final step in the synthesis of pantothenic acid is the coupling of β-alanine or one of its salts with pantolactone. If β-alanine is used, a temperature of about 180°[16] is necessary to effect reaction, presumably because the zwitterion form of the amino acid is relatively inactive toward attacking the carbonyl group of pantolactone. The procedures in which salts of β-alanine are used in the coupling with pantolactone are often carried out in refluxing anhydrous alcohol[17] and in aqueous solution.[18,19] These methods are usually complicated since the product, a salt of pantothenic acid, is first isolated as an amorphous hygroscopic solid by precipitation from alcoholic solution by the addition of ethyl acetate or acetone. A pure crystalline product is obtained only after crystallization from methanol.

We attempted to block zwitterion formation in β-alanine and thus free the amino group for reaction with pantolactone by adsorbing the amino acid on a strongly basic anion exchange resin (IR-410) to form the resin salt VII. Coupling with pantolactone was then carried out to form the resin pantothenate (VIII). The product was then displaced from the resin by calcium chloride solution. In addition to D(+)-calcium pantothenate (15% yield), we obtained a material (49% yield) which melted at 226–230° dec., approximately 30° higher than calcium pantothenate. Microbiological assay of this material with *lactobacillus arabinosus* indicated a D(+)-calcium pantothenate activity of 67%. The microbiological assay, the analytical data and the infrared spectrum indicated that the product was a mixed salt of pantothenic acid and 2,4-dihydroxy-3,3-dimethylbutyric acid (X).

We found that the reaction of D(−)-pantolactone with the calcium salt of β-alanine proceeded

(a) $NH_2CH_2CH_2COOH + Rz^+OH^- \longrightarrow Rz^+ {}^-OOCCH_2CH_2NH_2$

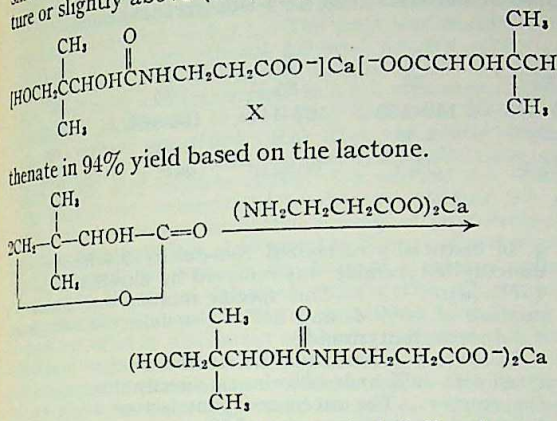
smoothly in methyl Cellosolve at room temperature or slightly above (35°) to yield calcium pantothenate in 94% yield based on the lactone.



The attractive aspect of using methyl Cellosolve as the solvent in this reaction was that the product, D(+)-calcium pantothenate, crystallized directly from the reaction mixture in excellent yield in an analytically pure condition.

Experimental[20]

(+)-N-D-Dulcityl-D-2,4-dihydroxy-3,3-dimethylbutyramide (IVa).—D(−)-Galactamine (0.585 g., 3.2 millimoles) and 0.763 g. (5.9 millimoles, 81% excess) of D(−)-pantolactone were fused in a test-tube on a steam-bath for 4 hr. The hard glass which formed on cooling was pulverized and triturated with 5 ml. of absolute ethanol. The residual solid was dissolved in 12 ml. of hot ethanol, filtered and stored in a refrigerator overnight. The copious white solid which precipitated was removed by filtration, washed with ethanol and dried, yielding 0.68 g. (68%) of IVa, m.p. 115–116°. Recrystallization from hot absolute ethanol yielded 0.56 g. of (+)-N-D-dulcityl-D-2,4-dihydroxy-3,3-dimethylbutyramide, m.p. 117–118°, $[\alpha]_D$ +11°.

Anal. Calcd. for $C_{12}H_{25}NO_8$: C, 46.29; H, 8.09; N, 4.50. Found: C, 46.28; H, 8.12; N, 4.66.

(−)-N-D-Dulcityl-L-2,4-dihydroxy-3,3-dimethylbutyramide (IVb).—D(−)-Galactamine (1.4 g., 78 millimoles), 1.4 g. (10 millimoles, 34% excess) of L(+)-pantolactone and 75 ml. of absolute ethanol were heated to reflux with stirring for 12 hr. The resulting yellow reaction mixture was clarified by centrifugation and was stored at room temperature overnight. The solid which separated was removed by centrifugation. Recrystallization from ethanol yielded an analytical sample, m.p. 122–123°, $[\alpha]_D$ −33°.

Anal. Calcd. for $C_{12}H_{25}NO_8$: C, 46.29; H, 8.09; N, 4.50. Found: C, 46.63; H, 8.10; N, 4.24.

The Resolution of Pantolactone with D(−)-Galactamine. (a) Typical Resolution Involving "α"-(−)-Dulcitylpantamide (IVb). The Isolation of "β"-(−)-Dulcitylpantamide (IVc).—Pantolactone (17.4 g., 0.134 mole), 11.2 g. (0.062 mole) of D(−)-galactamine and 200 ml. of absolute ethanol were heated to reflux with vigorous stirring in a nitrogen atmosphere for 7 hr. The cloudy reaction mixture was filtered yielding a clear pale yellow filtrate (*p*H 8). The ethanol was removed under reduced pressure and the residual sirup was dissolved in 40 ml. of hot water. The excess pantolactone was removed by extraction with five 40-ml. portions of methylene chloride, and the aqueous solution was concentrated under reduced pressure to a viscous pale yellow sirup which was dried by repeated distillation of absolute ethanol. The dried residue was dissolved in 65 ml. of hot ethanol, seeded with "α"-(−)-dulcitylpantamide and stored at 3°. Five crops of crystals were removed over a period of two weeks. The pertinent data for these crops are summarized in Table I. After the removal of the fifth crop, the mother liquor was concentrated to a sirup which was dissolved in 25 ml. of water and extracted well with methylene chloride. The aqueous solution was evacuated at 15 mm. to remove residual methylene chloride and was filtered through a column of Darco–Celite (1:2) (5 cm. × 1 cm.). The golden yellow solution was decolorized effectively by this treatment. The filtrate was concentrated under reduced pressure to a viscous sirup which was dissolved in 18 ml. of hot ethanol. The solution was seeded with (+)-dulcitylpantamide and stored at 3°. After two days, a white crystalline solid, crop 6, was removed by filtration, 2.0 g. (11%), m.p. 149–152°, $[\alpha]_D$ −25°. This material melted about 30° higher than any crop previously isolated in the resolution of pantolactone with galactamine. Crop 6 was recrystallized three times from ethanol–water to yield an analytical sample of "β"-(−)-dulcitylpantamide, m.p. 162.5–165°.

TABLE I

SUMMARY OF CROPS REMOVED FROM THE RESOLUTION IN WHICH "β" (−)-DULCITYLPANTAMIDE WAS ISOLATED

Crop	1	2	3	4	5	6
Weight, g.	6.7	1.4	2.1	0.5	1.0	2.0
Theor. amides, %	35	7	11	3	5	11
M.p., °C.	107–112	100–110	111–117	115–122	92–102	149–152
$[\alpha]_D$ (°)	−2	−20	−28	−29	0	−25
Major component,[a] %	71% D	71% "α"-L	89% "α"-L	91% "α"-L	75% D	82% "β"-L

[a] (+)-Dulcitylpantamide is designated D and (−)-dulcitylpantamide L.

Anal. Calcd. for $C_{12}H_{25}NO_8$: C, 46.29; H, 8.09; N, 4.50. Found: C, 46.46; H, 8.32; N, 4.37.

(b) Resolution Involving "β"-(−)-Dulcitylpantamide.—Pantolactone (100 g., 0.769 mole, 99% excess) was dissolved in 500 ml. of absolute ethanol, and about 100 ml. of the ethanol was removed by distillation to dry the lactone. The solution was cooled below the boiling point, D(−)-galactamine (70 g., 0.387 mole) was added and the suspension was stirred vigorously at the reflux temperature in a nitrogen atmosphere for 17.5 hr. The reaction mixture (*p*H 7) was cooled to room temperature, and the solid which was present was removed by filtration, 47.2 g. (29% of the theoretical amides), m.p. 161.5–163.5°, $[\alpha]_D$ −30°. The filtrate was concentrated under reduced pressure to a sirup which was taken up in 200 ml. of warm water. The aqueous solution was extracted six times with 125 ml. portions of methylene chloride, the combined extracts were dried over anhydrous sodium sulfate and concentrated under reduced pressure to a semi-solid (50 g., 100%) recovered pantolactone. The aqueous solution was concentrated under reduced pressure to a burnt orange colored sirup which was dried by distillation of 100 ml. of absolute ethanol and dissolved in 200 ml. of hot alcohol. It was seeded with "β"-(−)-dulcitylpantamide and stored at 30° for 4 hr. The white crystalline solid which separated was removed by filtration, washed with absolute ethanol and dried in a vacuum oven at 50°, (34.1 g., 28%) of the theoretical amides, m.p. 112–115°, $[\alpha]_D$ +9°. It is surprising that practically pure (+)-dulcitylpantamide was obtained in this crop in spite of the fact that the solution was seeded with the L(−)-isomer. After removal of two intermediate crops totaling 12.5 g. (10%), an additional crop of pure D(+)-diastereoisomer was isolated, 7.5 g. (6%), m.p. 103–111°, $[\alpha]_D$ +9°. A summary of the crystalline crops isolated in this resolution is presented in Table II.

Hydrolysis of N-D-Dulcityl-2,4-dihydroxy-3,3-dimethylbutyramide. Proof of Structure of the "β"-(−)-Enriched Form.—"β"-(−)-N-D-Dulcityl-L-2,4-dihydroxy-3,3-dimethylbutyramide (6.6 g., 0.0212 mole, m.p. 160–162.5°, $[\alpha]_D$ −30°, 93% (−)-diastereoisomer) was heated on a steam-bath with 40 ml. of 6% by volume hydrochloric acid

[20] All melting points are uncorrected. Specific rotations were taken in water at 23°, at a concentration of 1–4% in a 2-decimeter tube.

for 3 hr. The resulting solution was extracted with five 25-ml. portions of methylene chloride and the combined extracts were dried over anhydrous sodium sulfate. Removal of the solvent under reduced pressure afforded 2.3 g. (83%) of pantolactone which was purified for analysis by sublimation ($[\alpha]_D$ +43°, equivalent to 93% of the L(+)-enantiomorph). From another experiment in which the starting material to be hydrolyzed melted at 148–151°, the pantolactone which was obtained melted at 86.6–90°, $[\alpha]_D$ +16° [66% L(+)].

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.75. Found: C, 55.45; H, 7.61.

The aqueous phase was concentrated under reduced pressure to a white crystalline solid which was further dried by distillation of absolute ethanol, reslurried in ethanol and filtered to yield galactamine hydrochloride in 97% yield, m.p. 158–161°.

Anal. Calcd. for $C_6H_{16}ClNO_5$: Cl, 16.29. Found: Cl, 16.66.

A mixed melting point with an authentic sample of galactamine hydrochloride was not depressed and the infrared spectra of the two samples were identical.

(b) D(+)-Form.—(+)-N-D-Dulcityl-D-2,4-dihydroxy-3,3-dimethylbutyramide (31.0 g., 99.7 millimoles) was hydrolyzed by the above procedure to yield 12.2 g. (94% yield) of D-(−)-pantolactone ($[\alpha]_D$ −48°, 98% D(−)-enantiomorph). The galactamine hydrochloride was dissolved in 500 ml. of deionized water and the resulting solution was passed through a ¾″ × 18″ column of Rohm and Haas IR-410 anion exchange resin in the hydroxide cycle at the rate of 5 ml. per minute. The column was washed with water until the *p*H of the effluent was 7.5. The aqueous solution of galactamine was then concentrated to dryness under reduced pressure in a nitrogen atmosphere. The white crystalline residue was dried by repeated distillation of absolute ethanol and finally by evacuation with an oil-pump to yield 17.3 g. of galactamine (96%), m.p. 142–146°.

Anal. Calcd. for $C_6H_{15}NO_5$: neut. equiv., 181.2. Found: neut. equiv., 188.

This material when treated with D(−)-pantolactone yielded (+)-dulcitylpantamide in 90% yield in one crop of crystals. The mother liquor was not worked up further for additional crops.

The Racemization of L(+)Pantolactone. (a) **Trisodium Phosphate Procedure.**—L(+)-Pantolactone [19.2 g., 0.148 mole, $[\alpha]_D$ +45° (H_2O)] was fused with 0.96 g. of trisodium phosphate decahydrate with stirring at 160° for 18 hr. The product was then flash-distilled to yield 18.5 g. (95.4%) of racemic pantolactone, $[\alpha]_D$ +1°.

(b) **Soft-glass Procedure.**—L(+)-Pantolactone (10 g.) was fused at 195° with 2.1 g. of powdered soft glass with stirring for 16 hr. The lactone was then flash-distilled at 15 mm. to yield 9.7 g. (97%) of racemic pantolactone, $[\alpha]_D$ 0°.

Racemization of L(−)-N-D-Dulcityl-L-2,4-dihydroxy-3,3-dimethylbutyramide.—Sodium metal (0.5 g., 0.022 gram atom) was dissolved in absolute methanol in a stainless steel autoclave with careful exclusion of moisture. L(−)-N-D-Dulcityl-2,4-dihydroxy-3,3-dimethylbutyramide (5.0 g., 0.165 mole) was added, and the reaction mixture was heated at 100° for 2 hr. The methanol was removed under reduced pressure and the residue was taken up in 125 ml. of water. The aqueous solution was passed through a bed of Rohm and Haas IR-120 cation exchange resin in the hydrogen cycle (1 cm. × 17 cm.) to remove caustic. The effluent solution was concentrated to a sirup under reduced pressure yielding 4.1 g. of residue (82%) which was dissolved in 20 ml. of absolute ethanol and stored at 3°. After 3 days 1.4 g. of essentially racemized N-D-dulcityl-2,4-dihydroxy-3,3-dimethylbutyramide was removed by filtration, m.p. 127–137°, $[\alpha]_D$ −13°. This specific rotation corresponds to a mixture of 46% *d*- and 54% *l*-N-D-dulcityl-2,4-dihydroxy-3,3-dimethylbutyramide.

In another experiment the reaction mixture was hydrolyzed with 10% hydrochloric acid directly after removal from the reactor. The racemized pantolactone which was isolated had a specific rotation of 0°.

The Coupling of β-Alanine and D(−)-Pantolactone. The Synthesis of D(+)-Calcium Pantothenate. (a) **Calcium Metal in Methyl Cellosolve.**—In a 3-necked, round-bottomed flask equipped with a stirrer and a condenser fitted with a drying tube were placed 3.5 g. (87.3 millimoles) of calcium turnings and 200 ml. of methyl Cellosolve. The methyl Cellosolve was heated to the reflux temperature under nitrogen with stirring for 1 hr. After cooling, the flask was immersed in a constant temperature bath at 35°, and 15.6 g. (0.175 mole) of β-alanine was added and stirring was continued for 1 hr. D(−)-Pantolactone (25.2 g., 0.194 mole, 10% excess) was then added and stirring was continued at 35° for about 2 hr. Celite (1.0 g.) was added to the black solution, and it was filtered through a pressure filter in a nitrogen atmosphere to remove the black coloration. The filtrate was transferred to another 3-necked flask equipped with a mechanical stirrer and a nitrogen inlet and the flask was placed in a 35° constant temperature bath. The clear solution was seeded with D(+)-calcium pantothenate and stirred in a nitrogen atmosphere for 7 hr. The white solid which separated was removed by filtration and washed on the filter with 300 ml. of methyl Cellosolve. The product was dried in a vacuum desiccator over concentrated sulfuric acid for two days; however, this treatment did not remove the methyl Cellosolve completely. The residual solvent was removed in a vacuum oven at 50° (24 hr.). The yield of D(+)-calcium pantothenate was 36.0 g. (87%), m.p. 193.5–195°, $[\alpha]_D$ +27°. A second crop, 0.38 g. (1%), was obtained by stirring the mother liquor further at 35°, m.p. 193.5–195°.

Anal. Calcd. for $C_{18}H_{32}CaN_2O_{10}$: C, 45.36; H, 6.77; N, 5.88; Ca, 8.41. Found: C, 45.64; H, 6.85; N, 6.21; Ca, 8.23; bioassay (*Lactobacillus arabinosus*), 100%.

The filtrates were concentrated under reduced pressure to remove methyl Cellosolve. The residue was taken up in 60 ml. of 10% hydrochloric acid, and the solution was heated on a steam-bath for 4 hr. After cooling, the aqueous solution was extracted with chloroform (*ca.* 150 ml.), and the chloroform solution was dried over anhydrous sodium sulfate. The chloroform was removed under reduced pressure leaving 4.0 g. of recovered pantolactone. An aliquot of the recovered lactone, after sublimation, had a specific rotation of −48°. The yield of D(+)-calcium pantothenate based on pantolactone was 94%.

The methyl Cellosolve used in this reaction must be distilled before use to eliminate heavy metal contamination of the final product. From one lot of methyl Cellosolve which was shipped from the manufacturer in a one-gallon metal container, a 100-ml. aliquot yielded 80 mg. of residue on evaporation. After ignition, the 60 mg. of ash which was obtained contained magnesium, calcium, lead, silicon and a trace of iron. D(+)-Calcium pantothenate which was prepared in this lot of methyl Cellosolve contained 5000 p.p.m. of heavy metals whereas the U.S.P. allowable limit is 20 p.p.m.[21]

(b) **Ion Exchange Resin.**—A solution of 10 g. of β-alanine (0.113 mole) in 1000 ml. of deionized water was passed through a column of IR-410 anion exchange resin

[21] "The National Formulary," 10th Edition, Edwards Brothers, Inc., Ann Arbor, 1955, p. 122.

(OH^- cycle) ($^3/_4'' \times 18''$). The column was washed with 500 ml. of water, and the effluent was concentrated to dryness to determine the amount of β-alanine that came through the column (residue = 0 g.). The resin was washed with 1000 ml. of absolute ethanol followed by dry ether. A vacuum was then applied to the column to dry the resin. The dried resin was transferred to a 1-l. erlenmeyer flask, and 32.5 g. (0.25 mole) of D(−)-pantolactone in 200 ml. of absolute ethanol was added. The flask was gently shaken for 67 hr. at 25°. The resin was removed by filtration and washed well with absolute ethanol followed by dry ether. The filtrate was concentrated to dryness yielding 9.0 g. (50% recovery of the theoretical excess) of pantolactone. Calcium chloride (6.2 g., 0.56 mole) in 200 ml. of water was passed through the resin (in the form of a column again) followed by 500 ml. of deionized water. The effluent was concentrated to dryness yielding a sirup-like residue, 31.7 g., which was dried by distillation of absolute ethanol. It was dissolved in hot methanol, seeded with a trace of D(+)-calcium pantothenate and set aside at room temperature overnight. The white solid that formed on standing was removed by filtration, 13.0 g. (49% yield), m.p. 226–230° dec., $[\alpha]_D$ +21°. A bioassay with *L. arabinosus* indicated that this material was 67% D(+)-calcium pantothenate.

Anal. Calcd. for calcium pantothenate, $C_{18}H_{32}CaN_2O_{10}$: C, 45.36; H, 6.77; N, 5.88; Ca, 8.41. Found: C, 44.56; H, 6.85; N, 3.97; Ca, 9.57.

From the bioassay and the analytical data, it was obvious that the product was not D(+)-calcium pantothenate but was instead a mixed salt, calcium pantothenate-pantoate. Calcd. for $C_{15}H_{27}CaNO_9$: C, 44.43; H, 6.71; N, 3.46; Ca, 9.89. Found: C, 44.56; H, 6.85; N, 3.97; Ca, 9.57. The calcium pantothenate portion of the molecule represents about 64% of its total weight, in good agreement with the 67% activity determined in the bioassay.

A second crop of solids (4.1 g., 15.4%) was obtained after storage for an additional 24 hr. which proved to be D(+)-calcium pantothenate, m.p. 193–196°. Bioassay with *l. arabinosus* indicated a purity of 90%.

Acknowledgments.—The authors are grateful to Dr. J. L. Johnson and Mrs. G. S. Fonken for infrared analyses, to Mr. W. A. Struck and his associates for optical rotations and microanalyses and to Mr. L. Stubberfield and associates for bioassays.

Pyridine-1-oxides. III. Oxidative Coupling of 4-Nitro-3-picoline-1-oxide[1]

BY E. C. TAYLOR, A. J. CROVETTI[2] AND N. E. BOYER

RECEIVED NOVEMBER 7, 1956

4-Nitro-3-picoline-1-oxide (I) undergoes a facile oxidative coupling upon treatment in alkaline medium with oxygen, sodium nitrite or *n*-butyl nitrite to give 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl (II). Several reactions of II are discussed.

In the course of an investigation of the chemistry of pyridine-1-oxides, 4-nitro-3-picoline-1-oxide (I) was prepared and utilized as a key intermediate for the preparation of derivatives of nicotinic acid[3] and for a new synthesis of the alkaloid ricinine.[4] In the hope of extending further the usefulness of this versatile intermediate, an attempt was made to prepare 4-nitro-3-pyridyl aldehyde *via* the corresponding oxime by treatment of 4-nitro-3-picoline-1-oxide with *n*-butyl nitrite in the presence of a molar quantity of sodium ethoxide in ethanol. This method is similar to that reported by Lapworth[5] for the conversion of *o*-nitrotoluene to its oxime. Upon mixing the reactants at 0°, a rapid and pronounced color change from green-blue to red-brown took place with the simultaneous separation of a yellow, alkali-insoluble product (A). The same product was also obtained, although in lower yield, when a suspension of I in water containing an excess of sodium nitrite and a molar quantity of sodium hydroxide was shaken at room temperature or when oxygen was passed through a mixture of I in aqueous sodium hydroxide or in sodium ethoxide in ethanol.

The anticipated oxime structure for the product A was immediately suspect on the basis of its insolubility in alkali. Microanalytical values were almost identical with those calculated for I, but a molecular weight determination revealed that the product A was actually a "dimer" of I. An oxidative coupling had thus taken place to give 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl (II) (A) under conditions reminiscent of the oxidative coupling of *o*- and *p*-nitrotoluenes to the corresponding bibenzyls.[6–14] It is noteworthy that treatment of 4-nitropyridine-1-oxide with sodium nitrite and sodium hydroxide leads only to reduction to the corresponding azo compound,[15] and treatment of 4-nitro-2-picoline-1-oxide with sodium alkoxides results in normal nucleophilic displacement of the nitro group.[16]

It is curious that the formation of II from 4-nitro-3-picoline-1-oxide (I) has not been noted previously. Thus, Katritzky[17] treated I with sodium benzylate in benzyl alcohol and noted the formation of an intense green coloration (similar to that

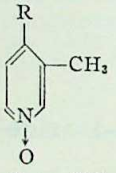
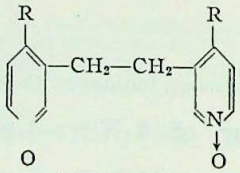
observed here with sodium ethoxide), but no product was isolated from the reaction. Using similar conditions, Itai and Ogura[18] isolated 4-benzyloxy-3-picoline-1-oxide in 21.5% yield; it seems possible that the low yield of product may have been due to concomitant formation of the "dimer" II.

A careful examination of the reaction of I with sodium ethoxide in the presence of oxygen revealed that, in addition to the predominant formation of II, 4,4′-diethoxy-1,1′-dioxy-3,3′-dipicolyl (III, 0.72% yield), 4-ethoxy-3-picoline-1-oxide (IV, 2.9% yield) and a red solid (V, ~5% yield when pure) were formed. By addition of I and *n*-butyl nitrite to a solution of sodium ethoxide in ethanol, the yield of III could be raised to 19% without concomitant formation of II. Since II could not be converted to III with sodium ethoxide in ethanol, even under strenuous conditions, it would appear that III must arise by oxidative coupling of IV initially formed by the reaction of I with sodium ethoxide.



I, R = $-NO_2$
IV, R = $-OC_2H_5$

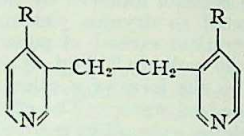


II, R = $-NO_2$
III, R = $-OC_2H_5$
VI, R = $-OH$
VII, R = $-Cl$
VIII, R = $-NHOH$

Formation of the red solid V also was noted in the other preparations of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl (II), and it could be formed directly from II by hydrogenation in dimethylformamide solution in the presence of palladium-on-carbon catalyst. It was a highly deliquescent material which proved difficult to purify; microanalysis of both V and its picrate indicated a probable empirical formula of $C_{12}H_{11}N_3O_3$, in which one nitrogen atom appears to have been lost from the "dimer" II, perhaps by cyclization across the 4,4′-positions. However, no definitive structure for this compound can be advanced at this time.

Hydrolysis of 4,4′-diethoxy-1,1′-dioxy-3,3′-dipicolyl (III) with two molar equivalents of aqueous potassium hydroxide yielded the dipotassium salt of 4,4′-dihydroxy-1,1′-dioxy-3,3′-dipicolyl (VI); hydrolysis with barium hydroxide yielded the corresponding barium salt, from which VI could be obtained by treatment with sulfuric acid. Attempts to prepare VI directly from II either with alkali or with alkaline hydrogen peroxide were unsuccessful. Somewhat surprisingly, III failed to react with liquid ammonia or with a mixture of sodium amide and liquid ammonia.

Although II failed to react with sodium alkoxides (a reaction typical of 4-nitropyridine-1-oxides),[15] it reacted readily with acetyl chloride to give 4,4′-dichloro-1,1′-dioxy-3,3′-dipicolyl (VII). The chlorine atoms in VII proved to be amazingly inert toward nucleophilic displacement. Thus, VII was recovered unchanged after refluxing in glacial acetic acid for 6 hr., after treatment with liquid ammonia at atmospheric pressure for 30 hr. or after refluxing in concentrated ammonium hydroxide. When VII was heated in a sealed steel bomb with liquid ammonia at 150° for 6 hr., 4,4′-dichloro-3,3′-dipicolyl (IX) was formed, and no displacement of chlorine was observed. This unusual deoxygenation reaction was confirmed by an independent preparation of IX involving catalytic reduction of VII in aqueous hydrochloric acid.



IX, R = $-Cl$
X, R = $-NH_2$

Catalytic reduction of II in aqueous hydrochloric acid led to the exclusive formation of 4,4′-dihydroxylamino-1,1′-dioxy-3,3′-dipicolyl (VIII). Further reduction to the corresponding diamine could not be achieved in this medium. When the reduction was carried out in glacial acetic acid as solvent, 4,4′-diamino-3,3′-dipicolyl (X) was formed, in which the N-oxide functions had also been reduced.

The possibility of utilizing these intermediates for the preparation of condensed heterocyclic systems containing large rings is under investigation.

Experimental[19]

4,4′-Dinitro-1,1′-dioxy-3,3′-dipicolyl (II). Method A.—One hundred and twenty grams (0.78 mole) of 4-nitro-3-picoline-1-oxide was dissolved in 3 l. of absolute ethanol by heating on a steam-bath and the resulting solution was chilled in an ice-bath. To it was added 86 g. (0.83 mole) of cold (0°) *n*-butyl nitrite, followed by the slow addition of a cold (0°) solution of 18 g. (0.78 mole) of sodium in 500 ml. of absolute ethanol. During the addition the reaction mixture was stirred continuously and maintained at 0° by means of a salt–ice-bath. The color of the mixture turned from red to green to blue-green; ten minutes after addition of the sodium ethoxide solution was complete, the color changed to dark brown. The reaction mixture was stirred at 0° for 6 hr. and then poured into 5 l. of ice-cold water. The precipitated yellow solid was collected by filtration, dissolved in concentrated hydrochloric acid and reprecipitated by the addition of water; yield 63 g. (53%), m.p. 240° dec. An analytical sample, m.p. 242° dec., was prepared by repetition of the above procedure.

Anal. Calcd. for $C_{12}H_{10}N_4O_6$: C, 47.1; H, 3.3; N, 18.3; mol. wt., 306.2. Found: C, 47.2; H, 3.2; N, 18.2; mol. wt., 317.0.

Method B.—To a solution of 1.3 g. of sodium hydroxide in 200 ml. of water was added 5.0 g. of 4-nitro-3-picoline-1-oxide. Oxygen was bubbled through the mixture at room temperature (35°) for a total of 3 hr.; a reaction commenced within the first ten minutes. The suspended solid was then filtered, washed with water and dried to yield 1.92 g. (39%) of the "dimer," m.p. 240° dec. The same material was formed in 24% yield when sodium nitrite was used as the oxidizing agent.

Method C.—A solution of 4.60 g. (0.20 mole) of sodium in 250 ml. of absolute ethanol was added slowly to a suspension of 30.8 g. (0.20 mole) of 4-nitro-3-picoline-1-oxide in 1.5 l. of absolute ethanol maintained at 0°. The solution acquired a blue-green color upon the addition of the first few drops of the base; the color soon changed to red. Oxygen was bubbled through the solution for 10 hr.; the temperature was maintained at 0° for the first 2 hr. and then allowed to warm up to 20°. Oxygen was again bubbled through the reaction mixture for 1 hr. after it had stood overnight at room temperature. Filtration then yielded 21 g. of a crude solid product and a dark green filtrate (see below). The solid was extracted with three 400-ml. portions of boiling chloroform, dissolved in concentrated hydrochloric acid and reprecipitated by the addition of ice-water to give 11.5 g.

(38%) of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl, m.p. 240° dec.

4,4′-Diethoxy-1,1′-dioxy-3,3′-dipicolyl (III).—By evaporation of the chloroform extracts above and fractional crystallization of the residue from chloroform, there was obtained 0.22 g. (0.72%) of pale yellow prisms, m.p. 237°. Recrystallization from ethanol raised the m.p. to 245–246° dec.

Anal. Calcd. for $C_{16}H_{20}N_2O_4$: C, 63.1; H, 6.6; N, 9.2. Found: C, 63.0; H, 6.6; N, 9.2.

By modification of the conditions of the "dimerization" reaction, the yield of this product could be significantly improved. Thus, to a solution of 15 g. (0.65 mole) of sodium in 200 ml. of absolute ethanol was added a solution of 50 g. (0.32 mole) of 4-nitro-3-picoline-1-oxide and 40 g. (0.39 mole) of *n*-butyl nitrite in 1.8 l. of absolute ethanol. The resulting blue-green solution was stirred at 0° for 2 hr. and then at room temperature for an additional 2 hr. Filtration of the solid product and fractional crystallization from ethanol yielded as the least soluble fraction 9.40 g. (19%) of 4,4′-diethoxy-1,1′-dioxy-3,3′-dipicolyl, m.p. 245–246° dec. No 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl was formed in this reaction, and no 4-nitro-3-picoline-1-oxide could be recovered.

4-Ethoxy-3-picoline-1-oxide (IV).—The dark green ethanolic filtrate (method C above) was concentrated to a small volume under reduced pressure to give a brownish-yellow solid and a very dark filtrate. Treatment of the solid with absolute ethanol yielded a small amount (2 g.) of unreacted 4-nitro-3-picoline-1-oxide. The dark filtrate was evaporated to dryness and the residue extracted several times with small portions of ether. Evaporation of the ether extracts yielded 0.9 g. (2.9%) of colorless crystals, m.p. 135–136°. Recrystallization from absolute ethanol raised the melting point to 139–140°. The melting point of this compound has been reported previously as 134–135°.[16]

Anal. Calcd. for $C_8H_{11}NO_2$: C, 62.7; H, 7.2; N, 9.2. Found: C, 62.6; H, 7.2; N, 9.2.

Red Side Product (V).—The residue obtained in the above isolation of 4-ethoxy-3-picoline-1-oxide was a red, deliquescent solid. A similar solid was obtained by concentration of the filtrates from methods A and B. It was extracted with boiling chloroform and the red chloroform extracts evaporated to dryness under reduced pressure. Suspension of the residue in ethanol, filtration and recrystallization of the remaining solid from dry chloroform yielded a bright red solid, m.p. 242° dec., which was extremely hygroscopic.

Anal. Calcd. for $C_{12}H_{11}N_3O_3 \cdot 1.5H_2O$: C, 52.9; H, 5.2; N, 15.4. Found: C, 52.1; H, 5.1; N, 15.6.

Addition of picric acid to an aqueous solution of this material yielded a yellow picrate, m.p. 161° dec., which was recrystallized from water.

Anal. Calcd. for $C_{12}H_{11}N_3O_3 \cdot C_6H_3N_3O_7 \cdot {}^1/_2H_2O$: C, 44.7; H, 3.1; N, 17.4. Found: C, 44.7; H, 3.4; N, 16.9.

The same material was obtained from 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl as follows: a mixture of 320 ml. of dimethylformamide, 9.19 g. of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl and 1.50 g. of 5% palladium-on-carbon catalyst was hydrogenated at 80° and 3 atmospheres pressure for 18 hr. The reaction mixture was then filtered to remove the catalyst and unreacted "dimer," and the red filtrate was concentrated to give 5.5 g. of a red, hygroscopic solid. Conversion of this material to its picrate (m.p. 161°) showed it to be identical with the red compound obtained above.

4,4′-Dihydroxy-1,1′-dioxy-3,3′-dipicolyl (VI).—A mixture of 9.13 g. (0.03 mole) of 4,4′-diethoxy-1,1′-dioxy-3,3′-dipicolyl, 3.37 g. (0.06 mole) of potassium hydroxide and 70 ml. of water was heated under reflux for 20 hr., cooled to room temperature and diluted with a 1:1 mixture of ethanol and acetone. The voluminous, yellow solid which separated was recrystallized from water; yield 6.74 g. (69%), m.p. 355° dec.

Anal. Calcd. for $C_{12}H_{10}N_2O_4K_2$: C, 44.4; H, 3.1; N, 8.6. Found: C, 44.4; H, 3.2; N, 8.6.

By dissolving the dipotassium salt in water and adding palladium chloride, the dipalladium salt of 4,4′-dihydroxy-1,1′-dioxy-3,3′-dipicolyl was obtained as red-brown crystals, m.p. 175–180°.

The barium salt was obtained conveniently by direct hydrolysis of 4,4′-diethoxy-1,1′-dioxy-3,3′-dipicolyl with an equivalent amount of aqueous barium hydroxide. The salt separated from the reaction solution in quantitative yield upon cooling.

Decomposition of the barium salt with sulfuric acid yielded 4,4′-dihydroxy-1,1′-dioxy-3,3′-dipicolyl as a pale yellow solid, m.p. 165–166°, which readily could be recrystallized from water. A satisfactory analytical sample could not be obtained from this material, however, because of its tenacious retention of small amounts of inorganic ions. It is best identified as its dipotassium salt as described above.

4,4′-Dichloro-1,1′-dioxy-3,3′-dipicolyl (VII).—To 90 ml. of cold (0°) acetyl chloride was added 9.19 g. of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl and the mixture heated under reflux on a steam-bath for 2 hr. The reaction mixture was then poured on 450 g. of crushed ice, the solution adjusted to *p*H 6 with sodium carbonate and extracted several times with chloroform. The combined extracts were dried over anhydrous sodium sulfate and evaporated to dryness. The solid residue was triturated with cold water containing a little sodium carbonate and then recrystallized from ethanol to give 6.02 g. (70%) of white needles, m.p. 212–214° dec. Recrystallization from water raised the melting point to 219° dec.

Anal. Calcd. for $C_{12}H_{10}Cl_2N_2O_2$: C, 50.5; H, 3.5; N, 9.8. Found: C, 50.5; H, 3.8; N, 9.7.

This compound was converted to its dihydrochloride salt, m.p. 245° dec., by recrystallization from 10% aqueous hydrochloric acid.

Anal. Calcd. for $C_{12}H_{12}Cl_4N_2O_2$: C, 40.3; H, 3.4; N, 7.9. Found: C, 40.6; H, 3.6; N, 8.2.

4,4′-Dichloro-3,3′-dipicolyl (IX). Method A.—A mixture of 100 ml. of liquid, anhydrous ammonia and 2.73 g. of 4,4′-dichloro-1,1′-dioxy-3,3′-dipicolyl was sealed in a steel reaction vessel and heated with shaking at 150° for 6 hr. The bomb was then cooled, the excess ammonia bled off and the solid residue recrystallized from aqueous ethanol to give colorless crystals, m.p. 110–111°. The product was further purified by sublimation at 100° (0.02 mm.); m.p. 115–115.5°.

Anal. Calcd. for $C_{12}H_{10}N_2Cl_2$: C, 56.9; H, 4.0; N, 11.1. Found: C, 57.0; H, 4.0; N, 10.5.

Recrystallization of this material from a mixture of dilute hydrochloric acid and ethanol gave the dihydrochloride salt, m.p. 291° dec., which could be sublimed readily at 200° (0.05 mm.).

Anal. Calcd. for $C_{12}H_{12}N_2Cl_4$: C, 44.2; H, 3.7; N, 8.6. Found: C, 44.4; H, 3.7; N, 8.5.

Treatment of 4,4′-dichloro-3,3′-dipicolyl in aqueous ethanol with picric acid yielded a yellow crystalline picrate, m.p. 228° dec., which was purified readily by sublimation at 200° (0.005 mm.).

Anal. Calcd. for $C_{12}H_{10}N_2Cl_2 \cdot 2C_6H_3N_3O_7$: C, 40.5; H, 2.3; N, 15.8. Found: C, 40.5; H, 2.2; N, 15.7.

Method B.—A solution of 2.26 g. of 4,4′-dichloro-1,1′-dioxy-3,3′-dipicolyl in a mixture of 100 ml. of water and 10 ml. of concentrated hydrochloric acid containing 0.8 g. of 5% palladium-on-carbon catalyst was hydrogenated at 3 atmospheres pressure and at room temperature until hydrogen absorption ceased. The catalyst was removed by filtration and the acid filtrate was evaporated to dryness under reduced pressure. Recrystallization of the residue from a mixture of dilute hydrochloric acid and ethanol yielded the dihydrochloride of 4,4′-dichloro-3.3′-dipicolyl, m.p. 291° dec., identical in all respects with the sample prepared above. Likewise, a sample of the free base (m.p. 115°) was also identical with the authentic sample prepared above.

4,4′-Dihydroxylamino-1,1′-dioxy-3,3′-dipicolyl (VIII).—Hydrogenation of 8.42 g. of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl in 300 ml. of absolute ethanol containing 6 ml. of concentrated hydrochloric acid in the presence of 5% palladium-on-carbon catalyst at 50° under 3 atmospheres pressure was carried out until hydrogen absorption ceased. The reaction mixture was then concentrated to about half its volume, cooled and filtered, and the resulting solid was recrystallized from aqueous hydrochloric acid to give 8.51 g. (88%) of long, colorless prisms, m.p. 228° dec.

Anal. Calcd. for $C_{12}H_{16}N_4O_4Cl_2$: C, 41.0; H, 4.6; N, 16.0. Found: C, 41.0; H, 4.4; N, 15.9.

The dihydrochloride could be converted readily to the yellow free base, m.p. 295–300° dec., by dissolving in water

and precipitating with ammonium hydroxide. This material proved to be difficult to purify, however, because of its sparing solubility in organic solvents and its tendency to decompose slowly in high boiling solvents such as dimethylformamide. It is best purified and characterized as its dihydrochloride as described above.

4,4′-Diamino-3,3′-dipicolyl (X).—To a suspension of 6.12 g. of 4,4′-dinitro-1,1′-dioxy-3,3′-dipicolyl in 200 ml. of glacial acid was added 4.5 g. of 5% palladium-on-carbon catalyst, and the mixture was hydrogenated at 3 atmospheres pressure and at 50° until hydrogen absorption ceased (about 5 hr.). The hydrogenation mixture was heated to 70° and filtered from the catalyst, and the filtrate was cooled and diluted with ether. The voluminous white solid which separated was collected by filtration and recrystallized from acetic acid to give 6.68 g. (100%) of 4,4′-diamino-3,3′-dipicolyl diacetate as colorless crystals, m.p. 115–116°.

Anal. Calcd. for $C_{16}H_{22}N_4O_4$: C, 57.5; H, 6.6; N, 16.8. Found: C, 57.2; H, 6.8; N, 16.9.

The free base was prepared in 75% yield by addition of aqueous sodium hydroxide to a saturated aqueous solution of the above diacetate. Recrystallization of the precipitated solid from ethanol–acetone yielded colorless prisms, m.p. 250–251°.

Anal. Calcd. for $C_{12}H_{14}N_4$: C, 67.3; H, 6.6; N, 26.2. Found: C, 67.2; H, 6.5; N, 26.3.

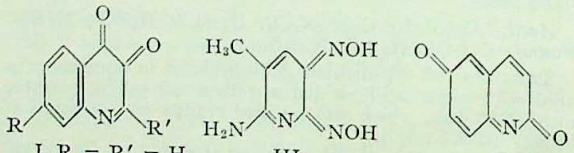
Azaquinones. I. Oxidation of Certain Hydroxy- and Aminopyridones[1]

BY J. H. BOYER AND S. KRUGER

RECEIVED JANUARY 26, 1957

Hydroxylation at unsubstituted α-positions during oxidation of aminopyridones, V and VI (R = H, CH_3), or 3-hydroxypyridone-2 with manganese dioxide, chromium trioxide or potassium bromate (preferred) brought about the formation of tautomeric hydroxyazaquinones (VII ⇄ VIII, R = H, CH_3), isolated as quinhydrones. Reductive acetylation produced 2,3,6-triacetoxypyridine (X, R = H). Attempts to prepare 4-azabenzoquinone were unsuccessful.

Kudernatsch introduced azaquinones to the chemical literature by an oxidation of 2,3-dihydroxypyridine.[2] More recently 4-azanaphthquinone-1,2 (I)[3] as an impure yellow powder, its 3-hydroxy-6-methyl- derivative (II)[4] as light yellow needles and the dioxime (III) of 3-aza-4-amino-5-methylbenzquinone-1,2[5] as red needles have been reported. Derivatives of 1-azanaphthquinone-2,6 (IV) were considered as intermediates in the oxidation of derivatives of 6-hydroxycarbostyril into red carbostyril-5,6-quinones.[6]



I, R = R′ = H
II, R = CH_3, R′ = OH

III

IV

Two general methods for the preparation of azaquinones were selected for preliminary investigations. The oxidation of certain aminopyridones is reported here; the transformation of azaquinone dioximes into quinones is under investigation.

Satisfactory oxidations of aminopyridones (V, VI, R = H, CH_3) were carried out in cold sulfuric acid with deficient amounts of manganese dioxide, chromium trioxide or potassium bromate (preferred). Bromate oxidation of 5-aminopyridone-2 (VI, R = H) occurred at a convenient rate at 0° whereas 3-aminopyridone-2 (V, R = H) required cooling to −20° for control of the reaction. Attempts to oxidize 3-aminopyridone-4 with deficient amounts of bromate even at −50° led to the formation of intractable tars. From each of 3- and 5-aminopyridone-2 and from 3-hydroxypyridone-2, a deep purple solid was obtained and was separated into two fractions by Soxhlet extraction with ethanol.

Oxidation of V (R = CH_3) and VI (R = CH_3) was successful at higher temperatures (*ca.* 25°); however, to avoid decomposition a deficient amount of bromate again was necessary. The deeply colored products appeared to be quinhydrones (VIII · VI and VII · V, R = CH_3). A condensation product from VII · V (R = CH_3) and phenylhydrazine was identified with a reported product from phenylhydrazine and XI.[7] This established the occurrence of hydroxylation at unsubstituted α-positions during the oxidation of V, VI (R = CH_3). Hydroxylation of a pyridine ring had previously been observed in the oxidation of 2-hydroxy-7-methylquinoline,[4] in the oxidation of 1,4-dihydroxyisoquinoline into yellow phthalonimide (X)[8a] and in the permanganate oxidation of 3,4-dihydroxypyridine-6-carboxylic acid into 2,3,4-trihydroxypyridine-6-carboxylic acid.[8b]

Elemental analyses and reductive acetylation demonstrated that hydroxylation, presumably at an α-position, had also occurred during the oxidation of V, VI (R = H) into hydroxyazabenzquinones (VII ⇄ VIII, R = H) and their quinhydrones with 2,3,6-trihydroxypyridine. The trihydroxypyridine was an expected product of the reversible oxidation–reduction between an aminopyridone and an hydroxyazaquinone. Impure quinhydrones, VII·V or VIII·VI (R = H), were apparently obtained in certain experiments. At-

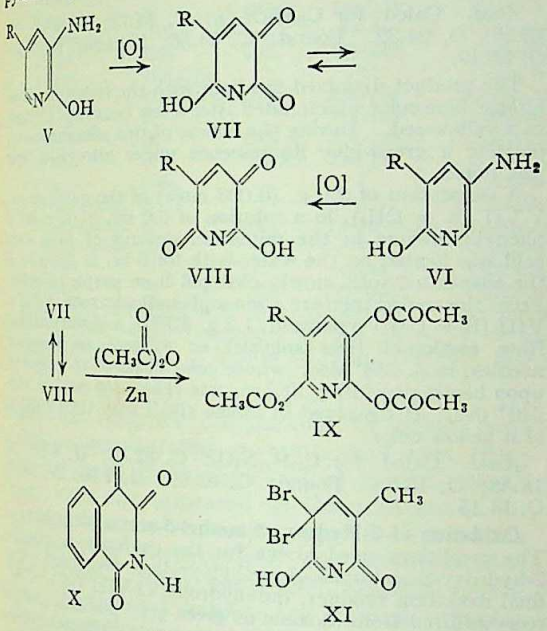
tempts to repeat Kudernatsch's preparation of 3-azabenzquinone-1,2, a brown-violet powder, from 3-hydroxypyridone-2 and manganese dioxide[2] resulted, instead, in the formation of hydroxyazaquinones or their quinhydrones, identical with the oxidation products from the corresponding aminopyridone. Unidentified material was obtained upon refluxing samples of the oxidation product in acetic anhydride; however, reductive acetylation produced the previously unknown, 2,3,6-triacetoxypyridine (IX, R = H) in good yield.



Experimental[9]

Reduction of Nitropyridones.—According to a method described by Crowe for the reduction of 3-nitro-4-hydroxypyridine,[10] 3-nitropyridone-2[11] and 5-nitropyridone-2[11] were reduced by tin and hydrochloric acid to 3-aminopyridone-2 hydrochloride and 5-aminopyridone-2 hydrochloride in 85–90% yields.

Oxidation of 2-Hydroxy-5-aminopyridine.—A suspension of 3.0 g. (0.02 mole) of the amine hydrochloride in 25 ml. of concentrated sulfuric acid was warmed gently until hydrogen chloride evolution had ceased. The mixture was cooled and poured onto 50 g. of ice. A solution of 1.1 g. (0.0066 mole; 0.010 mole required for oxidation to the hydroquinone, $C_{10}H_8N_2O_6$; 0.0134 mole for the quinone, $C_5H_3NO_3$) of potassium bromate in 25 ml. of water was then rapidly added with stirring. The temperature of the reaction was not allowed to rise above 5°. The reaction mixture remained for several hours at 3–5° as a purple precipitate slowly separated. This was isolated by filtration, washed with ice-water and dried. A Soxhlet extraction of the dried solid with absolute ethanol was extended over a one-week period; however, several hours were sufficient for the extracting liquid portions to become colorless. After several recrystallizations from N,N-dimethylformamide and from molten acetanilide, the Soxhlet insoluble fraction separated as purple-brown micro-crystals with a metallic green sheen, 0.80 g. (47%).[12] It was very insoluble in all common organic solvents and had an indefinite decomposition range above 300°.

Anal. Calcd. for $C_5H_3NO_3$: C, 47.99; H, 2.42; N, 11.20. Calcd. for $C_{10}H_8N_2O_6$: C, 47.62; H, 3.20; N, 11.11. Found: C, 48.14, 48.16; H, 2.83, 2.70; N, 11.61, 11.99.

Upon concentration and cooling, the alcohol solution obtained from the Soxhlet extraction afforded red-brown leaflets, 0.40 g. (23%, total yield 70%).[12] This fraction was slightly soluble in common solvents and recrystallized from ethanol or methanol as purple-brown rhombs with indefinite decomposition above 300°. With the exception of ethanol solubility these two fractions appeared to be identical.

Anal. Calcd. for $C_5H_3NO_3$: C, 47.99; H, 2.42; N, 11.20. Calcd. for $C_{10}H_8N_2O_6$: C, 47.62; H, 3.20; N, 11.11. Found: C, 47.86, 47.65; H, 2.72, 3.31; N, 11.50, 11.15.

Attempts to carry out the oxidation with the theoretical amount of potassium bromate (at least 0.50 mole per mole of aminopyridone) led to excessive decomposition of organic material. The oxidation was also carried out with chromium trioxide in sulfuric acid.

Both the soluble and insoluble fractions of oxidation product dissolved in alkali. The formation of an intense blue color faded rapidly as decomposition progressed with the absorption of oxygen and evolution of ammonia. The alkaline solutions finally became red-yellow and fluoresced in ultraviolet light.

Oxidation of 2-Hydroxy-3-aminopyridine.—A suspension of 1.0 g. (0.0066 mole) of 2-hydroxy-3-aminopyridine hydrochloride in 10 ml. of concentrated sulfuric acid was warmed until evolution of hydrogen chloride gas had ceased. The solution was then maintained at −20° as 0.3 g. (0.003 mole; 0.0066 mole required for oxidation to the hydroquinone $C_{10}H_8N_2O_6$; 0.010 mole for the quinone, $C_5H_3NO_3$) of chromium trioxide in 5 ml. of concentrated sulfuric acid was added with stirring. The mixture was held at −20° for an additional 2 hr., slowly warmed to room temperature, poured onto ice and filtered. The purple precipitate (0.25 g., 62%)[12] was identical with the oxidation product obtained from 2-hydroxy-5-aminopyridine and separated into soluble and insoluble fractions upon Soxhlet extraction with absolute ethanol.

Reductive Acetylation.—A mixture of 0.1 g. (0.8 mmole) of either the ethanol-soluble or the ethanol-insoluble fraction of the above oxidation product obtained from the oxidation of either 2-hydroxy-3-aminopyridine or 2-hydroxy-5-aminopyridine and 0.5 g. zinc dust in 3 ml. of acetic anhydride was heated at water-bath temperature until all solid material had dissolved and the solution became pale yellow. A pale blue fluorescence to ultraviolet light developed during the reaction. The hot solution was filtered and excess solvent was removed *in vacuo*. Upon recrystallization from ethanol the residue separated as pale yellow crystals, 0.15 g. (75%), m.p. 135–140°. Further purification of a chloroform solution of the product by chromatographic separation on an alumina column easily was followed by the compound's characteristic blue fluorescence to ultraviolet light. The product upon additional recrystallization from ethanol produced pale cream platelets, m.p. 159°, of 2,3,6-triacetoxypyridine (X, R = H).

Anal. Calcd. for $C_{11}H_{11}NO_6$: C, 52.15; H, 4.38; N, 5.53; O, 37.94. Found: C, 52.58; H, 4.30; N, 5.78; O, 36.90.

Samples of 2,3,6-triacetoxypyridine obtained from each hydroxyazaquinone fraction obtained from each of the isomeric aminopyridones were identical as established by m.p. and mixture m.p. determinations.

Oxidation of 2,3-dihydroxypyridine by either Kudernatsch's procedure using manganese dioxide or by the present method using potassium bromate led to the formation of the ethanol-soluble and -insoluble fractions obtained above. A trace amount of an unidentified light yellow solid, m.p. >300° dec., was slowly collected over a period of two days upon attempted sublimation of a sample of the insoluble fraction at 250–280° (10^{-4} mm.) (*Anal.* Found: C, 47.62; H, 3.20; N, 11.11). In agreement with the previous results both fractions were transformed by reductive acetylation into 2,3,6-triacetoxypyridine, m.p. 159°.

Attempts to oxidize **3-amino-4-hydroxypyridine hydrochloride**[13] were unsuccessful and led to the formation of intractable red tars even with insufficient amounts of oxidizing agent at −50°.

Preparation of 3-Nitro-4-azidopyridine.—A solution of 3.2 g. (0.02 mole) of 3-nitro-4-chloropyridine and 2.6 g. (0.04 mole) of sodium azide in 23 ml. of methanol and 2 ml. of water was warmed to 35–40° for 10 minutes. The solution was filtered and concentrated to half its volume. Upon cooling, the azide separated as pale yellow crystalline rods, 2.55 g. (76.5%), m.p. 89° dec.

Anal. Calcd. for $C_5H_3N_5O_2$: C, 36.36; H, 1.83; N, 42.42. Found: C, 36.28; H, 2.03; N, 41.94.

Upon warming slightly above 90° for a few seconds decomposition occurred with a violent evolution of gas and formation of a yellow oil which changed rapidly into a dark-colored insoluble solid residue which neither melted nor decomposed under 300°.

Aminomethylpyridones.—Nitration of 2-amino-5-methylpyridine[14] followed by diazotization and hydrolysis afforded 2-hydroxy-3-nitro-5-methylpyridine, m.p. 253–255°, in 38% yield. To a suspension of 30.8 g. (0.2 mole) of this nitro compound in 400 ml. of 2% acetic acid, an excess of iron filings was added. The mixture was warmed on the water-bath with occasional stirring until the yellow color of the nitro compound had disappeared. The mixture was then neutralized with calcium carbonate, filtered while hot and the precipitate was washed several times with hot water. An excess of acetic anhydride was added with stirring to the filtrate, externally cooled in an ice-bath. The isolated precipitate was recrystallized from ethanol from which 2-hydroxy-3-acetamido-5-methylpyridine separated as rhombic leaflets, m.p. 253° (with slight sublimation), 22.2 g. (67%). A change in crystalline form from rhombic leaflets into needles occurred around 220°.

Anal. Calcd. for $C_8H_{10}N_2O_2$: C, 57.83; H, 6.03; N, 16.87. Found: C, 57.89; H, 6.05; N, 17.14.

Nitration of 2-amino-3-methylpyridine[14] followed by diazotization and hydrolysis brought about the formation of 2-hydroxy-3-methyl-5-nitropyridine in 71% yield.[15] According to the above directions it was reduced and acetylated in 69% yield. Upon recrystallization from ethanol, 2-hydroxy-3-methyl-5-acetamidopyridine separated as colorless needles, m.p. 247°.

Anal. Calcd. for $C_8H_{10}N_2O_2$: C, 57.83; H, 6.03; N, 16.87. Found: C, 57.44; H, 6.36; N, 16.45.

Oxidation of 2-Hydroxy-3-acetamido-5-methylpyridine.—A suspension of 3.0 g. (0.018 mole) of 2-hydroxy-3-acetamido-5-methylpyridine in 50 ml. of 16% (by volume) sulfuric acid was heated at 95–100° for 5 minutes. Longer heating at this stage diminished the final yield. The pale yellow solution was cooled to 25°, and 1.0 g. (0.006 mole) of potassium bromate in 25 ml. of water was added in one portion. The solution turned purple immediately and was cooled externally so that the temperature was held under 40°. A marked decrease in yield was observed if the temperature at this stage was allowed to reach 50–55°. A violet-brown precipitate separated from a blue solution upon standing at room temperature for 2 hr. and in the refrigerator for 24 hr. The crude product, 0.7 to 1.0 g. (29 to 42%), was washed with cold water and dried. An increase in the molar ratio of bromate resulted in nearly complete destruction of this product. Recrystallization from methanol allowed the separation of thin birefringent green-gray leaflets of impure quinhydrone, V·VII (R = CH_3), indefinite decomposition above 300°, from a deep purple supernatant liquid.

Anal. Calcd. for $C_{12}H_{12}N_2O_4$: C, 54.73; H, 4.98; N, 15.96; O, 24.32. Found: C, 54.56; H, 4.94; N, 14.99; O, 25.49.

The product dissolved in alkali with the formation of an intense blue color which faded after a few hours and changed to a yellow-red. During the course of this alkaline decomposition a green-blue fluorescence under ultraviolet light was noted.

A suspension of 2.0 g. (0.008 mole) of the quinhydrone, V VII (R = CH_3), in a solution of 5.0 ml. (0.05 mole) of phenylhydrazine in the minimum amount of 10% acetic acid was heated on the water-bath for 6 hr. as the color of the suspended solid slowly changed from purple to brown. From the cooled mixture a monophenylhydrazone of VII ⇄ VIII (R = CH_3) separated, 1.2 g. (67%), and recrystallized from methanol (less soluble) or ethanol as brown-red needles, m.p. 254° dec., whose color changed to yellow-red upon heating to 210°; lit.[7] reports yellow-red needles, m.p. 240° dec. It dissolved in dilute alkali with the formation of a yellow color.

Anal. Calcd. for $C_{12}H_{11}N_3O_2$: C, 62.88; H, 4.85; N, 18.38; O, 13.89. Found: C, 62.69; H, 4.90; N, 18.11; O, 14.15.

Oxidation of 2-Hydroxy-3-methyl-5-acetamidopyridine.—The conditions used above for the oxidation of isomeric 2-hydroxy-3-acetamido-5-methylpyridine were used. The final oxidation product, quinhydrone VI·VIII (R = CH_3), recrystallized from dioxane as green-gray platelets and decomposed above 300°. The deep purple dioxane solutions of this product were stable for short times only and soon became red-yellow in color with the simultaneous formation of a green-blue fluorescence to ultraviolet light. It was also soluble in alkali with decomposition and with the development of a green-blue fluorescence.

Anal. Calcd. for $C_{12}H_{13}N_3O_4$: C, 54.73; H, 4.98; N, 15.96; O, 24.32. Found: C, 55.02; H, 4.88; N, 15.07; O, 24.63.

The Pyridylethylation of Indole and Related Reactions

BY ALLAN P. GRAY AND WESLEY L. ARCHER

RECEIVED JANUARY 19, 1957

Pyridylethylation of indole and 1-substituted indoles in refluxing glacial acetic acid smoothly yielded 3-indolylethylpyridine derivatives. In ethanol containing a catalytic amount of sodium ethoxide, indole added to 4-vinylpyridine to provide 4-(1-indolylethyl)-pyridine. Under alkaline conditions indene yielded monopyridylethylated products which are tentatively formulated as 3-indenyl derivatives. Indole and 1-methylindole readily condensed with pyridinecarboxaldehydes in glacial acetic acid at room temperature to give relatively unstable di-indolylmethylpyridine products. Fischer cyclization in polyphosphoric acid of the phenylhydrazones of 3- and 4-acetylpyridine afforded the corresponding 2-indolylpyridines. The methobromide of 4-(2-indolyl)-pyridine gave no evidence of anhydronium base formation. Catalytic hydrogenation of the methobromides of many of the indolyl-substituted pyridines yielded the 1-methylpiperidine derivatives.

A general interest in pyridine derivatives with relatively large substituents[1] prompted this investigation. Although primary concern in the present paper is with a study of the reactions of indole and its 1-substituted derivatives with vinylpyridines and pyridinecarboxaldehydes, preparations of some related bases also are discussed.

Pyridylethylation.—The experiments of Doering and Weil[2] established 2- and 4-vinylpyridine as

electrophilic reagents comparable to other conjugated α,β-unsaturated systems, and this reactivity has been much exploited in recent years.[3] Reports have also appeared on the addition of indole and its derivatives to conjugated olefins such as acrylonitrile,[4] nitroethylene[5] and to substituted acrylic acids.[6] Under controlled alkaline conditions, N-substituted indoles are formed, whereas acid catalysis, high temperatures or use of a Grignard reagent directs reaction to the 3-position. Although Reich and Levine[3] have 2-pyridylethylated pyrrole at the 1-position under alkaline conditions, no report of the pyridylethylation of indole has come to our attention.

In the present work main interest centered on the preparation of 3-substituted indole derivatives. Acetic acid was found to provide an excellent solvent-catalyst for this purpose. Thus, refluxing a glacial acetic acid solution of indole and 4-vinylpyridine smoothly afforded 4-(3-indolylethyl)-pyridine (I) in approximately 70% yield. The 2-indolylethylpyridines II through VII, listed in Table I, were prepared in similar fashion. On the other hand, when indole was 4-pyridylethylated in an ethanol solution containing small amounts of sodium ethoxide and copper sulfate (polymer inhibitor), 4-(1-indolylethyl)-pyridine (VIII) was obtained in 57% yield.

Although an ample basis already exists for the structural assignments, a few points may be worthy of mention. In this connection may be noted the infrared spectrum[7] of I which exhibits an intense absorption band in the N–H stretching region. The spectrum of VIII, however, possessed a very weak band in the same region, suggesting the contamination of this compound by a small amount of I. (This is not too surprising in view of the long appreciated difficulties in obtaining *pure* 1-alkylated indole derivatives.) Catalytic hydrogenation of the methobromide of 2-(3-indolylethyl)-pyridine (IV) readily provided 2-(3-indolylethyl)-1-methylpiperidine (XI), the melting point of which agreed with that of the compound obtained by the catalytic hydrogenation of the condensation product from 3-indolecarboxaldehyde and 2-picoline methohalide (see footnote *d*, Table II). Finally, as is apparent from Table I, 1-methyl- and 1-benzylindole also smoothly afforded pyridylethylated derivatives in hot glacial acetic acid.

The 1-substituted indoles, as anticipated,[8] were more sluggish than indole in the acetic acid catalyzed reaction, albeit comparable yields of the products were obtained after more prolonged refluxing. It is interesting to note that acetic acid solutions of 1-methylindole (but not indole) developed an emerald green color on warming. Although this is suggestive of the formation of the indolenine salt, it probably has no mechanistic bearing on the reaction. Indeed, the only logical path for acid catalysis would seem to be *via* protonation of the vinylpyridine, thus polarizing the molecule and lowering the transition state energy.[9] Yields obtained from 4-vinylpyridine were somewhat better than from the 2-isomer and markedly

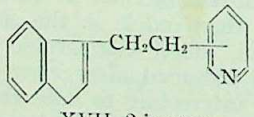
[a,b,c] See corresponding footnotes of Table I. [d] J. Finkelstein and J. Lee, U. S. 2,695,290 (1954), reported m.p. 138–140°; A. M. Ackerman and H. Veldstra, *Rec. trav. chim.*, **73**, 629 (1954), gave m.p. 141° for this compound prepared by a different method. [e] Low melting solid, b.p. 165–167° (0.5 mm.).

better than from 2-vinyl-5-ethylpyridine (see Experimental part); this, however, could have been a result of differences in ease of isolation of the products.

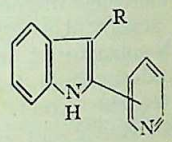
In connection with this program, indene was added, under alkaline conditions, to both 2- and 4-vinylpyridine. Catalysis with either sodium ethoxide or sodamide furnished rather modest yields of monopyridylethylated indene products accompanied by considerable tar. Optimum yields were obtained when excess indene was used. Increasing the proportion of vinylpyridine lowered the yield of mono-derivative, although no pure poly-pyridylethylated materials were isolated. In comparison, cyanoethylation using Triton B affords tris-(cyanoethyl)-indene.[10] Although no experimental evidence as to structure was obtained, these products are tentatively formulated as 3-indenylethylpyridines in view of the facile isomerization of 1-substituted into the presumably more stable 3-substituted indenes under very mild alkaline conditions.[11]



XVII, 2-isomer
XVIII, 4-isomer

Pyridinecarboxaldehyde Reactions.—Indole has long been known to condense readily with carbonyl compounds, *e.g.*, under acid or Grignard conditions. This nucleophilic reactivity has been fruitfully exploited in the Mannich reaction and in the preparation of arylidene and diindolylmethyl derivatives.[12] The corresponding reactions of indole and of 1-methylindole with the pyridinecarboxaldehydes proceeded exothermically in glacial acetic acid at room temperature to provide fair yields (50–75%) of the diindolylmethylpyridine derivatives described in Table III. As has been previously noted for diindolylmethyl derivatives,[12] these products were relatively unstable and underwent disproportionation and air oxidation to highly colored materials.

XIX, 3-isomer, R = H
XX, 4-isomer, R = H



Related Derivatives.—3- and 4-(2-indolyl)-pyridine were prepared by the Fischer indole synthesis from the phenylhydrazone of the corresponding acetylpyridine. Although a few (3-alkyl-2-indolyl)-pyridines have been prepared[13] by Fischer cyclization from the appropriate pyridyl ketone, apparently none of the *unsubstituted* 2-indolylpyridines have been obtained previously. In this context it is noteworthy that attempted cyclization of the phenylhydrazone of 4-acetylpyridine under the conditions successfully employed[13] for the preparation of the 2- and 3-isomers of XIX in which R = methyl or ethyl (*i.e.*, hydrogen chloride in refluxing ethanol) resulted in almost quantitative recovery of the starting phenylhydrazone. Even hydrogen chloride in refluxing glacial acetic acid gave back only starting material (80% recovery). XIX and XX were satisfactorily (55–65% yield) obtained, however, by somewhat harsher treatment with polyphosphoric acid.[14] The markedly

It might be noted in passing that in attempted Mannich reactions of indole with *substituted* aldehydes in place of formaldehyde (benzaldehyde, *p*-dimethylaminobenzaldehyde) and dimethylamine in aqueous acetic acid at room temperature, good yields of phenyldiindolylmethane and *p*-dimethylaminophenyldiindolylmethane (respectively) were obtained as the only products (unpublished results from this Laboratory).

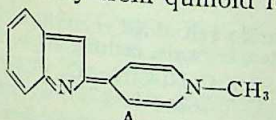
[a] These compounds melt with decomposition. [b,c] See corresponding footnotes of Table I.

greater stability of the phenylhydrazones of methyl *vs.* methylene ketones to acid is well known and presumably can be ascribed to the relative stabilities of the respective carbonium ions (prim. *vs.* sec.). Reaction of the phenylhydrazone of 3-acetylpyridine in polyphosphoric acid was decidedly less violent than that of the 4-isomer, the product was obtained in poorer yield and accompanied by more tar.

Of incidental interest is the fact that the methobromide of XX (or XIX) gave no indication of anhydronium base formation in aqueous alcohol by titration with 0.1 *N* NaOH.[15] In contrast to the carboline anhydronium bases, the properties of which seemed to correspond more closely to the charge-separated structures,[15] the present information points up the importance of resonance contributions to stability from quinoid forms; *i.e.*, A



A

should contribute very little to over-all stabilization.[16]

Catalytic hydrogenation of the methobromides of a number of the indolyl-substituted pyridines readily yielded the corresponding 1-methylpiperidines; most of these are listed in Table II.

NOTES ADDED IN PROOF.—After this paper had been accepted for publication, the abstract of an article [S. Sugasawa, M. Terashima and Y. Kanaoka, *Pharm. Bull.* (Japan), 4, 16 (1956) [*C. A.*, 51, 3593*d* (1957)]] appeared describing the preparation of 2-, 3-, and 4-(2-indolyl)-pyridine by essentially the same procedure (polyphosphoric acid cyclization) employed here. Physical properties of the products and derivatives are in good agreement. It is recognized, as mentioned in a private conversation with Dr. W. E. Noland at the Miami meeting, that pure 3,3′-diindolylmethylpyridines should be colorless. The analytical data and the fact that the compounds are all monoacidic bases argue against formulation of the materials as the rosindole oxidation products. This question is being further investigated.

Acknowledgment.—The authors are grateful to Dr. C. J. Cavallito for continued interest and encouragement. Ionic halogens and basic nitrogens were determined by Mr. Dean F. Cortright.

Experimental[17]

Intermediates.—1-Methylindole, b.p. 114–115° (14 mm.), $n^{25}D$ 1.6038, was obtained in 80–85% yield by the reaction of indole with sodamide and dimethyl sulfate in dry toluene[18] at steam-bath temperatures. 1-Benzylindole, b.p. 145–147° (0.3 mm.), m.p. 43°, was prepared essentially as described by Plieninger.[18] The vinylpyridines were obtained from the Reilly Tar and Chemical Corp. and the pyridinecarboxaldehydes from the Aldrich Chemical Co. Dr. F. Cislak of Reilly kindly supplied samples of 3- and 4-acetylpyridine.

Pyridylethation at the 3-Position of the Indole Nucleus.—These reactions were run in hot glacial acetic acid, usually with approximately equimolar proportions of the reactants. Frequently the vinylpyridine was freshly distilled prior to use, although the commercial product (containing inhibitor) gave perfectly satisfactory results. The products were purified either by recrystallization (I, IV, VI), *via* the hydrochloride (II), or by distillation (III, V, VII). Yields averaged 65–75% with 4-vinylpyridine, 50–65% with 2-vinylpyridine and only 25–30% with 2-vinyl-5-ethylpyridine.

A. 4-(3-Indolylethyl)-pyridine (I).—A solution of 26.0 g. (0.25 mole) of 4-vinylpyridine (undistilled) and 23.4 g. (0.2 mole) of indole in 100 ml. of glacial acetic acid was refluxed (oil-bath) for 3 hr. The solution was concentrated *in vacuo* and the residue made weakly basic with dilute alkali. The resultant crystalline precipitate was recrystallized from aqueous isopropyl alcohol to yield 30.6 g. (69%) of I, m.p. 149–151°.

B. 4-(1-Methyl-3-indolylethyl)-pyridine (II).—To a refluxing (emerald green) solution of 1965 g. (15 moles) of 1-methylindole in 4.5 liters of glacial acetic acid was added, dropwise with stirring, 1590 g. (15 moles) of 4-vinylpyridine. After 22 hr. refluxing the solution was concentrated under reduced pressure. The residue was dissolved in dilute hydrochloric acid, the solution was filtered and then treated with concentrated hydrochloric acid in order to precipitate the hydrochloride salt of the product. (This step removed tarry, polymeric basic materials which were otherwise diffi-

cult to separate.) The collected salt was dissolved in water and the solution was made alkaline with ammonia to precipitate 2580 g. (73% yield) of II, m.p. 91–93°. Recrystallization from aqueous acetone raised the melting point to 96–98°.

C. **2-(1-Methyl-3-indolylethyl)-pyridine (V).**—A solution of 30 g. (0.23 mole) of 1-methylindole and 25 g. (0.24 mole) of 2-vinylpyridine in 100 ml. of glacial acetic acid was refluxed for 18 hr. After removal of the solvent under reduced pressure, the residue was dissolved in dilute hydrochloric acid, the aqueous solution was washed with ether, made alkaline and extracted with ether. Concentration of the dried extract left an oil which was distilled to yield 26.3 g. (49%) of V, b.p. 170–185° (0.5 mm.), $n^{25}D$ 1.6140.

4-(1-Indolylethyl)-pyridine (VIII).—To 50 ml. of ethanol containing 0.5 g. of sodium and 0.5 g. of cupric sulfate was added 29.2 g. (0.25 mole) of indole and 52.4 g. (0.5 mole) of 4-vinylpyridine. The reaction mixture was heated in a sealed tube for 4 hr. at 140–150° (oil-bath temperature), allowed to cool to room temperature, filtered and the filtrate was concentrated *in vacuo*. The residue was taken up in ether, extracted with acid, the acid solution was made alkaline and extracted with ether. Drying and removal of the ether left a red oil which was distilled *in vacuo*. Redistillation afforded 31.7 g. (57% yield) of VIII as an oil which crystallized on standing, b.p. 160–165° (0.1 mm.), m.p. 41–45°. A weak absorption band in the N–H stretching region of the infrared indicated that this product was contaminated by a little of the 3-isomer.

4-(3(?)-Indenylethyl)-pyridine (XVII).—A mixture of 50.0 g. (0.43 mole) of freshly distilled indene and 1 g. of metallic sodium dissolved in 5 ml. of ethanol was heated to 80°, and 23.0 g. (0.22 mole) of 4-vinylpyridine (undistilled) was added dropwise with stirring. Stirring was continued and the reaction mixture was heated for 5 hr. at 80°. The ethylene dichloride extract of the cooled mixture was washed with water, dried over sodium sulfate and distilled. A fraction which immediately crystallized, b.p. 145–170° (0.3 mm.), was charcoaled and recrystallized from Skellysolve B to give 16.6 g. (34% yield) of XVII, m.p. 96–97°. The picrate melted at 176° dec. after recrystallization from ethanol.

Anal. Calcd. for $C_{16}H_{15}N$: N, 6.33. Found: N (basic), 6.52.

The methobromide of XVII, recrystallized from ethanol, melted at 210–212° dec.

Anal. Calcd. for $C_{17}H_{18}BrN$: C, 64.56; H, 5.74; Br, 25.27. Found: C, 64.66; H, 5.50; Br (ionic), 25.27.

2-(3(?)-Indenylethyl)-pyridine (XVIII).—To 116 g. (1.0 mole) of indene and 2.0 g. of powdered sodamide in 300 ml. of dry toluene, stirred and brought to reflux in an oil-bath, was added, dropwise, 52.5 g. (0.5 mole) of 2-vinylpyridine in 50 ml. of toluene. Stirring was continued and the reaction mixture was refluxed for 5 hr. The solution was separated from considerable tarry material and distilled *in vacuo*. Redistillation afforded 33.0 g. (30% yield) of XVIII, b.p. 145–155° (0.4 mm.), $n^{25}D$ 1.5987.

Anal. Calcd. for $C_{16}H_{15}N$: N, 6.33. Found: N (basic), 6.39.

The hydrochloride formed colorless crystals from isopropyl alcohol–ether, m.p. 148–150° dec.

Anal. Calcd. for $C_{16}H_{16}ClN$: C, 74.55; H, 6.26; Cl, 13.76. Found: C, 74.25; H, 6.19; Cl (ionic), 13.58.

3-(2-Indolyl)-pyridine (XIX).—To the polyphosphoric acid prepared from 36 g. of phosphorus pentoxide and 20 g. of 85% phosphoric acid was added 30.8 g. of the crude, powdered phenylhydrazone of 3-acetylpyridine (m.p. 139–141°[19]). The mixture was stirred by hand with a thermometer and gradually heated in an oil-bath until the internal temperature reached 125–130°. At this point a vigorous reaction ensued. The reaction flask was immediately removed from the oil-bath as the temperature shot rapidly to >230°. After the reaction had subsided (in 3–4 minutes), the flask was cooled under a cold water tap to an internal temperature of about 90° and diluted with water. The tarry, aqueous mixture was washed with ethyl acetate, made alkaline with a saturated solution of sodium carbonate and exhaustively extracted with chloroform. The chloroform extract was dried over a mixture of anhydrous sodium sulfate and sodium carbonate and concentrated to dryness. The crystalline residue was charcoaled in ethanol, the solution was diluted with water, decanted from the initial tarry precipitate and diluted with more water to yield, after refrigeration, 15.6 g. (55%) of crude product, m.p. 166–173°. Further recrystallization (with charcoaling) from ethanol–water afforded XIX as almost colorless platelets, m.p. 173–175°.

Anal. Calcd. for $C_{13}H_{10}N_2$: N (basic), 7.21. Found: N (basic), 6.86.

The hydrochloride salt of XIX formed pale yellow crystals from methanol–ether, m.p. 259–261° dec.

Anal. Calcd. for $C_{13}H_{11}ClN_2$: C, 67.68; H, 4.81; Cl, 15.37. Found: C, 68.02; H, 4.96; Cl (ionic), 15.03.

The methiodide crystallized from methanol–ethyl acetate in clusters of small, yellow, prismatic needles, m.p. 248–250° dec.

Anal. Calcd. for $C_{14}H_{13}IN_2$: C, 50.02; H, 3.90. Found: C, 50.18; H, 3.79.

The methobromide, recrystallized from methanol–ether, melted at 266–268° dec.

Anal. Calcd. for $C_{14}H_{13}BrN_2$: C, 58.14; H, 4.53; Br, 27.64. Found: C, 57.94; H, 4.65; Br (ionic), 27.43.

4-(2-Indolyl)-pyridine (XX).—This compound was prepared similarly to the 3-isomer. The reaction was considerably more vigorous, however, and afforded a cleaner product in better yield. An intimate mixture of polyphosphoric acid (60 g. of phosphorus pentoxide and 32 g. of 85% phosphoric acid) and 51.2 g. of the crude, powdered phenylhydrazone of 4-acetylpyridine (m.p. 143–146°[20]) was stirred with a thermometer and gradually heated until the internal temperature reached 115–120°. The flask was removed from the bath as a violent reaction accompanied by considerable fuming took place. The temperature rose to 280–285° in less than five minutes. When the reaction had subsided (in an additional 2–3 minutes), the mixture was cooled under a cold water tap, taken up in water and washed with ethyl acetate. The mixture of water and solid was made alkaline with excess saturated sodium carbonate and triturated until all of the insoluble salts had been converted to base. The solid precipitate was collected, exhaustively extracted with hot ethanol and the solution charcoaled. XX crystallized from the refrigerated ethanol solution in cream-colored plates, m.p. 208–209°; the yield was 30.6 g. (65%).

Anal. Calcd. for $C_{13}H_{10}N_2$: N (basic), 7.21. Found: N (basic), 7.21.

The hydrochloride salt of XX crystallized from methanol–ether in pale yellow crystals, melting above 285°.

Anal. Calcd. for $C_{13}H_{11}ClN_2$: C, 67.68; H, 4.81; Cl, 15.37. Found: C, 67.62; H, 4.77; Cl (ionic), 15.25.

The methiodide formed tiny, orange cubes from methanol–ethyl acetate, melting with decomposition at 260°.

Anal. Calcd. for $C_{14}H_{13}IN_2$: C, 50.02; H, 3.90. Found: C, 49.99; H, 3.71.

The methobromide, crystallized from methanol–ether, showed m.p. 272–274° dec.

Anal. Calcd. for $C_{14}H_{13}BrN_2$: C, 58.14; H, 4.53; Br, 27.64. Found: C, 58.76; H, 4.60; Br (ionic), 27.37.

Catalytic Hydrogenation of Indolyl-pyridine Methobromides.—The following are representative examples. Crude salts were used in those cases in which no methobromide is listed in Table I.

A. **4-(3-Indolylethyl)-1-methylpiperidine (IX).**—A solution of 8.0 g. (0.025 mole) of the methobromide of I dissolved in 100 ml. of analytical grade methanol containing 0.5 g. of platinum oxide (Adams catalyst; added under nitrogen) was hydrogenated in an Adams–Parr apparatus at 40 p.s.i. and room temperature. Hydrogen absorption ceased in 20 minutes. The filtered solution was evaporated to dryness, the residue was dissolved in warm water, the solution made alkaline and the resultant precipitate was recrystallized from aqueous ethanol to yield 4.3 g. (69%) of IX as fine, colorless needles, m.p. 171–173°.

B. **3-(2-Indolyl)-1-methylpiperidine (XXI).**—A solution of 6.1 g. (0.021 mole) of the methobromide salt of XIX in 200 ml. of 75% methanol was hydrogenated over 0.5 g. of Adams catalyst at 45 p.s.i. and room temperature. Hy-

drogenation was complete in less than 1 hr. The filtered solution was evaporated to a thick resin which was taken up in water, treated with alkali and extracted into ether. The dried ether extract was concentrated to a crystalline residue. Recrystallization from aqueous ethanol and then from benzene–Skellysolve B afforded 2.55 g. (56% yield) of XXI, m.p. 118–120°.

Anal. Calcd. for $C_{14}H_{18}N_2$: N (basic), 6.54. Found: N (basic), 6.24.

XXI hydrochloride showed m.p. 204–206° dec. after recrystallization from ethanol–ether.

Anal. Calcd. for $C_{14}H_{19}ClN_2$: C, 67.05; H, 7.64. Found: C, 66.89; H, 7.27.

C. **4-(2-Indolyl)-1-methylpiperidine (XXII).**—Similarly, 18.8 g. of XX methobromide was hydrogenated to yield, after recrystallization from ethanol, 9.2 g. (67%) of XXII in the form of colorless prisms, m.p. 183–187°.

Anal. Calcd. for $C_{14}H_{18}N_2$: N (basic), 6.54. Found: N (basic), 6.57.

XII hydrochloride formed glistening plates from aqueous methanol–acetone, m.p. 259–260° dec.

Anal. Calcd. for $C_{14}H_{19}ClN_2$: C, 67.05; H, 7.64; Cl, 14.14. Found: C, 66.85; H, 7.73; Cl (ionic), 13.89.

Condensation of Indoles with Pyridinecarboxaldehydes.—These reactions were carried out in acetic acid at room temperature. The products were relatively unstable, rapidly oxidizing in air to highly colored materials and were stored under nitrogen.

A. **4-(3,3′-Diindolylmethyl)-pyridine (XIII).**—To a solution of 32.1 g. (0.3 mole) of 4-pyridinecarboxaldehyde in 150 ml. of glacial acetic acid, cooled in an ice-bath, was added 70.2 g. (0.6 mole) of indole. The mixture was allowed to warm to room temperature. As the indole dissolved, a moderately exothermic reaction took place, and the resultant solution developed a deep purple color. After standing for 18 hr., the solution was diluted with aqueous hydrochloric acid to precipitate a purple hydrochloride salt which was recrystallized from ethanol–ether. Addition of aqueous alkali to an ethanol solution of the hydrochloride precipitated the base. This was crystallized from benzene–ethanol with the addition of Skellysolve B to provide 73 g. (75% yield) of yellow-orange crystals of XIII, m.p. 152–155° dec.

B. **4-[Bis-(1-methyl-3-indolyl)-methyl]-pyridine (XIV).**—Some heat was evolved on dissolving 5.0 g. (0.047 mole) of 4-pyridinecarboxaldehyde and 12.2 g. (0.094 mole) of 1-methylindole in 50 ml. of glacial acetic acid at room temperature. After standing for 21 hr. the deep purple solution was worked up as described above. The isolated base was recrystallized from benzene–Skellysolve B, affording 8.9 g. (54% yield) of flesh-colored crystals of XIV, m.p. 186–188° dec.

Some Chlorinated 4-Indanols: Preparation and Proof of Structures[1]

BY J. S. BUCK,[2] R. A. CUTLER, F. C. NACHOD, R. G. POWLES, R. RAKOCZY, T. J. SLAUSON AND B. F. TULLAR

RECEIVED FEBRUARY 2, 1957

Chlorination of 4-indanol with sulfuryl chloride yields 5-chloro-4-indanol and 7-chloro-4-indanol. The structure assignment has been carried out by analysis of the infrared spectra as well as by unambiguous synthesis. It is shown that the OH stretching frequencies of the two isomeric chloro-4-indanols coincide with the corresponding frequencies of *o*-chloro- and *p*-chlorophenol. Chemical structure proof starts with *p*-chlorophenyl β-chloropropionate which rearranges with $AlCl_3$ to 5,β-dichloro-2-hydroxypropiophenone which in turn cyclizes to form 4-chloro-7-hydroxy-1-hydrindone. The latter compound is reduced with Zn in HCl to the corresponding 7-chloro-4-indanol.

The recent availability of 4-indanol[3] (I) from the coal hydrogenation process prompted us to investigate some of its chlorinated derivatives as potential antiseptic agents. The reaction of one equivalent of sulfuryl chloride on 4-indanol yielded a mixture from which two white crystalline products were isolated. The more abundant of the two melted at 91.0–93.7° and was assumed to be 7-chloro-4-indanol (III). This assumption was later proved correct by infrared studies and by synthesis by another route as outlined below (V → VI → VII → III). From the filtrates of the chlorination mixture there was obtained a smaller amount of a substance melting at 70.4–73.1° which appeared to be 5-chloro-4-indanol (II). Actual proof of this structure was supplied by infrared spectral analyses.

The reaction of 4-indanol (I) with two equivalents of sulfuryl chloride yielded a mixture from which a solid was isolated melting at 54.5–56.8°. That this product was indeed 5,7-dichloro-4-indanol (IV) was proved by showing that treatment of either 5-chloro- (II) or 7-chloro-4-indanol (III) with sulfuryl chloride yielded this same material.

Physicochemical Data.—The spectra of the two isomeric chloroindanols (II and III) and the unchlorinated starting material I in CS_2 solution are sufficiently different to permit differential assays. The 7-chloro-4-indanol (III) has a strong band at 12.35 μ while the 5-chloro analog II does not absorb in this region, which is used to estimate the former compound. In the 9.5 to 10.5 μ region both compounds show doublets, the 7-chloro-4-indanol absorbing at 9.98 and 10.11 μ and the 5-chloro-4-indanol at 9.98 and 10.05 μ. The intensity of the first and second maximum are reversed with respect to the pair. Distortion (in the case of 0.4 to 0.6 mole fraction of the 7-chloro compound) or peak ratio assays (in the case of 0.8 to 1.0 mole fraction of the 7-chloro compound) establish their relative concentration. Unchlorinated starting material shows a doublet at 12.97 and 13.12 μ where neither of the monochloro derivatives absorbs.

Structure Assignment of 5- and 7-Chloro-4-indanol *via* Infrared Spectra.—The two isomeric indanols can be compared with *o*- and *p*-chlorophenol with respect to the geometry of their substituents. The trimethylene bridge of the indanol should not influence the position of the OH stretching frequency to any extent just as it would not exert any marked effect upon the dipole moment of the molecule. Dipole-dipole interaction, *viz.*,

mixed (Cl···H–O) hydrogen bonding, should reduce the OH frequency for 5-chloro-4-indanol as it does for *o*-chlorophenol. The OH absorption maxima found were identical for the respective pairs of chlorophenol and chloroindanol; *p*-chlorophenol and 7-chloro-4-indanol in CS_2 solution absorb sharply at 2.786 μ while *o*-chlorophenol and 5-chloro-4-indanol under the same conditions absorb sharply at 2.823 μ. The damping of the OH frequency does indeed shift the absorption maximum to a longer wave length as postulated.

Acknowledgments.—The authors are indebted to Messrs. M. E. Auerbach and K. D. Fleischer and staff for the microanalyses and to Miss C. M. Martini and Mrs. M. Becker for assistance in the spectroscopical aspects of the work.

Experimental[4]

4-Chloro-7-indanol (III). Method A.—To a stirred solution of 194 g. (1.45 moles) of 4-indanol[5] and a small crystal of iodine in 100 ml. of glacial acetic acid was added 123 ml. (1.52 moles) of sulfuryl chloride over a period of ten minutes. External cooling was applied to keep the temperature below 55°. After an additional hour of stirring, the yellowish-orange solution was poured onto ice and made neutral to litmus with 35% sodium hydroxide solution. The solid which separated amounted to 230 g. (1.37 moles) (95%) and melted at 50–65°. Two recrystallizations from hexane, including treatment with charcoal in the first, gave 115 g. (47%) of white needles, m.p. 91.0–93.7°.

Anal. Calcd. for C_9H_9ClO: C, 64.10; H, 5.38; Cl, 21.03. Found: C, 64.59; H, 5.35; Cl, 20.90.

Method B (Chlorination without Solvent).—In a flask equipped with stirrer, thermometer, dropping funnel and gas vent, 469 g. (3.5 moles) of 4-indanol was melted by warming to 60°. After addition of a small crystal of iodine, 340 ml. (560 g., 4.2 moles) of sulfuryl chloride was added dropwise within 10 min. After an initial temperature surge to 75° the rate was such that it reached a level of about 65°. After complete addition, stirring and heating (70–75°) were continued for 1 hr. At that point 1.5 liters of water was added and heating and stirring (70–75°) were continued for an additional half hour. Slow cooling to 40° produced solidification of the mixture, and the product was filtered at room temperature and washed with cold water. Drying in a vacuum oven overnight yielded 583 g. of crude product (99%).

Infrared analyses (*vide infra*) indicated 88% of 7-chloro-4-indanol (III), 11% of 5-chloro-4-indanol (II) and 1% of unreacted starting material I. Recrystallization of this mixture from hexane gave a 75%[6] yield of 7-chloro-4-indanol, m.p. 90–92° (uncor.).

Isolation of 5-Chloro-4-indanol (II).—The solvent was removed by distillation from the hexane filtrates remaining after the purification of the 7-chloro-4-indanol (method A) to give 85 g. of dark oil. The latter was distilled at 2.5 mm. and four fractions of colorless oil collected. Crystallization of the first two fractions [b.p. range of 72–101° (uncor.)] from hexane yielded 12 g. of 5-chloro-4-indanol which melted at 70.4–73.1° after an additional recrystallization from hexane.

Anal. Calcd. for C_9H_9ClO: C, 64.10; H, 5.38; Cl, 21.03. Found: C, 64.02; H, 5.58; Cl, 20.75.

Crystallization of the third and fourth fractions from hexane gave additional amounts of 7-chloro-4-indanol.

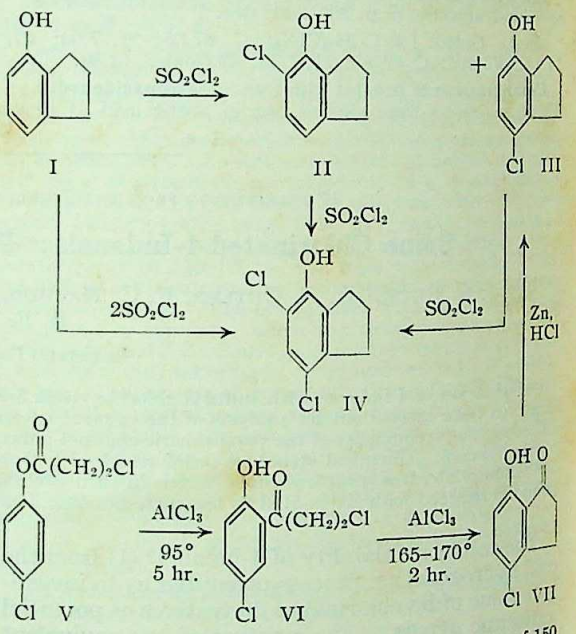
5,7-Dichloro-4-indanol (IV).—A stirred solution consisting of 40.5 g. (0.3 mole) of 4-indanol and a small crystal of iodine dissolved in 100 ml. of acetic acid was treated with 52 ml. (0.64 mole) of sulfuryl chloride and worked up similar to Method A above. A crude yield of 62 g. of low melting solid was obtained which gave 23 g. of pure 5,7-dichloro-4-indanol after two recrystallizations from pentane; m.p. 54.5–56.8°.

Anal. Calcd. for $C_9H_8Cl_2O$: Cl, 34.92; neut. equiv., 203.06. Found: Cl, 34.60; neut. equiv., 201.8.

The same product was obtained by the action of sulfuryl chloride on an acetic acid solution of either 7-chloro-4-indanol (III) or 5-chloro-4-indanol (II) according to the procedure outlined in Method A.

Chemical Proof of Structure of 7-Chloro-4-indanol (III),[7] *p*-Chlorophenyl β-Chloropropionate (V).—Molten *p*-chlorophenol was stirred and treated dropwise with an equimolecular amount of β-chloropropionyl chloride. After the addition was complete, the reaction mixture was allowed to stir for 3 hr. at room temperature and then heated for 1 hr. on a steam-bath. Distillation of the resulting oil gave a 90% yield of the desired product boiling at 152–156° (uncor.) at 11 mm., $n^{25}D$ 1.5306.

Anal. Calcd. for $C_9H_8Cl_2O_2$: Cl, 32.38. Found: Cl, 32.4.



4-Chloro-7-hydroxy-1-indanone (VII).[8]—A mixture of 150 g. (0.69 mole) of chlorophenyl β-chloropropionate with 350 g. of anhydrous aluminum chloride was heated 5 hr. at 95° and then 1 hr. at 160–170°. The mixture was quenched with ice and water. The product which separated was collected on a filter and washed well with water. Recrystallization from isopropyl alcohol, including treatment with charcoal, gave 45 g. (0.246 mole) (35.7%) of 4-chloro-7-hydroxy-1-indanone, m.p. 118–122° (uncor.).[9] By increasing the heating time at 165–170° to 2 hr., the yield of crude indanone (VII) was raised to 70% and none of the intermediate VI was recovered.

After recrystallization from ethyl acetate pure 4-chloro-

(4) All melting points are corrected unless otherwise specified.

(5) M.p. 45–47°.

(6) The increased yield over that of Method A is due mainly to the excess of sulfuryl chloride (20% employed.) When the reaction was run with no solvent and only a 5% excess of chlorinating agent was used, the yield was comparable to that obtained in Method A. Infrared analyses of the resulting crude product indicated that about 5% of it consisted of unchlorinated 4-indanol (I).

(7) The over-all procedure employed in this structure proof is similar to that used by R. A. Barnes, E. R. Kraft and L. Gordon, THIS JOURNAL, 71, 3523 (1949), for the preparation of 7-bromo-4-indanol.

(8) F. Mayer, H. Phillipps, F. W. Ruppert and A. T. Schmitt, *Ber.*, **61B**, 1966 (1928), prepared this same compound (m.p. 122°) by the action of $AlCl_3$ on β-(2-chloro-5-methoxyphenyl)-propionyl chloride.

(9) From the liquors 30 g. of somewhat impure 5,β-dichloro-2-hydroxypropiophenone (VI) was recovered; m.p. 75–78° (uncor.). A 96% yield of this same compound was obtained by heating the *p*-chlorophenyl β-chloropropionate with one and one half times its weight of $AlCl_3$ at 120° for 20 minutes. After quenching in ice and two recrystallizations of the resulting solid from hexane the pure rearranged product VI was obtained as coarse white crystals; m.p. 89.8–90.8°. *Anal.* Calcd. for $C_9H_8Cl_2O_2$: C, 49.36; H, 3.68; Cl, 32.38. Found: C, 49.67; H, 4.17; Cl, 32.4.

7-hydroxy-1-indanone (VII) was obtained, m.p. 119.7–121.4°.

Anal. Calcd. for $C_9H_7ClO_2$: C, 59.20; H, 3.86; Cl, 19.42. Found: C, 59.16; H, 3.99; Cl, 19.50.

7-Chloro-4-indanol (III from VII).—A mixture of 450 g. (0.247 mole) of 4-chloro-7-hydroxy-1-indanone in 2 liters of toluene with 2 liters of acetic acid and 1500 g. of freshly amalgamated zinc (10 mesh) was heated with strong mechanical stirring under reflux at 90°, and 5 liters of hydrochloric acid was added during 4 hr. The heating and stirring were continued another 4 hr. with occasional additions of hydrochloric acid to a total of 7 liters.

The mixture was cooled and separated from undissolved zinc. The water layer was separated and washed with one liter of toluene. The combined toluene extracts were concentrated *in vacuo*. The residue was crystallized from 1 liter of "Skellysolve C" after decolorizing with charcoal yielding a 300 g. first crop of 7-chloro-4-indanole, m.p. 90–92°. By concentration and cooling and recrystallization a second crop of 35 g. was collected melting at the same point; total yield 335 g. (81%).

After recrystallization from 1.5 liters of ethylene dichloride, 310 g. of pure 7-chloro-4-indanol (II) was obtained, m.p. 91.2–92.8°.

Anal. Calcd. for C_9H_9ClO: Cl, 21.03. Found: Cl, 21.0.

A mixture melting point with the original sample of 7-chloro-4-indanol prepared by Method A was not depressed.

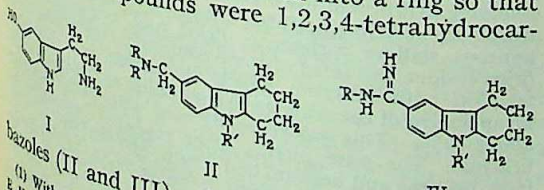
Indole Carboxamidines and Aminomethylindoles as Antimetabolites of Serotonin

BY E. SHAW AND D. W. WOOLLEY[1]

RECEIVED JANUARY 30, 1957

A number of antimetabolites of serotonin have been synthesized and studied in both isolated smooth muscles and in normal animals. These compounds were 1,2,3,4-tetrahydrocarbazoles (dialkylindoles) with $-CH_2-NR_2$ or $-C(=NR)-NH_2$ in the 6-position. Some had a benzyl group attached to the indole nitrogen as well. Methods for the synthesis of these compounds are described.

The early studies of the structural changes necessary to convert the hormone serotonin (I) into a specific antimetabolite of it had shown that one good way was to move the amino group from its position in the side chain of the hormone to position 5 in the indole nucleus.[2,3] The 5-amino-indoles, with alkyl groups in positions 3 (or 2 and 3) were active antiserotonins. However, they possessed the disadvantage that they were destroyed readily in living mammals. This defect apparently resided in the fact that they were substituted *p*-phenylenediamines which are liable to attack by some of the cytochrome-containing enzyme systems.[4] Since a basic group seemed to be needed somewhere in the molecule to confer high activity, the idea arose that the amino group of the aminoindoles might be protected from enzymic attack by placing a carbon atom between it and the indole nucleus. To test this postulate some 5-indolecarboxamidines and some 5-aminomethylindoles were synthesized and examined biologically for antiserotonin activity. These compounds contained either a $-C(=NH)-$ or a $-CH_2-$ between the basic nitrogen and the indole ring. For convenience in the practical syntheses, the alkyl groups in positions 2 and 3 were incorporated into a ring so that all of the compounds were 1,2,3,4-tetrahydrocarbazoles (II and III). Some of them proved to be relatively potent antimetabolites which were effective even in whole animals. Previous work had shown[5] that this was a rather rare property among antagonists of this hormone. The majority of existing antiserotonins were only effective on isolated tissues.



I II III

Experimental Part[6]

1,2,3,4-Tetrahydrocarbazole-6-carboxamide.—*p*-Aminobenzamide (7.0 g.) dissolved in water (55 ml.) and concentrated hydrochloric acid (20 ml.), was diazotized at −5° with sodium nitrite solution (3.5 g. in 25 ml. water). The filtered diazonium solution was poured into a cold solution of stannous chloride dihydrate (25 g.) in concentrated hydrochloric acid (25 ml.). After 15 minutes the tin complex was collected by suction filtration and converted to the hydrazine by treatment of a cold suspension in water (50 ml.) with 40% aqueous sodium hydroxide (20 ml.). *p*-Hydrazinobenzamide so obtained was combined with cyclohexanone in aqueous acetic acid in the usual manner. The crude hydrazone was refluxed in concentrated hydrochloric acid (20 ml. per g.) for 30 minutes. The resultant oil was dissolved in ethyl acetate which was washed with dilute alkali, dried and concentrated. The product crystallized in a yield of 45% (for the cyclization step) and had m.p. 217–219°.

Anal. Calcd. for $C_{13}H_{14}N_2O$: C, 72.89; H, 6.59; N, 13.08. Found: C, 73.41; H, 6.41; N, 12.83.

The intermediate hydrazine and hydrazone were too unstable to purify profitably.

1,2,3,4-Tetrahydrocarbazole-6-carboxhydrazide.—1,2,3,4-Tetrahydrocarbazole-6-carboxylic acid[7] was converted to the ethyl ester when refluxed for six hours with ten volumes of 2 *N* ethanolic hydrogen chloride. After recrystallization from ethanol, a 75% yield of ester, m.p. 117–119°, was obtained.

The ethyl ester (11.4 g.) was then refluxed in absolute alcohol (85 ml.) and 100% hydrazine hydrate (56 ml.) for 21 hours. The solution was concentrated in an air stream until crystals appeared; water was added and the product was filtered, washed with 50% aqueous alcohol and desiccated *in vacuo*. The material so obtained, 10.0 g. (93%), m.p. 197–199°, was used in the next step. An analytical sample crystallized from ethanol had m.p. 201–203°.

Anal. Calcd. for $C_{13}H_{15}N_3O$: C, 68.09; H, 6.59; N, 18.33. Found: C, 68.51; H, 6.38; N, 18.94.

1,2,3,4-Tetrahydrocarbazole-6-carboxylic Acid Dimethylamide.—1,2,3,4 - Tetrahydrocarbazole - 6 - carboxhydrazide (10 g.) in glacial acetic acid (150 ml.) was treated with aqueous sodium nitrite solution (3.5 g. in 10 ml. water) at 15°. The reaction mixture was then partitioned between ether (700 ml.) and water (200 ml.). After the ether layer had been washed with successive portions of aqueous bicarbonate, it was dried briefly with anhydrous sodium carbonate and filtered. A slow stream of dimethylamine was passed into the ethereal azide solution for six hours. Finally the mixture was evaporated to dryness in an air stream and the residue stirred with water and filtered. After recrystallization from ethyl acetate, 8.0 g., m.p. 188–190°, was obtained, a yield of 75%. In earlier runs a different crystalline modification was isolated with m.p. 150–151°. It could be converted to the higher melting form if its solutions were seeded with the latter.

Anal. Calcd. for $C_{16}H_{18}N_2O$: C, 74.35; H, 7.49; N, 11.56. Found: C, 74.47; H, 7.51; N, 11.64.

Amidation of the ester with dimethylamine failed.

6-Dimethylaminomethyl-1,2,3,4-tetrahydrocarbazole.—The preceding N,N-dimethylamide (5.7 g.) was stirred overnight with a suspension of lithium aluminum hydride (2.5 g.) in dry ether (750 ml.). The excess hydride was cautiously decomposed in the usual way with aqueous sodium potassium tartrate and the product extracted from the ether layer with several 50-ml. portions of 0.5 *N* hydrochloric acid. The base was precipitated by addition of alkali to the acid extracts and was recrystallized from ethanol in a yield of 70%, m.p. 161–163°.

Anal. Calcd. for $C_{15}H_{20}N_2$: C, 78.91; H, 8.83; N, 12.27. Found: C, 78.72; H, 8.82; N, 12.35.

6-Aminomethyl-1,2,3,4-tetrahydrocarbazole Hydrochloride.—1,2,3,4-Tetrahydrocarbazole-6-carboxamide (2.0 g.) was reduced with lithium aluminum hydride (1.0 g.) in dry ether (250 ml.) as in the preceding example. The product was extracted from the ether solution with 0.5 *N* HCl (3 × 30 ml.). When the acid extracts were made alkaline, the base crystallized, 0.65 g., m.p. 142–145°. For convenience, it was converted to the hydrochloride, m.p. 255–257° dec.

Anal. Calcd. for $C_{13}H_{17}N_2Cl$: C, 65.95; H, 7.23. Found: C, 65.54; H, 6.93.

9-Benzyl-6-dimethylaminomethyl-1,2,3,4-tetrahydrocarbazole Hydrochloride.—A solution of 1,2,3,4-tetrahydrocarbazole-6-N,N-dimethylcarboxamide (10 g.) in benzene was added to a suspension of sodium hydride (1.5 g.) in benzene (400 ml.) in an atmosphere of nitrogen. The mixture was refluxed for one-half hour. Benzyl chloride (5.2 ml.) was added and the refluxing was continued overnight. To decompose excess hydride, absolute ethanol (10 ml.) was introduced. The benzene layer was washed with water, dried and evaporated to dryness. The benzylated amide was not crystallized. Instead the residue was taken up in anhydrous ether and added to a suspension of lithium aluminum hydride (4.0 g.) in ether (1 liter). After the mixture had been stirred for two days, the excess hydride was decomposed in the usual way with aqueous sodium potassium tartrate and the product was extracted from the ether layer with *N* hydrochloric acid (2 × 100 ml.). The hydrochloride of the product which had crystallized immediately in the acid extracts was filtered, washed with dilute hydrochloric acid, and desiccated *in vacuo* with moistened pellets of sodium hydroxide. The hydrochloride thus isolated always had a characteristic m.p. of 84–87° but was hydrated to a variable degree in different preparations. After recrystallization from water, lustrous flakes, 7.0 g., of the same m.p. were obtained. After drying for several hours at 65° and 1 mm. this material was analytically pure as anhydrous hydrochloride[8] and represented a yield of 50% for the two steps. Recrystallization from absolute alcohol gave a product with a m.p. of 198–199°.

Anal. Calcd. for $C_{22}H_{27}N_2Cl$: C, 74.45; H, 7.67; N, 7.89. Found: C, 74.34; H, 7.48; N, 7.98.

This anhydrous high melting form was reconverted to the form melting at 84–87° by recrystallization from water.

This same compound was prepared by direct benzylation of 6-dimethylaminomethyl-1,2,3,4-tetrahydrocarbazole in liquid ammonia in the presence of sodamide. The yield was 46%.

***p*-Hydrazinobenzamidine Dihydrochloride.**—*p*-Aminobenzamidine dihydrochloride was prepared by low pressure hydrogenation of *p*-nitrobenzamidine[9] in ethanol with palladized charcoal. The filtrate was concentrated to a small volume and the product precipitated by the addition of concentrated hydrochloric acid. Yields of 85%, m.p. 290–291°, resulted. Although lit. m.p. is 320° cor.,[10] the material obtained was analytically pure.

Anal. Calcd. for $C_7H_{11}N_3Cl_2$: Cl^-, 34.1; N, 20.19. Found: Cl^-, 34.4; N, 20.44.

Diazotization of *p*-aminobenzamidine dihydrochloride (5.0 g.) in 2 *N* hydrochloric acid (80 ml.) was carried out at −10° with a solution of sodium nitrite (1.75 g.) in water (5 ml.). A cold solution of stannous chloride dihydrate (25 g.) in concentrated hydrochloric acid (25 ml.) was added. After 20 minutes, the tin complex was filtered with suction and washed with ice-water. The precipitate in water (125 ml.) was treated with hydrogen sulfide and the filtrate concentrated to a small volume with reduced pressure until the appearance of crystals. After refrigeration, the product was collected. It was recrystallized from water (15 ml.) by the addition of *N* ethanolic HCl (60 ml.) in the form of long needles, m.p. 269–270° dec., 2.9 g.

Anal. Calcd. for $C_7H_{12}N_4Cl_2$: C, 37.68; H, 5.42; N, 25.11. Found: C, 37.80; H, 5.34; N, 25.14.

1,2,3,4-Tetrahydrocarbazole-6-carboxamidine Hydrochloride.—*p*-Hydrazinobenzamidine dihydrochloride (3.0 g.) in water (90 ml.) was treated with cyclohexanone (2 ml.). The yellow solution was made strongly alkaline with 6 *N* sodium hydroxide whereupon the hydrazone separated as an oil which crystallized. After the mixture was chilled, the product was filtered, washed with water and desiccated *in vacuo*. The crude hydrazone melted at 225–226° dec. Purification proved unprofitable.

The hydrazone (2.2 g.) was refluxed for 30 minutes in concentrated hydrochloric acid (22 ml.). The hydrochloride of the product which formed as an oil crystallized on standing. It was dissolved in hot water (20 ml.). The solution was cooled for four hours, filtered from an insoluble impurity and crystallized from the filtrate by addition of 6 *N* hydrochloric acid (2 ml.) to yield 1.6 g. (44%), m.p. 193–195°. It was recrystallized from hot 0.5 *N* hydrochloric acid.

Material dehydrated at 100° *in vacuo* was hygroscopic; satisfactory analyses were obtained on anhydrous material allowed to hydrate in a moist atmosphere until no further gain in weight occurred. The uptake indicated a monohydrate.

Anal. Calcd. for $C_{13}H_{16}N_3Cl \cdot H_2O$: C, 58.30; H, 6.72; N, 15.69. Found: C, 58.93; H, 6.71; N, 15.88.

The free base was obtained as a gum by treatment of the hydrochloride with aqueous NaOH. In some preparations, this gum was obtained crystalline by solution in ethanol and partial evaporation of the solvent. Occasionally the gum could not be induced to crystallize. The free base melted at 171–173°.

Anal. Calcd. for $C_{13}H_{15}N_3$: C, 73.20; H, 7.09; N, 19.70. Found: C, 73.16; H, 6.75; N, 19.52.

6-Cyano-1,2,3,4-tetrahydrocarbazole.—The hydrazone from cyclohexanone and *p*-cyanophenylhydrazine[11] formed in the usual manner (m.p. 174–175°) was refluxed in concd. hydrochloric acid (15 ml. per g.) for 15 minutes. Longer refluxing hydrolyzed the nitrile. The precipitated gum was dissolved in ethyl acetate which was then washed with aqueous sodium carbonate, dried and evaporated. The dried residue was freed of some contaminating amide by extraction with ether in which the amide was insoluble. Evaporation of the ether gave crystalline nitrile in a yield of about 70%. This was generally used without further purification. The pure nitrile, after repeated crystallization from benzene and hexane, had a m.p. of 117–119°.

Anal. Calcd. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.28. Found: C, 79.24; H, 6.31; N, 14.23.

Attempts to convert the nitrile to an imino ether in ether

(8) The m.p. of this anhydrous material was considerably lower than that of the anhydrous material obtained by crystallization from alcohol.

or chloroform resulted only in the formation of a hydrochloride of the starting material. Amidines were therefore prepared by alternate routes.

9-Benzyl-6-cyano-1,2,3,4-tetrahydrocarbazole.—6-Cyano-1,2,3,4-tetrahydrocarbazole (2.0 g.) in benzene (75 ml.) was converted to a sodium salt with sodium hydride (0.25 g.) followed by dimethylformamide (5 ml.). Benzyl chloride (1.2 ml.) was then introduced and the reaction mixture was refluxed for two hours. After decomposition of unreacted hydride with ethanol the benzene solution was washed, dried and concentrated. The residue in a small volume of benzene was applied to a column of alumina (3.4 × 30 cm.) and eluted with the same solvent containing 2% ethanol. The first fraction which emerged crystallized on removal of the solvent. The crystals were thinned with alcohol and water for filtration and provided 1.6 g., 56% of product melting at 117–118°. The analytical sample obtained from the same solvents had m.p. 120–121°.

Anal. Calcd. for $C_{20}H_{18}N_2$: C, 83.87; H, 6.34; N, 9.78. Found: C, 84.02; H, 6.38; N, 9.99.

1,2,3,4-Tetrahydrocarbazole-6-N-phenylcarboxamidine Hydrochloride.[12]—6-Cyano-1,2,3,4-tetrahydrocarbazole (3.1 g.) and aniline *p*-toluenesulfonate (4.3 g.) were heated for one hour at 220° and the cooled melt was partitioned between chloroform and *N* sodium hydroxide. The chloroform layer was washed with water followed by 3 *N* hydrochloric acid which precipitated the amidine hydrochloride as a gum. The latter was either crystallized from 80% ethanol or, with smaller losses, purified as the picrate, m.p. 258–259°, in a yield of 49%. The hydrochloride had a m.p. of 266–267°.

Anal. Calcd. for $C_{19}H_{20}N_3Cl$: C, 70.04; H, 6.18; N, 12.90. Found: C, 70.33; H, 6.05; N, 12.63.

9-Benzyl-1,2,3,4-tetrahydrocarbazole-6-N-phenylcarboxamidine Hydrochloride.[12]—9-Benzyl-6-cyano-1,2,3,4-tetrahydrocarbazole (1.5 g.) was heated with aniline *p*-toluenesulfonate (1.4 g.) for one hour at 200° and worked up as in the preceding example. Saturated sodium chloride solution was added to help break emulsions in the extraction step. When the chloroform layer was shaken with *N* hydrochloric acid (20 ml.) the product remained dissolved in the chloroform layer as the hydrochloride. The chloroform was dried and concentrated to a small volume whereupon the product crystallized. After recrystallization from alcohol and ether, the hydrochloride was obtained in a yield of 50%, m.p. 272–273°.

Anal. Calcd. for $C_{26}H_{26}N_3Cl$: C, 75.09; H, 6.30; N, 10.10. Found: C, 74.85; H, 6.03; N, 10.44.

Pharmacological Results

Antiserotonin Activity as Measured on Artery Rings.—The method of Woolley and Shaw[3] was used, which depended on the measurement of the concentration of the analog required to overcome the contraction caused in ring-shaped segments of carotid arteries by a fixed amount of serotonin. The results of these tests are shown in Table I where it can be seen that most of the analogs possessed activity. The increased potency of the dimethylaminomethyl over the aminomethyltetrahydrocarbazole was noteworthy. One would expect the latter to be deaminated readily, and this may explain partly the observed difference.

Antiserotonin Activity on Isolated Rat Uterus.—The method introduced by Erspamer[13] was used in the manner previously described from this Laboratory.[5] The results of these tests are also shown in Table I. The variation in relative potency of a single compound on the two tissues is noteworthy. Clearly, most of the analogs were antimetabolites on the uterus as well as on the carotid artery.

Antiserotonin Activity as Measured against the

(12) Cf. general method of Oxley and Short, *J. Chem. Soc.*, 147 (1946).

TABLE I

ANTISEROTONIN ACTIVITIES OF THE ANALOGS AS MEASURED WITH ISOLATED TISSUE IN VITRO

1,2,3,4-Tetrahydrocarbazoles	Inhibition index in sheep arteries[a]	Inhibition index in rat uterus[b]
6-Carboxamidine	6	25
6-N-Phenylcarboxamidine[c]	200	50
6-Aminomethyl	20	..
6-N,N-Dimethylaminomethyl	2	10
9-Benzyl 6-N,N-dimethylaminomethyl[c]	..	300

[a] These values represent the number of mg. of analog required to antagonize the contracting action of 1 mg. of serotonin creatinine sulfate and were determined from the point of half maximal effect. The concentration of serotonin in the bath was 0.2 γ/ml. [b] Inhibition index has the same connotation as above. The amount of serotonin in the bath was 0.05 γ/ml. The analog was left in contact with the tissue for two minutes before addition of serotonin. [c] These analogs endowed the tissues with an insensitivity to serotonin that persisted long after washing. The acetyl choline response was not affected by them.

Pressor Action in Dogs.—The compounds were examined according to the methods previously described.[4,5] When given by the intravenous route two of the compounds (the dimethylaminomethyltetrahydrocarbazole and the tetrahydrocarbazole N-phenylcarboxamidine) proved to be quite effective. Data are summarized in Table II. By the oral route, however, the former was without demonstrable antiserotonin action on dogs. Daily doses of 45 mg. per kg. for 4 days failed to protect against the pressor effect of serotonin. In fact this compound given orally potentiated serotonin. The N-phenylcarboxamidine fed at 3.5 and 7.5 mg. per kg. per day partially protected 2 dogs but in one the effect was slight.

Hypotension Caused by the 1,2,3,4-Tetrahydrocarbazole 6-N-Phenylcarboxamidine in Dogs.—When given intravenously in doses of 2–7 mg. per kg. to anesthetized dogs the tetrahydrocarbazole 6-N-phenylcarboxamidine caused a sharp fall in arterial blood pressure (usually about 20 mm. of Hg). In two of five animals, however, the hypotension was very severe, and in one of these the pressure fell to zero with 9 mg. per kg. Sometimes the hypotension persisted for an hour or more. This kind of action has been rare among antiserotonins, but was noted recently with the benzyl analog of bufotenin.[14]

Behavioral Changes Caused by 9-Benzyl-6-dimethylaminomethyl - 1,2,3,4 - tetrahydrocarbazole.—Although the dimethylaminomethyltetrahydrocarbazole did not cause any noticeable behavioral changes when fed to normal dogs or mice, the corresponding benzyl derivative, *viz.*, 9-benzyl-6-dimethylamino-methyl-1,2,3,4-tetrahydrocarbazole brought about an alteration which might be called a psychosis. Dogs fed daily 25 mg. per kg. of this analog mixed with their food ate it readily for 3 or 4 days. They then developed a most pronounced aversion to the taste of it, whereas in the first days they did not object at all. This aversion was so great that the animals refused to touch any food containing the drug. At the time that this distaste arose, the attitude and behavior

TABLE II

AMOUNTS OF ANALOGS REQUIRED BY THE INTRAVENOUS AND BY THE ORAL ROUTE TO PROTECT DOGS FROM THE PRESSOR ACTION OF SEROTONIN

1,2,3,4-Tetrahydrocarbazoles	No. of dogs	I.V. dose,[a] mg./kg. Av.	Extreme range	Oral dose, mg./kg./day
6-Carboxamidine	1	No effect at 6	.....	.....
6-N-Phenylcarboxamidine	4	0.4[b]	0.14–0.5	.....
	2	..	.....	Some protection at 3.5 and 7.5 but not complete
6-N,N-Dimethylaminomethyl	4	1.6	0.7–2.7	.....
	2	..	.....	No protection at 45[c]
9-Benzyl 6-N,N-dimethylaminomethyl	1	..	Less than 2.5	.....
	4	..	....	Partial at 25[d]

[a] Amount required to reduce to half the pressor response of the standard dose of serotonin (usually 50 gamma per kg.). [b] Complete protection was not achieved in some of the dogs with doses ten times this amount, although partial protection was always seen. [c] Both dogs showed an increase in the pressor effect of serotonin after eating this compound. [d] Two dogs showed only slight protection; one showed good protection; and one showed no protection but instead there was augmentation of the pressor response

of the animals became quite changed. Some raced around the room excitedly and without obvious purpose. One animal was so distracted that in running constantly about the room he would bump into articles of furniture. The behavioral changes varied from animal to animal, but of the 4 dogs tested all showed the slow onset and the delayed development of distaste for food mixed with the analog. In all, the symptoms could be summarized as marked excitement. A further sign was seen in all, *viz.*, constant slow movement of the head from side to side in a horizontal plane. This motion was continued regularly for hours.

When dogs exhibiting the influence of this compound were anesthetized with Nembutal, the sleeping time was always prolonged so that they would not awaken for about 24 hours. When ingestion of the compound was stopped, the behavior of the animals returned to normal within a few days.

In mice, the intraperitoneal injection of this compound (30 mg. per kg.) brought about neurological changes similar to those seen in dogs. Chief of these were the excitement, and the turning of the head from side to side regularly and rhythmically. In a mouse it is not as easy to recognize behavioral changes which can be called psychotic with any assurance, and none which could be so labeled were observed. The walking backwards as seen in mice given lysergic acid diethylamide[15] was never seen. However, just as in dogs, the sleeping time caused by a standard dose of Nembutal was markedly increased.

Curious Prolonged Action of 9-Benzyl-6-dimethylaminomethyl - 1,2,3,4 - tetrahydrocarbazole as an Antipressor Agent in Dogs.—When dogs were fed this compound for 4 days (25 mg. per kg. per day) and then tested for their protection against the pressor effects of serotonin, the results were not dramatic. Only partial protection could be found (*cf.* Table II). When the feeding of the compound was then stopped, and the dogs were challenged at long intervals thereafter, their protection was sometimes found to have lasted or even increased. This effect was noticeable for periods ranging (in various dogs) from a few days to many weeks. The dimethylaminomethyltetrahydrocarbazole which lacked the benzyl group did not cause this prolonged and progressive effect.

Discussion

Although a basic group seems to be necessary in a serotonin analog for it to show marked antiserotonin activity, the results of the present study illustrate the degree of freedom which may be enjoyed in the location of this group. The insertion of a carbon atom between the indole ring and the basic nitrogen has resulted in the attainment of compounds which are much more potent than the corresponding aminoindoles.

The fact that these new antimetabolites were relatively inactive as antipressor agents when fed, or at least, were not as active as when injected intravenously, should be borne in mind. The reason why this should be so is unknown. Compounds such as 6-dimethylaminomethyl-1,2,3,4-tetrahydrocarbazole have had incorporated in them the features designed to protect them from destruction by deamination or from a variety of oxidative enzyme systems, and yet they failed to act by the oral route. Perhaps they may have been excreted too rapidly, or may have been destroyed in unsuspected ways.

The pronounced effects of 9-benzyl-6-dimethylaminomethyl-1,2,3,4- tetrahydrocarbazole are noteworthy for 2 reasons. Firstly, the abnormal behavior which it caused lends support to the idea first proposed by Woolley and Shaw[16] that serotonin plays a role in mental processes.

The second point of interest about this compound was that 6-dimethylaminomethyl-1,2,3,4-tetrahydrocarbazole, which differed from it only in lacking the benzyl group, did not call forth the abnormal behavior. Neither did it exhibit the curious delayed and prolonged action as an antipressor agent. Recently, the conferment of striking properties on another antiserotonin by introduction of a benzyl group has been illustrated by comparison of BAS with the corresponding unbenzylated analog.[5,17] In both cases prolonged action and increased potency resulted from introduction of the benzyl group.

Preparation and Reactions of 2-Nitropyridine-1-oxides

BY ELLIS V. BROWN

RECEIVED FEBRUARY 7, 1957

2-Nitropyridine-1-oxide and a number of its homologs have been prepared by the action of mixtures of fuming sulfuric acid and 27.5% hydrogen peroxide on the corresponding aminopyridine-1-oxides. Displacement of nitro by chloro has given the 2-chloropyridine-1-oxides, and these were identified where possible by means of their 4-nitro derivatives.

Because of the many reactions which it undergoes, the importance of 4-nitropyridine-1-oxide is well established,[1] and it is of interest to compare its behavior with that of the 2-isomer; however, attempts to prepare 2-nitropyridine-1-oxide by the oxidation of 2-nitropyridine have been unsuccessful.[2] We wish to report the synthesis of compounds of this class by the oxidation of 2-aminopyridine-1-oxides. Starting with the commercially available 2-aminopyridine and its homologs, we acetylated, oxidized to the corresponding N-oxides with peracetic acid (20%) and then hydrolyzed with sodium hydroxide. All of these compounds except the 4,6-dimethyl were prepared by us as the hydrochlorides and reported in another connection.[3] The aminopyridine-1-oxide and the 6-methyl-2-aminopyridine-1-oxide subsequently were reported by Adams and Miyano.[4]

The free aminopyridine-1-oxides listed in Table I were then oxidized using a mixture of 30% fuming H_2SO_4 and 27% hydrogen peroxide at 10–20°. The reaction mixture was poured onto the ice, neutralized to congo red paper with ammonium hydroxide, extracted with ether or butyl alcohol and evaporated to give the product. The yields and melting points of the 2-nitropyridine-1-oxides so prepared are listed in Table II.

TABLE I

2-AMINOPYRIDINE-1-OXIDES

Substituent	Yield, %	M.p., °C.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found
3-Methyl-	68	164–165				
4-Methyl-	65	128–129	58.06	58.18	6.45	6.50
5-Methyl-	72	130–132	58.06	58.13	6.45	6.35

	40	108–109	50.00	50.12	4.76	4.90

We have proved the structure of these new compounds by two reactions. The first is reduction of the N-oxide function to give the corresponding nitropyridines. All of these except the 4,6-dimethyl-2-nitropyridine have been made by Wiley and Hartman[5] by the oxidation of the aminopyridines with the fuming sulfuric acid–hydrogen peroxide mixture following the original preparation of 2-nitropyridine by Kirpal.[6] The new 4,6-dimethyl-2-nitropyridine we have prepared using the same procedure. Ochiai[1] had previously shown that 4-nitropyridine-1-oxide could be reduced to 4-nitropyridine by warming with phosphorus trichloride. By this same means we have prepared the 2-nitropyridines from the 2-nitropyridine-1-oxides and compared the compounds by melting points and mixed melting points.

A second proof was the complete reduction by catalytic hydrogenation of the 2-nitropyridine-1-oxides back to the original 2-aminopyridines. These were compared by melting points and mixed melting points and found to be identical.

When one reduces 4-nitropyridine-1-oxide with palladium at low hydrogen pressure, 4-aminopyridine-1-oxide is prepared. We have not been able to realize this reaction since complete reduction of the 2-nitro compound occurs. The 2-aminopyridine-1-oxides prepared as indicated previously are stable to air, the 4-aminopyridine-1-oxides can usually only be isolated as the hydrochlorides since they oxidize in air to the azo compound.

The nitro group in the 4-nitropyridine-1-oxides is readily replaced by chlorine using acetyl chloride, and we have displaced the nitro group in our 2-nitropyridine-1-oxides in the same manner thus preparing the corresponding 2-chloropyridine-1-oxides. For comparison it was necessary to prepare these compounds by the oxidation of the chloropyridines. Some of these chloropyridines have been prepared by previous workers. We used the method of Siede[7] in preparing all of the compounds listed in Table III. His method consists of simply diazotizing the available aminopyridines in concentrated hydrochloric acid at 0° and allowing the mixture to warm, neutralizing with ammonium

hydroxide, extracting with ether and distilling. Although the 2-bromopyridine-1-oxides have been prepared previously, the corresponding chloro compounds have not. We oxidized all of the chloropyridine homologs with 20% peracetic acid in the usual manner and the 2-chloropyridine-1-oxide hydrochlorides were compared by melting point and mixed melting point and appear to be identical, although the rather wide melting range of these salts was somewhat unsatisfactory. We therefore nitrated them with nitric–sulfuric acid mixture to give the 4-nitro-2-chloropyridine-1-oxides, and these are listed in Table IV. After nitrating the products from the acetyl chloride reaction, comparison of melting points and mixed melting points established their identity.

TABLE IV

2-CHLORO-4-NITROPYRIDINE-1-OXIDES

Substituent	M.p., °C.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found
.....	152–153	34.38	34.51	1.72	1.88
3-Methyl-	145–146	38.19	38.23	2.65	2.50
5-Methyl-	154–155	38.19	38.31	2.65	2.69
6-Methyl-	106–107	38.19	38.14	2.65	2.81

Although no quantitative data have been obtained, there was a very obviously faster rate of reaction of acetyl chloride with 2-nitropyridine-1-oxide than with 4-nitropyridine-1-oxide in the cold, nitrogen dioxide being evolved rapidly.

Experimental

Preparation of 2-Aminopyridine-1-oxides.—All of the compounds listed in Table I were prepared from commercially available 2-aminopyridine and its homologs in the same manner. One mole of aminopyridine was refluxed 1 hr. with 100 ml. of acetic anhydride, and the acetylaminopyridine was isolated by distillation at reduced pressure or crystallization in the usual manner. The acetylaminopyridine so prepared was oxidized by a mixture of 150 ml. of glacial acetic acid and 125 ml. of 40% peracetic acid.[8] In the beginning the temperature was moderated by a cooling bath, and then the temperature was held at 70° for 3 hr. Evaporation *in vacuo* and crystallization from toluene completed the preparation of the acetylaminopyridine-1-oxides. For the hydrolysis, 72 g. of acetylaminopyridine-1-oxide was refluxed in 500 ml. of water containing 60 g. of sodium hydroxide for 3 hr. At the end of this time, the solution was acidified and evaporated under reduced pressure. The free aminopyridine-1-oxides were then isolated from the residue by crystallization from absolute ethanol (Table I).

Preparation of 2-Nitropyridine-1-oxides.—The compounds listed in Table II were prepared by oxidation of the free amino compounds listed in Table I. To a mixture of 100 ml. of fuming sulfuric acid (30%) and 50 ml. of 27.5% hydrogen peroxide[8] prepared below 20° was added a solution of 9 g. of the aminopyridine-1-oxide in 50 ml. of concd. sulfuric acid. The temperature was held at 10–15° during the addition and then maintained at 25° for 24 hr. The reaction mixture was poured onto cracked ice, neutralized with concd. ammonium hydroxide and extracted with ether, butanol or both. Evaporation of the solvent under reduced pressure and temperature not exceeding 50° gave the crude products which were recrystallized from absolute ethanol (Table II).

Reduction of the N-Oxide Function.—Following the procedure of Ochiai,[1] 1 g. of 2-nitropyridine-1-oxide was refluxed in 20 ml. of chloroform with 2 ml. of phosphorus trichloride, cooled, neutralized with sodium hydroxide and the chloroform evaporated to dryness. Crystallization from petroleum ether afforded the nitropyridines which showed no depression in melting point when mixed with the products prepared by the method of Wiley and Hartman.[5] 2-Nitro-4,6-dimethylpyridine was prepared from the commercially available 2-amino-4,6-dimethylpyridine by the method of Wiley and Hartman[5] and melted at 59–60°. The yield was 50%. *Anal.* Calcd. for $C_7H_8N_2O_2$: C, 55.26; H, 5.26. Found: C, 55.32; H, 5.30. The product from reduction of the N-oxide function of 2-nitro-4,6-dimethylpyridine-1-oxide showed no depression of melting point when mixed with this nitropyridine.

Catalytic Reduction of 2-Nitropyridine-1-oxides.—One gram of the nitropyridine-1-oxide was dissolved in 50 ml. of absolute ethanol, treated with 0.5 g. of 5% palladium-on-charcoal in a Parr low pressure hydrogenator at 45 lb. per sq. inch of hydrogen pressure. When no more hydrogen was absorbed, the catalyst was filtered, the solvent evaporated and the product identified as the aminopyridine in each case.

Replacement of Nitro Group by Chloro.—Two grams of the 2-nitropyridine-1-oxide was treated with 20 ml. of acetyl chloride. A violent reaction evolving nitrogen oxides took place at once. The reaction mixture was refluxed for 0.5 hr., evaporated to dryness and the 2-chloropyridine-1-oxides isolated as the hydrochlorides by recrystallization from butanol (Table III).

Preparation of the 2-Chloropyridine-1-oxides.—All of the 2-chloropyridines were prepared by the method of Siede.[7] To a mixture of 500 ml. of concd. hydrochloric acid and 36 g. of the aminopyridine cooled to 0° was added 35 g. of sodium nitrite in the usual manner. The reaction mixture was allowed to come to room temperature overnight and was then steam distilled and fractionated *in vacuo*. Two tenths mole of the 2-chloropyridines was treated with 25 ml. of glacial acetic acid and 22 ml. of 40% peracetic acid. The temperature was moderated to 70° then held at 70° for 3 hr. A slight excess of concd. hydrochloric acid was added, and the solvent was removed at reduced pressure. The chloropyridine-1-oxide hydrochlorides were recrystallized from butanol (Table III).

Nitration of the 2-Chloropyridine-1-oxides.—To a mixture of 2.2 g. of the above hydrochloride dissolved in 3 ml. of concd. sulfuric acid was added a mixture of 2.5 ml. of fuming HNO_3 (sp. gr. 1.50) and 5 ml. of concd. sulfuric acid. The reaction mixture was heated on a steam-bath for 4 hr., neutralized with sodium carbonate and extracted with benzene. Evaporation of the benzene left practically quantitative yields of crude nitro compounds which were recrystallized from absolute ethanol (Table IV).

Acknowledgment.—We are grateful to the Lasdon Foundation for a grant-in-aid of this project.

SOUTH ORANGE, NEW JERSEY

(8) We are grateful to the Buffalo Electrochemical Company for a generous supply of 40% peracetic acid and 27.5% hydrogen peroxide.

Phosphorus Compounds. I. Reduction of Benzylphosphonium Compounds with Lithium Aluminum Hydride[1]

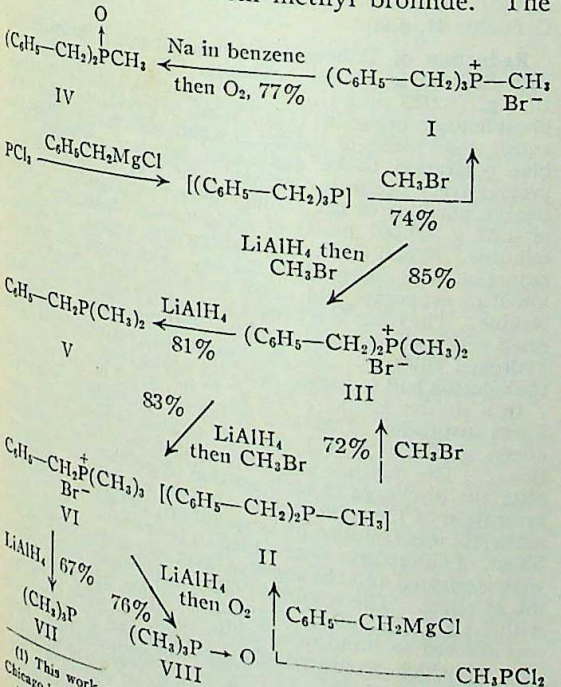
BY WILLIAM J. BAILEY AND SHELDON A. BUCKLER[2]

RECEIVED JANUARY 11, 1957

Lithium aluminum hydride in tetrahydrofuran was employed to remove a benzyl group from a benzylphosphonium compound in high yield to produce a tertiary phosphine. Reduction followed by alkylation of the resulting phosphine was shown to be a very excellent method for the replacement of a benzyl group with an alkyl group. This procedure can conveniently be used for the stepwise synthesis of a variety of tertiary phosphines. Thus tribenzylmethylphosphonium bromide (I), prepared in a 74% yield from phosphorus trichloride, was reduced with lithium aluminun hydride, and the product was alkylated to produce dibenzyldimethylphosphonium bromide (III) in an over-all yield of 85%. III, in turn, was reduced and the phosphine was alkylated in a similar manner to produce benzyltrimethylphosphonium bromide (VI) in an over-all yield of 83%. Further reduction of VI with lithium aluminum hydride produced trimethylphosphine in a 67% yield.

The reductive cleavage of benzyl groups bonded to nitrogen, oxygen and sulfur is a well-known phenomenon and has received considerable study. It recently has been the subject of a comprehensive review.[3] Reductions have been effected by both catalytic and chemical means, and the chief utility of this reaction has been to remove, under relatively mild conditions, benzyl groups which had served as blocking agents in some preliminary reactions. This is a report of the extension of this reductive cleavage to benzyl-containing phosphonium compounds, accomplished most effectively by lithium aluminum hydride.

Tribenzylmethylphosphonium bromide (I) was used for the preliminary study of the reductive cleavage of benzyl groups. The bromide I was readily prepared in a 74% yield by the reaction of 3 moles of benzylmagnesium chloride with phosphorus trichloride, followed by direct treatment of the ethereal extracts with methyl bromide. The intermediate tribenzylphosphine was not isolated because of the facile air oxidation of benzyl-containing phosphines.



Benzylammonium compounds have been reduced by hydrogen with palladium catalyst[4] and sodium amalgam[5]; the latter method has had the widest applicability. For example, Emde[5a] found that dibenzyldimethylammonium chloride was reduced to benzyldimethylamine in 91% yield by sodium amalgam in aqueous solution.

Attempts to reduce I by hydrogen and palladium were unsuccessful, even at elevated temperature and pressure. An initial success was realized by the use of sodium in liquid ammonia. When small pieces of sodium were added to a slurry of the phosphonium compound I in this medium, discharge of the blue coloration was observed until four equivalents of sodium had been consumed. No further reduction occurred. A distinct phosphine odor was present after the ammonia had been removed by evaporation, but no product corresponding to the removal of the two benzyl groups could be isolated. When the experiment was repeated with only two equivalents of sodium, the product corresponding to the removal of one benzyl group, dibenzylmethylphosphine (II), was formed. Since II was oxidized easily in air, it was not isolated but was converted to its methyl bromide derivative, dibenzyldimethylphosphonium bromide (III), which was isolated in a 29% over-all yield. When this experiment was performed without a nitrogen atmosphere, the phosphine was converted directly to its oxidation product, dibenzylmethylphosphine oxide (IV), which was isolated in a 39% over-all yield.

Reduction of the benzylphosphonium compound I by means of sodium in warm ethanol was also successfully carried out. Again, the product was isolated as the oxide IV, in a 64% over-all yield. The I also was debenzylated by means of sodium in refluxing benzene; 77% of the theoretical amount of IV was isolated in this case. However, lithium aluminum hydride in tetrahydrofuran proved to be the most convenient as well as the most effective debenzylating agent for all the benzylphosphonium compounds studied. When a slurry of finely pow-

dered I was heated under reflux in a tetrahydrofuran solution of the hydride for 5.5 hr., the reduction product was obtained as its methyl bromide derivative III in an 85% over-all yield. No appreciable amount of reduction was observed, however, when diethyl ether was used as the solvent.

A similar study of the conditions required for debenzylation was carried out on the dibenzyldimethylphosphonium bromide (III). An alternative preparation of III was carried out in a 72% yield by the reaction of 2 moles of benzylmagnesium chloride with methyldichlorophosphine, followed by treatment of the resulting phosphine II with methyl bromide. In contrast to the work of Emde[5a] with dibenzyldimethylammonium compounds, III was not reduced with sodium amalgam. When the phosphonium derivative III was treated with this same reagent, no phosphine was detected and no other evidence of reduction was observed. Stannous chloride in acidic solution proved to be equally ineffectual as a reducing agent. In spite of the fact that sodium in liquid ammonia, in warm ethanol or in refluxing benzene produced some debenzylation of I, none of these combinations was at all successful for the reduction of III. Apparently the lower solubility of III, compared to I, could account for this difference. However, when the dibenzylphosphonium derivative III was reduced with lithium aluminum hydride in tetrahydrofuran, the debenzylated product, benzyldimethylphosphine (V), was isolated in an 81% yield. When the ethereal extracts from a similar reaction were treated directly with methyl bromide, benzyltrimethylphosphonium bromide (VI) was obtained in an 83% yield. VI also was successfully reduced by lithium aluminum hydride. The product, trimethylphosphine (VII), was isolated in a 67% yield by slow distillation of the reducing mixture without preliminary hydrolysis. The true yield was probably greater, and the amount obtained reflects the difficulty in the separation of a small amount of VII from the tetrahydrofuran, which boils only 27° higher. That this was the case was shown by the introduction of a slow stream of air through a solution of crude VII combined with the higher boiling tetrahydrofuran fraction. Trimethylphosphine oxide (VIII) was obtained in a 76% over-all yield.

The action of lithium aluminum hydride has thus been shown to be a very effective method for debenzylating phosphonium compounds containing one, two or three benzyl groups. All these reactions proceeded smoothly and in reasonably high yields. The reaction is thought to proceed selectively in the sense that only one benzyl group is removed at a time, since even if a large excess of lithium aluminum hydride was used, the products corresponding to the removal of one benzyl group were the only ones isolated. The reaction can be envisioned as proceeding by hydride attack on a benzyl carbon atom, followed by ejection of the neutral tertiary phosphine with its free pair of electrons. The formal positive charge on the phosphorus atom, even though partially neutralized in a complex, probably furnishes the driving force for the reaction. The tertiary phosphine formed probably does not react further because of the absence of a positive charge or because of the necessity for the development of a negative charge on the phosphorus atom during the reduction.

The over-all result of the alkylation of a benzylphosphine, followed by reductive cleavage of the product, is the replacement of a benzyl group by an alkyl group. The extension of these observations to the synthesis of unsymmetrical, tertiary phosphines will be reported separately.

Experimental[6]

Except where otherwise noted, all phosphines, solutions of phosphines and Grignard reagents were prepared and handled in an atmosphere of nitrogen purified by passage through basic pyrogallol traps.

Tribenzylmethylphosphonium Bromide (I).—Benzylmagnesium chloride, prepared in the usual way from 12.2 g. (0.5 mole) of magnesium, 63.3 g. (0.5 mole) of freshly distilled benzyl chloride and 400 ml. of anhydrous ether, was diluted with 100 ml. of additional ether and cooled in a salt–ice bath. A solution of 22.0 g. (0.16 mole) of phosphorus trichloride in 100 ml. of ether was added over a period of 1.5 hr. with cooling and stirring. After the stirring was continued for an additional 30 minutes, the mixture was hydrolyzed by the addition of 150 ml. of water, followed by 200 ml. of a saturated ammonium chloride solution, at a rate such that gentle refluxing ensued. Stirring was stopped, the solids were allowed to settle and most of the ether solution was removed through a glass tube by the application of an excess nitrogen pressure. After 250 ml. of chloroform was added and the mixture was stirred, the layers were separated. The organic layers were combined, cooled in an ice-bath and treated with 30.4 g. (0.32 mole) of methyl bromide. The mixture was allowed to stand under a Dry Ice condenser for 40 hr. The precipitated crystalline salt was then removed by filtration and was washed thoroughly with ether to give 47.5 g. (74%) of slightly impure tribenzylmethylphosphonium bromide (I), m.p. 222–226°. Two recrystallizations from the minimum quantity of ethanol gave 41.0 g. (64%) of pure material, m.p. 229–229.5°.

Anal. Calcd. for $C_{22}H_{24}BrP$: C, 66.17; H, 6.06. Found: C, 66.00; H, 5.90.

Reduction of Tribenzylmethylphosphonium Bromide (I) with Sodium in Liquid Ammonia.—To a stirred slurry of 10.0 g. (0.025 mole) of finely powdered tribenzylmethylphosphonium bromide (I) in 100 ml. of liquid ammonia were added small pieces of sodium at a rate sufficient to allow the blue coloration to be discharged between additions. (A progressively deepening orange color was observed as successive portions of the sodium were discharged.) A total of 2.32 g. (0.101 mole) of sodium was consumed in 265 minutes. When additional sodium was added, no further reduction was observed in 2.5 hr. The ammonia was allowed to evaporate and water and ether were added to the residue. The ether layer (with a strong phosphine odor) was dried with sodium sulfate and was saturated with anhydrous hydrogen chloride. No precipitate was formed even after the solution had remained at 0° for a long time.

In a similar fashion, 20.0 g. (0.05 mole) of the bromide I was suspended in 200 ml. of liquid ammonia and was reduced with 2.30 g. (0.1 mole) of sodium (added in six portions). The mixture was stirred vigorously for 10 minutes after the discharge of each portion of sodium to ensure saturation of the solvent with starting material. After the ammonia was removed by evaporation, 100 ml. of water and 50 ml. of chloroform were added to the residue. The layers were separated and the aqueous layer was extracted with 100 ml. of ether. The combined organic solutions were treated with 7.1 g. (0.075 mole) of methyl bromide, and the mixture was allowed to stand in a tightly stoppered flask for 40 hr. The oil which separated was removed and it crystallized when it was stored at −20°. Recrystallization from methylisobutylcarbinol yielded 4.45 g. (29%) of dibenzyldimethylphosphonium bromide (III), m.p. 138–141°. Further recrystallization from methylisobutylcarbinol–petroleum ether produced analytically pure III, m.p. 141–142°.

(6) The authors are grateful to Dr. Mary Aldridge and Kathryn Gehlman for the analyses. All melting points and boiling points are corrected.

Anal. Calcd. for $C_{16}H_{20}BrP$: C, 59.45; H, 6.24; Br, 24.73; P, 9.59. Found: C, 59.23; H, 6.37; Br, 24.61; P, 9.43.

In a similar experiment conducted without a nitrogen atmosphere, dibenzylmethylphosphine oxide (IV) was obtained in a 39% yield by the removal of the ammonia by evaporation after reduction, followed by the addition of water and the subsequent removal of the white solid thus obtained. Recrystallization from benzene–petroleum ether gave white needles of the phosphine oxide IV, m.p. 133.5–134.0°.

Anal. Calcd. for $C_{15}H_{17}OP$: C, 73.75; H, 7.02; P, 12.68. Found: C, 73.71; H, 6.75; P, 12.61.

Reduction of I with Sodium in Alcohol.—To a solution of 5.0 g. (0.0125 mole) of tribenzylmethylphosphonium bromide (I) in 40 ml. of warm anhydrous ethanol was added 0.58 g. (0.025 mole) of sodium in three portions. After all the sodium had reacted, 150 ml. of water was added and the resulting solution was extracted with two 150-ml. portions of ether. The organic solution was dried with Drierite, and the ether and ethanol were removed by evaporation. The oily residue gradually solidified when it was exposed to air. This material was recrystallized from benzene-petroleum ether to give 1.95 g. (64%) of dibenzylmethylphosphine oxide (IV) as white needles, m.p. 133.5–134.0°. This sample of IV showed no depression of melting point upon admixture with the oxide IV obtained from the sodium in liquid ammonia reduction described above.

Reduction of I with Sodium in Benzene.—A suspension of 5.0 g. (0.0125 mole) of tribenzylmethylphosphonium bromide (I) and 0.58 g. (0.025 mole) of sodium in 100 ml. of anhydrous benzene was heated under reflux for 5 hr. Since a few specks of sodium were unreacted, 10 ml. of anhydrous ethanol was then added. When all the sodium was consumed, 100 ml. of water was added. A solid, which was insoluble in either the aqueous or organic layer, was removed by filtration and was proved to be starting material, m.p. 228.5–229.5° (no depression with an authentic sample). The benzene layer was separated and the aqueous layer was extracted with ether. The combined organic solutions were concentrated by evaporation to give an oil which solidified when it was exposed to air. The solid was recrystallized from benzene–petroleum ether to give 1.85 g. (77% yield, when corrected for the amount of starting material recovered) of dibenzylmethylphosphine oxide (IV), m.p. 133.5–134.0°. This sample of IV showed no depression of melting point upon admixture with the substance obtained from sodium in liquid ammonia reduction described previously.

Dibenzyldimethylphosphonium Bromide (III). A. By Reduction of Tribenzylmethylphosphonium Bromide (I) with Lithium Aluminum Hydride.—To a suspension of 10.0 g. (0.025 mole) of finely powdered tribenzylmethylphosphonium bromide (I) in 125 ml. of dry tetrahydrofuran was added 0.6 g. (0.0158 mole) of lithium aluminum hydride, and the mixture was heated under reflux for 5.5 hr. Most of the tetrahydrofuran was then removed by distillation, and the residue was treated cautiously with 100 ml. of commercial ether and 80 ml. of 20% sodium potassium tartrate solution. The layers were separated and the aqueous layer was extracted with 75 ml. of ether. The combined ether extracts were placed in a pressure bottle with 10 ml. of methyl bromide, and the mixture was allowed to stand at room temperature for 48 hr. The crystalline solid which was deposited was removed by filtration and recrystallized from methylisobutylcarbinol–petroleum ether to give 6.90 g. (85% over-all yield) of dibenzyldimethylphosphonium bromide (III), m.p. 141–142°. There was no depression of the melting point when this material was mixed with an authentic sample of III. When diethyl ether was used as a solvent, the phosphonium compound I did not gradually dissolve (as was observed when tetrahydrofran was used) and only a slight phosphine odor was detected after the reaction mixture was heated under reflux for 24 hr.

B. From Methyldichlorophosphine.—Benzylmagnesium chloride was prepared from 24.3 g. (1.0 mole) of magnesium, 126.6 g. (1.0 mole) of freshly distilled benzyl chloride and 900 ml. of anhydrous ether. The reagent was cooled in an ice-bath while 53.8 g. (0.46 mole) of freshly distilled methyldichlorophosphine, b.p. 77–79°, (Army Chemical Center, Maryland) in 200 ml. of ether was added over a 2-hr. period with stirring. The mixture was stirred for an additional hour and then was hydrolyzed with 200 ml. of water and 300 ml. of a saturated ammonium chloride solution. The layers were separated and the aqueous layer was extracted with 200 ml. of ether. To the combined ether solutions was added 87.4 g. (0.92 mole) of methyl bromide, and this mixture was allowed to stand at room temperature in a stoppered flask for 48 hr. The solid was then collected by filtration and recrystallized from methylisobutylcarbinol–petroleum ether to yield 107 g. (72%) of dibenzyldimethylphosphonium bromide (III), m.p. 141–142°.

Attempted Catalytic Reduction of III.—To a solution of 5.0 g. (0.016 mole) of dibenzyldimethylphosphonium bromide (III) in 35 ml. of acetic acid (distilled from potassium permanganate) was added 2.5 g. of a freshly prepared 25% palladium-on-charcoal catalyst. The mixture was shaken in a hydrogen atmosphere at 100° and 900 lb./sq. inch for 15 hr. No uptake of hydrogen was observed and 92% of the starting material was recovered in pure form. Similar low pressure experiments with either III or tribenzylmethylphosphonium bromide (I) were unsuccessful.

Benzyldimethylphosphine (V).—A mixture of 45.0 g. (0.14 mole) of finely powdered dibenzyldimethylphosphonium bromide (III), 2.4 g. (0.063 mole) of lithium aluminum hydride and 300 ml. of dry tetrahydrofuran was heated under reflux for 5 hr. Most of the tetrahydrofuran was then removed by distillation and 300 ml. of commercial ether and 250 ml. of 20% sodium potassium tartrate solution were added cautiously. The layers were separated and the aqueous layer was extracted with two 100-ml. portions of ether. The combined ether solutions were dried with magnesium sulfate and the ether was removed by distillation through a 12-inch Vigreux column. The residue was fractionated through the same column to yield 17.1 g. (81%) of benzyldimethylphosphine (V), b.p. 87–89° (10 mm.), $n^{20}D$ 1.5416 [reported[7] b.p. 93–96° (12 mm.)].

Benzyltrimethylphosphonium Bromide (VI).—When 45.0 g. (0.14 mole) of dibenzyldimethylphosphonium bromide (III) was reduced by the exact procedure described above, the ether extracts were not distilled but were treated directly with an excess of methyl bromide in a stoppered flask for 48 hr. The solid was removed by filtration and recrystallized from methylisobutylcarbinol–petroleum ether to yield 28.6 g. (83% over-all yield) of benzyltrimethylphosphonium bromide (VI), m.p. 223–225° (reported[8] m.p. 222°).

Reduction of Benzyltrimethylphosphonium Bromide (VI) with Lithium Aluminum Hydride.—To a suspension of 18.0 g. (0.073 mole) of finely powdered benzyltrimethylphosphonium bromide (VI) in 100 ml. of dry tetrahydrofuran was added 1.52 g. (0.04 mole) of lithium aluminum hydride, and the mixture was heated under reflux for 3 hr. The reaction mixture was slowly fractionated through a 12-inch Vigreux column at a reflux ratio of 17:1. A total of 3.73 g. (67%) of trimethylphosphine, b.p. 40–43° (reported[9] b.p. 37.8°), was collected.

Distillation was then continued to collect all material boiling below 65°. This crude material was combined with the lower boiling fraction of pure trimethylphosphine (VII) and the mixture, dissolved in 100 ml. of anhydrous ether, was placed in a flask equipped with a gas-inlet tube and Dry Ice condenser. Dry air was bubbled through the solution for 5 hr., and the crystalline trimethylphosphine oxide (VIII) which formed was removed by filtration. The solid was dried in a vacuum desiccator to give 5.10 g. (76% yield based on VI) of slightly impure trimethylphosphine oxide (VIII), m.p. 135–137° (sealed capillary). Recrystallization of this crude material from tetrahydrofuran–ethyl acetate produced the pure oxide VIII, m.p. 137–138° (reported[10] m.p. 137.5–138.5°).

Organic Phosphorus Compounds. I. The Conversion of the Chloroaluminate Complexes, $[RPCl_3][AlCl_4]$, to Alkyl Alkylphosphonochloridates and Dialkyl Alkylphosphonates

BY FRIEDRICH W. HOFFMANN,[1] THOMAS C. SIMMONS AND LOUIS J. GLUNZ III

RECEIVED JANUARY 21, 1957

Phosphorus trichloride can be converted in methylene chloride solution in good yields by a simple one-batch procedure with alkyl chloride and aluminum chloride to the intermediate chloroaluminate complexes, $[RPCl_3][AlCl_4]$ (I) or $[RPCl_3][Al_2Cl_7]$, and by alcoholysis further to alkyl alkylphosphonochloridates or dialkyl alkylphosphonates. It is shown that the complexes I are converted by alcoholysis stepwise to $[RP(O)Cl][AlCl_4]$, $[RP(O)OR'][AlCl_4]$ and finally to $[RP(O)(OR')_2 \cdot AlCl_3]$, all of which can be decomposed with water to yield $RP(O)Cl_2$, $RP(O)(OR')Cl$ and $RP(O)(OR')_2$, respectively, and hydrated aluminum salts.

Introduction.—The various methods described in the literature for the preparation of phosphonic acids and their derivatives[2] have been supplemented recently by a simple general procedure which utilizes the ready formation of complexes of the type $[RPCl_3][AlCl_4]$ (I) from equimolar amounts of alkyl chloride, aluminum chloride and phosphorus trichloride.[3-5]

Treatment of the complexes I in methylene chloride solution with 7–11 mole equivalents of water gives the corresponding alkylphosphonyldichloridates, $RP(O)Cl_2$ (II), generally in good yields.[3-5] Perren and Kinnear[5] also demonstrated by one example that the I can be converted directly with ethanol to the corresponding diethyl alkylphosphonate, in their example the ethylphosphonate, $C_2H_5P(O)(OC_2H_5)_2$ (III).

The mechanisms proposed by Clay[3] and by Kinnear and Perren[4] for the formation of the dichlorides II differ with regard to the first step of the reaction. While Clay assumes that the first mole equivalent of water attacks the cation of the complex I forming by hydrolytic cleavage a $[RP(O)Cl]^+$ cation and thus a new ionic complex $[RP(O)Cl][AlCl_4]$ (IV), the British authors believe the first step of the hydrolysis to be a hydrolytic cleavage of the ionic complex I into $H[AlCl_4]$ and $RPCl_3 \cdot OH$. The intermediate, having an unstable electron decet around the phosphorus atom, is then stabilized by elimination of HCl resulting in the formation of II.

Since ethanolysis of the complex $[C_2H_5PCl_3][AlCl_4]$ (V) is reported[5] to give III in 92% yield, while its hydrolysis resulted in the isolation of 82% of $C_2H_5P(O)Cl_2$ (VI), it appears that the complexes I can be utilized, at least in some cases, directly as starting materials for the synthesis of valuable organic phosphorus derivatives without the intermediate isolation of the dichlorides II. Clarification of the mechanism of the solvolysis of I would allow a proper selection of suitable conditions for the conversion to products other than II. Therefore, a study of the stepwise alcoholysis of I was undertaken. The results of this investigation enabled us to devise a useful method for the synthesis of alkyl alkylphosphonochloridates and dialkyl alkylphosphonates directly from the appropriate alkyl halides.

Summary of Results.—The complex $[CH_3PCl_3][AlCl_4]$ (VII), suspended in methylene chloride solution, deposited upon treatment with one mole equivalent of absolute methanol at 25° the less soluble crystalline complex $[CH_3P(O)Cl][AlCl_4]$ (VIII), the composition of which was established by independent synthesis and by analysis. The high thermal stability of the distillable complex VIII indicates strong complexing of its components.

The postulated breakdown of the complexes I into II and $H[AlCl_4]$ by which Kinnear and Perren[4] explain the hydrolysis to II seems to be disproved by the formation of the complex VIII from its components. The tendency of II to enter into complex formation with aluminum chloride is much too high to allow its coexistence with the weak complex $H[AlCl_4]$ in a solution. If the products II and $H[AlCl_4]$ existed at any time in the reaction mixture, complex formation to IV would occur with the elimination of hydrogen chloride. In other words, the first step of the hydrolysis appears to proceed in the fashion suggested by Clay[3] with the formation of IV.

The treatment of complex VII with two mole equivalents of methanol resulted in the formation of another complex with the elimination of hydrogen chloride. This new complex analyzes for a composition of an adduct of methyl methylphosphonochloridate, $CH_3P(O)(OCH_3)Cl$, and aluminum chloride and may possibly be formulated as $[CH_3P(O)OCH_3][AlCl_4]$. The reaction of VII with an additional, *i.e.*, with three, mole equivalent of methanol gave again a complex which could be isolated as a stable solid from the reaction mixture. The resulting product had the approximate composition $CH_3P(O)(OCH_3)_2 \cdot AlCl_3$.

Conclusive evidence for the stepwise alcoholysis of I to new complex intermediates was obtained by ethanolysis of V in methylene chloride solution with one, two and three mole equivalents of absolute ethanol. The nuclear magnetic resonance (NMR) spectra of the resulting products were identical for all practical purposes with the spectra of the complexes prepared in methylene chloride solution from anhydrous aluminum chloride and VI, $C_2H_5P(O)(OC_2H_5)Cl$, (IX) and III, respectively. The chemical shift (δ) values for the various complexes prepared by alcoholysis of V and by direct synthesis from the components, and also for the

[a] Chemical shift, $\delta = (H \text{ sample} - H_{H_3PO_4}) \times 10^6/H_{H_3PO_4}$; the operating radio frequency for these measurements was 17 megacycles. [b] The spectra were taken in methylene chloride solution except where stated otherwise. [c] Without solvent. [d] From V and one mole of absolute ethanol. [e] From VI and $AlCl_3$. [f] From V and two moles of absolute ethanol. [g] From IX and $AlCl_3$. [h] From V and three moles of absolute ethanol. [i] From III and $AlCl_3$.

That VI is not formed by alcoholysis of V with one mole equivalent of ethanol is clearly demonstrated by the differences of the chemical shift values between VI and its complex with aluminum chloride, $[C_2H_5P(O)Cl][AlCl_4]$ (X). The presence of VI in quantities of more than 2–3% of the total amount of phosphorus in the solution of the alcoholysis product of V with one mole of ethanol and of the product from VI and aluminum chloride would have been observed in the spectra of the two samples of complex X.

The chemical shifts of −53.8 and −54.5 observed for the solvolysis product of V with two mole equivalents of ethanol and for the reaction product of IX with aluminum chloride, respectively, again prove the identity of the reaction products. The smaller shift of −45.0 shown by IX seems to indicate that the conversion of a covalent P–Cl bond to an ionic bond results in a larger chemical shift. The same observation is made in the conversion of VI to X. The NMR spectrum of the reaction product of V with three moles of ethanol was identical with that of the synthetic complex obtained from III and aluminum chloride. The absence of a chemical shift to a more negative value upon complexing III can be regarded, on the basis of the foregoing observations, as indicative for the absence of a conversion of a covalent P–O bond to an ionic bond and can best be explained by the non-ionic structure $[C_2H_5P(O)(OC_2H_5)_2\cdot AlCl_3]$ for the complex.

None of the conversion complexes formed by alcoholysis of I can be broken by the usual techniques, such as treatment with sulfuryl chloride, phosphorus oxychloride, triethylamine or fusion with sodium chloride, but requires hydration of the $[AlCl_4]^-$ anion to aluminum chloride hydrate and hydrogen chloride.

(6) The NMR spectra reported in this paper were measured and interpreted by Messrs. Harold Finegold and G. F. Svatos employing the same instrumentation and technique as described by Messrs. F. C. Lauterbur and Jerome Goldenson, THIS JOURNAL, 78, 3557 (1956). The authors gratefully acknowledge this valuable help.

The reaction scheme involved in the alcoholysis, synthesis and cleavage of the various complexes is illustrated in Fig. 1.

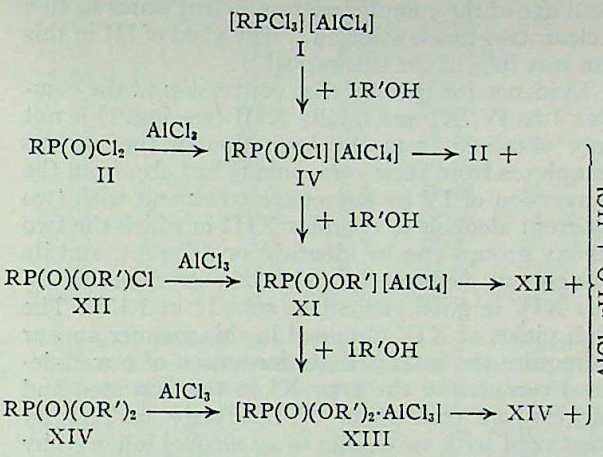

Fig. 1.

The first step of the alcoholysis of I (as well as of the hydrolysis) is the conversion to IV with the replacement of two chlorine atoms by one oxygen atom and the formation of alkyl chloride and hydrogen chloride. This reaction takes place in all probability by a nucleophilic displacement of a chloride ion on the phosphorus by the alkoxide ion followed by elimination of alkyl halide. A repetition of the nucleophilic displacement reaction on the cation of IV leads to the formation of the cation $[RP(O)OR']^+$ (XV). The conversion of IV to XI corresponds to the reaction of II with one mole equivalent each of an alcohol and a base leading to the chloridate XII. The role of the base is taken over in the system IV–R'OH by the displaced chloride ion which removes the proton as undissociated HCl. A similar situation prevails for the further alcoholysis of XI to XIII, except that here the nucleophilic attack of the alkoxide ion on the phosphorus atom of the cation XV results in a neutral molecule XIV, which forms an un-ionized complex with aluminum chloride. The chloride ion liberated from the anion $[AlCl_4]^-$ by the complexing is taken up by the proton originating from the alcohol.

Clay[3] and Kinnear and Perren[4] demonstrated that further treatment of the complex IV with one to fourteen moles of water (depending on the nature of the alkyl group) gives the corresponding II in good yields. The direct conversion of complex V with absolute ethanol until no further reaction occurred, followed by treatment with water,[5] showed that the isolation of the II is unnecessary for the synthesis of the phosphonates XIV. While the formation of XIV from II in acceptable yields requires the presence of two mole equivalents of a base as an acceptor for the liberated hydrogen chloride, no base is necessary in the conversion of I to XI and further to XIV. Complex V treated in methylene chloride solution with seven moles of ethanol (see run 5) and water added dropwise to the reaction mixture until the original gelatinous precipitate dissolved gave an 80% yield of III.

That not more than three mole equivalents of alcohol are actually required for the formation of III is demonstrated clearly by a run (no. 2) in which a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

solution of V in methylene chloride was at first treated for conversion to $C_2H_5P(O)(OC_2H_5)_2 \cdot AlCl_3$ with three mole equivalents of ethanol and then for cleavage of the complex with sufficient water to give a clear, two-phase solution. The yield of III in this run was 76% of the theoretical.

Evidence for the stepwise conversion of the complex I to IV, XI and finally XIII (see Fig. 1) is not only obtained from the formation of the various complexes from their components but also from the conversion of IV by successive treatment with two different alcohols to complex XIII in which the two alkoxy groups can be identical or different, and its subsequent cleavage to yield the corresponding esters XIV in good yields (see runs 11 and 13). The high yields of XIV obtained in this manner appear to require the intermediate formation of a well-defined complex of the type XI in the first step and suggest the conversion of I directly to XII by treatment with two moles of an alcohol followed by cleavage of the intermediate complex XI with a limited amount of water. This reaction sequence permits the conversion of phosphorus trichloride through the readily obtainable complexes I in a simple one-batch method to the valuable alkylphosphonochloridates XII (see runs 14–17) in acceptable yields.

Since the first mole of alcohol in the reaction with the complex I serves merely the purpose of replacing two chlorine atoms of the cation by an oxygen atom, any inexpensive alcohol, such as methanol or ethanol, can be employed in the first step of the alcoholysis. For the preparation of phosphonochloridates or phosphonates, the introduction of the desired alkoxy group or groups on the phosphorus atom can then be accomplished by means of the appropriate alcohol. The feasibility of this procedure is, in principle, demonstrated by run 13 in which the complex $[iso\text{-}C_3H_7PCl_3][AlCl_4]$ was first treated with ethanol (20% deficiency) and then with isopropyl alcohol (20% excess) and finally hydrolyzed with a limited amount of water to yield 62% of di-isopropyl isopropylphosphonate.

The methods of Clay[3] and of Kinnear and Perren[4] for the preparation of the II use the complexes I which are prepared in solid form. It was found, however, that the I also are formed readily in dry methylene chloride and that the resulting solutions can be converted further without the actual isolation of the complexes I. This procedure had in some cases the added advantage that discoloration of the reaction mixture which is observed in the formation of the I from isopropyl chloride can be avoided entirely. In general the complexes I are formed readily by adding the appropriate alkyl chloride slowly to a stirred solution of phosphorus trichloride in the solvent containing the equivalent amount of anhydrous aluminum chloride in suspension. Completion of the complex formation is indicated by the disappearance of the aluminum chloride.

While the reaction products from equimolar quantities of phosphorus trichloride, aluminum chloride and alkyl chloride gave generally the solvolysis products of the I in good yields, it was observed that similar runs with ethyl chloride led consistently to yields below 50% of the theoretical (see run 3). A methylene chloride solution of the complex V (prepared from the components without solvent), on the other hand, could be converted in 62% yield to IX (run 15) and in 80% yield to III (run 5). When a solution of the complex from ethyl chloride (prepared in methylene chloride) was evaporated under reduced pressure, the residue was not the solid complex I. The ratio of PCl_3: C_2H_5Cl:$AlCl_3$ was 1:1:2 in the residual viscous oily product. The same liquid material also was obtained by shaking a mixture of the reactants in the molar ratio 1:1:2 without solvent in a pressure bottle until the aluminum chloride had dissolved.

The formation of 1:1:2 complexes is described by Perren and Kinnear[5] without indicating the physical state of the resulting products. However, these authors make the general statement that the amount of complex-forming agent is not critical in determining the course of the reaction but is of importance to ensure the formation of liquid complexes.

The structure of the liquid complex of the composition $[C_2H_5Cl \cdot PCl_3 \cdot 2AlCl_3]$ can be either $[C_2H_5PCl_3][Al_2Cl_7]$ (XVI) or $[C_2H_5PCl_2]^{++}[2AlCl_4]^{--}$ (XVII). Since the complexes V and XVI have the same cation in common, identical NMR spectra are to be expected if the 1:1:2 complex possesses structure XVI. A structure of the type XVII, however, would result in a different chemical shift of the phosphorus resonance as compared to complex V. The δ-value of -128.6 for both, the 1:1:1 and the 1:1:2 complex, rules out formula XVII.

The formation of the complexes I from the components seems to proceed through the intermediate complexes $[RPCl_3][Al_2Cl_7]$ which react further with one mole equivalent of phosphorus trichloride and alkyl halide. A mixture of equal molar quantities of methyl chloride, phosphorus trichloride and anhydrous aluminum chloride mixed at Dry Ice temperature forms, when allowed to come to room temperature in a sealed Pyrex tube, in an exothermic reaction a clear, colorless liquid which solidifies on further shaking spontaneously within a few seconds to a solid crystal cake consisting of VII.[7] A similar observation was made in the preparation of the complex V, except that here the further conversion of the primarily formed XVI to V required heating to 60° or continued shaking overnight.

While the higher alkyl chlorides form the complexes I readily in methylene chloride as a reaction medium, the reaction of ethyl chloride in solution with phosphorus trichloride and aluminum chloride led only to XVI. This accounts for the low yield of III from ethyl chloride in run 3, when calculated on the basis of complex V instead of XVI as actually required.

For preparative purposes, the alcoholysis of I with absolute ethanol was preferable to that with other alcohols because of the solubility of the intermediate complexes in methylene chloride. When methanol was used instead of ethanol for the alcoholysis reactions, white crystals separated from the solutions and subsequent decomposition of the in-

[7] In the reaction of methyl chloride a very violent explosion occurred. In the preparation of the complex VII, the sealed tube should always be encased in a heavy steel pipe closed at the ends with steel screw caps.

[a] Diethyl cyclohexylphosphonate, previously prepared by R. Graf, *Chem. Ber.*, **85**, 9 (1952), b. 148° (1.5 mm.).

termediate complexes with excess water resulted in the formation of gelatinous precipitates, insoluble in more water or acid, which had to be separated by centrifugation.

The yields of chloridates or dialkyl esters obtained in the various alcoholysis runs (see Tables III, IV and V) are not representative of optimum results but can be improved without doubt. It is interesting to note that, although the I from *t*-butyl chloride and from carbon tetrachloride can be hydrolyzed to give the corresponding II in good yields,[4,8] the alcoholysis of the *t*-butyl complex with excess ethanol followed by hydrolytic cleavage gave only *t*-butylphosphonodichloridate, while that of the trichloromethyl complex resulted in the formation of intractable products.

The analytical values of the new phosphorus compounds obtained in this investigation are listed in Table II.

Acknowledgment.—We are indebted to the personnel of the Analytical Research Branch, Chemical Research Division, for the performance of all elemental analyses reported in this paper.

Experimental

Preparation of the Chloroaluminate Complexes.—The solid complexes $[CH_3PCl_3][AlCl_4]$ (VII) and $[C_2H_5PCl_3][AlCl_4]$ (V) were prepared by the method of Kinnear and Perren.[4] Thus, 0.55 mole of anhydrous aluminum chloride and 0.50 mole of phosphorus trichloride was charged to a Pyrex glass pressure bottle of 350-cc. capacity and cooled in a Dry Ice–acetone-bath. To the cooled mixture was then added 0.60 mole of precooled methyl or ethyl chloride. The sealed pressure container was shaken mechanically overnight, during which time the reaction mixture solidified to a colorless crystal cake. The preparation of V was speeded up by shaking the mixture of the reactants for approximately 1 hr. until the aluminum chloride had dissolved and then heating for another hour to 60°.

The liquid complex $[C_2H_5PCl_3][Al_2Cl_7]$ (XVI) was prepared in a similar fashion by shaking a mixture of 0.5 mole of phosphorus trichloride, 1.0 mole of anhydrous aluminum chloride and 70 cc. of ethyl chloride in a pressure bottle at room temperature until a clear solution was obtained.

All complexes of type I with alkyl groups higher than ethyl were prepared in methylene chloride as the reaction medium. The preparation of the complex from isopropyl chloride, representative of the general procedure, is described in detail.

Dry methylene chloride (200 cc.) was placed in a 1-l., three-neck, round-bottom flask equipped with dropping funnel, mercury-sealed stirrer, pot thermometer and reflux condenser. The system was protected against atmospheric moisture by a drying tube charged with anhydrous calcium chloride. Phosphorus trichloride (68.5 g., 0.5 mole) and 64 g. (0.5 mole) of powdered, anhydrous aluminum chloride (Baker and Adamson, reagent grade, sublimed) were added successively to the solvent. The aluminum chloride remained undissolved in the mixture. The contents of the flask was then cooled to 0° and 44 g. (0.55 mole) of isopropyl chloride was added to the vigorously stirred mixture dropwise at such a rate as to maintain the temperature between 5 and 15°. Throughout the entire addition, the reaction vessel was immersed in an ice–water-bath. As the reaction progressed, the aluminum chloride went slowly into solution. The resulting colorless solution of $[(CH_3)_2CHPCl_3][AlCl_4]$ was allowed to warm to room temperature and used for further reactions.

Alcoholysis of the Chloroaluminate Complexes.—In general, a solution of the appropriate complex in dry methylene chloride (prepared either as described in the preceding paragraph or by dissolving the solid I in methylene chloride) was stirred vigorously and the desired amount of the alcohol was added without external cooling dropwise at such a rate as to keep the mixture refluxing gently. After the addition of the alcohol was completed, the mixture was refluxed for a period of 2–8 hr. and then cooled. The resulting solutions were treated further with vigorous stirring with water or dilute hydrochloric acid in order to break up the conversion complexes formed by alcoholysis.

Method A.—The hydrolytic cleavage of the intermediate complexes was accomplished by adding sufficient water to the methylene chloride solution at 10–20° to dissolve the gelatinous precipitate which was formed initially. The resulting liquid layers were separated and the heavy methylene chloride layer concentrated in a Rinco evaporator[9] under reduced pressure. The residual liquid product was fractionated under reduced pressure.

Method B.[10]—In an alternate procedure for the hydrolytic decomposition of the conversion complexes, water was added at −25° with vigorous stirring or with shaking in a separatory funnel to the complex solution (cooled occasionally by adding Dry Ice pellets) in an amount just sufficient to coagulate the initially formed, gelatinous aluminum salt. The resulting granular precipitate was filtered on a büchner funnel from the clear supernatant solution, and the filtrate was concentrated in a Rinco evaporator. The product was isolated by distillation of the liquid residue under reduced pressure.

Because of the sensitivity of the phosphonochloridates toward water, the complexes of type XI were cleaved exclusively by method B. The hydrolytic decomposition of complexes of type XIII can be carried out by either one of the two methods.

Preparation of Ethyl Isopropylphosphonochloridate.—The following procedure illustrates the general method for the conversion of alkyl halides to alkyl alkylphosphonochloridates.

Isopropyl chloride (0.55 mole) was added in the usual manner to 0.5 mole of phosphorus trichloride and 0.5 mole of anhydrous aluminum chloride in 700 cc. of methylene

chloride. To the resulting solution of the complex $[(CH_3)_2CHPCl_3][AlCl_4]$ was added dropwise with stirring over a period of 1 hr. 46 g. (1 mole) of absolute ethanol. Refluxing of the resulting colorless solution was continued with stirring for an additional period of 6 hr. After cooling to −25°, the solution was treated with water, in portions of approximately 5 cc., and shaken vigorously in a separatory funnel for several minutes after the addition of each portion. The addition of water was continued until the gelatinous precipitate, first formed, had coagulated to give a readily removable, granular mass. A total of 85 cc. of water was required in this operation. The methylene chloride solution was filtered rapidly from the coagulated aluminum salt through a Büchner funnel and the filter cake washed three times on the filter with 50-cc. portions of methylene chloride. The solvent was removed from the combined filtrates under reduced pressure and the residue distilled *in vacuo* to yield 67.4 g. (79%) of ethyl isopropylphosphonochloridate, b.p. 51–53° (1.9 mm.) (see Table III).

TABLE III

CONVERSION OF $[RPCl_3][AlCl_4]$ TO $RP(O)(OR')Cl$[a]

16	i-C_3H_7[d]	C_2H_5	53	1.9	1.4357	79
17	CH_3[e]	n-C_3H_7	46	1.0	1.4332	32.5

[a] All runs were carried out by alcoholysis of the appropriate complex I with two mole equivalents or less of the suitable alcohol and working up the reaction mixture by method B. [b] VII (0.5 mole) suspended in 1500 cc. of methylene chloride was treated with 41 g. (0.9 mole) of absolute ethanol during 1.5 hr., refluxed for a period of 6 hr. and finally hydrolyzed at −30° with 110 cc. of water. [c] V (0.3 mole) was dissolved in 750 cc. of methylene chloride, treated with 25.8 g. (0.56 mole) of absolute ethanol and the mixture stirred 2 days at room temperature and finally treated at −20° with 60 cc. of water. [d] This run is described in detail in the Experimental section. [e] To VII (0.5 mole) suspended in 1300 cc. of methylene chloride was added at 10–15° 60 g. (1 mole) of 1-propanol and the mixture refluxed for 1 hr. and treated at −30° with 110 cc. of water. A liquid distillation residue of 13.9 g. decomposed upon attempted distillation under high vacuum to form a gelatinous semi-solid.

Similar conversions of I to phosphonochloridates were performed with the complexes V and VII under varying conditions. The results of these runs are listed in Table III. No attempt was made to establish optimum conditions in the various runs.

Preparation of Diethyl Isopropylphosphonate.—The complex $[(CH_3)_2CHPCl_3][AlCl_4]$ was prepared by the general procedure in 400 cc. of methylene chloride from 1.1 moles of isopropyl chloride and 1.0 mole each of phosphorus trichloride and anhydrous aluminum chloride. Absolute ethanol (322 g., 7 moles) was added dropwise with stirring to the resulting solution of the complex at such a rate that gentle refluxing was maintained. After the alcohol addition was completed, the mixture was refluxed with stirring for an additional period of 3 hr. The colorless solution was then cooled to 20°, and 500 cc. of water was added slowly with stirring. During the addition, the temperature was maintained below 25° by cooling with ice-water. At the beginning of the addition of the water, a white solid precipitated from the reaction mixture. This precipitate, however, dissolved gradually upon further water addition and had completely disappeared after approximately 400 cc. of water had been added. The two colorless layers of the reaction mixture were separated, and the upper aqueous layer was extracted with three 50-cc. portions of methylene chloride. The combined methylene chloride layer and washings were evaporated under reduced pressure at room temperature and the liquid residue was distilled to yield 127.8 g. (71%) of diethyl isopropylphosphonate, b.p. 56° (1.8 mm.) to 58° (2.25 mm.), $n^{25}D$ 1.4161.

In the same fashion were prepared the diethyl alkylphosphonates listed in Table IV.

Preparation of Ethyl Isopropyl Isopropylphosphonate.—The complex $[(CH_3)_2CHPCl_3][AlCl_4]$ (0.5 mole) was prepared from isopropyl chloride and aluminum chloride in 250 cc. of methylene chloride in exactly the same manner as described for the preparation of diethyl isopropylphosphonate. The resulting solution was diluted with 500 cc. of dry methylene chloride and treated dropwise with 46 g. (1 mole) of absolute ethanol. The reaction mixture was then refluxed for a period of 4 hr. and subsequently treated in the usual manner with 60 g. (1 mole) of isopropyl alcohol. Refluxing of the reaction mixture was continued for a period 8 hr. Subsequent dropwise addition of 300 cc. of water precipitated a white solid which was brought back into solution by the addition of 50 cc. of concentrated hydrochloric acid. Separation of the methylene chloride layer and processing in the usual manner yielded 77% of ethyl isopropyl isopropylphosphonate (see run 11, Table V).

TABLE IV

CONVERSION OF $[RPCl_3][AlCl_4]$ TO $RP(O)(OC_2H_5)_2$[a,b]

Run	R	B.p. °C.	B.p. Mm.	$n^{25}D$	Yield, calcd. on PCl_3, %
1	CH_3[c]	44	1.5	1.4119[o]	83.5

[a] Except where stated otherwise (runs 1 and 2), the alcoholysis of the I solution was carried out with 7 mole equivalents of absolute ethanol. [b] The solutions of the alcoholyzed complex were worked up by method A; all runs were performed in methylene chloride solution. [c] VII (0.25 mole) suspended in 500 cc. of methylene chloride was treated with 6 mole equivalents (1.5 moles) of absolute ethanol and the mixture refluxed for 3 hr. and decomposed with 200 cc. of water. [d] V (0.3 mole) in 150 cc. of methylene chloride was treated with 0.9 mole of absolute ethanol, refluxed for 8 hr. and hydrolyzed with 100 cc. of water. [e] Phosphorus trichloride (1 mole) and 1 mole of powdered, anhydrous aluminum chloride was treated at −10° with approximately 70 cc. of ethyl chloride, the mixture stirred for 2 hr. without cooling, treated with 420 cc. of absolute ethanol, refluxed for 8 hr. and decomposed with 60 cc. of concentrated hydrochloric acid in 400 cc. of water. [f] XVI from 0.5 mole of phosphorus trichloride, 1 mole of anhydrous aluminum chloride and 70 cc. of ethyl chloride in 300 cc. of methylene chloride was used. [g] Solid V (0.3 mole) dissolved in 150 cc. of methylene chloride; reflux time 3 hr.; decomposed with 100 cc. of water. [h] Described in detail in the Experimental section. [i] $[(CH_3)_2CHPCl_3][AlCl_4]$ (0.25 mole) was prepared in 150 cc. of methylene chloride from n-propyl chloride (see ref. 4); the final hydrolysis was carried out with 20 cc. of concentrated hydrochloric acid in 100 cc. of water. The infrared spectrum of the product was identical with that obtained of the product from run 6. [k] n-Butyl chloride (0.27 mole) (see ref. 4), 0.25 mole each of phosphorus trichloride and 100 cc. of solvent were employed; the final decomposition was performed with 100 cc. of water. [l] Cyclohexyl. [m] The complex I was prepared from 0.5-mole quantities each of cyclohexyl chloride, phosphorus trichloride and aluminum chloride in 200 cc. of solvent, treated with 3.8 moles of absolute ethanol, refluxed for 3 hr. and decomposed with 200 cc. of water. [n] See footnote *a* of Table II. [o] A. H. Ford-Moore and J. H. Williams, *J. Chem. Soc.*, 1465 (1947); b.p. 64° (4 mm.), $n^{16}D$ 1.4210. [p] B.p. 62° (2 mm.), $n^{15}D$ 1.4172 (Ford-Moore and Williams, ref. *o*).

Reaction of $[CH_3PCl_3][AlCl_4]$ with One Mole of Methanol.—To a vigorously stirred suspension of 107 g. (0.33 mole) of VII in 300 cc. of methylene chloride, maintained at 25° by cooling with water, was added dropwise in the course of 2 hr. a mixture of 10.6 g. (0.33 mole) of absolute methanol and 50 cc. of methylene chloride. After the addition of approximately one-half of the methanol–solvent mixture, the solid complex was completely dissolved. About 30 minutes after the methanol addition was complete, the clear, pale yellow solution became turbid and small colorless crystals began to precipitate. The mixture was stirred for an additional 3 hr. and was allowed to stand at room temperature

TABLE V

CONVERSION OF $[(CH_3)_2CHPCl_3][AlCl_4]$ (XVIII) TO $(CH_3)_2CHP(O)(OR')_2$[a]

Run	R'	B.p. °C.	Mm.	$n^{25}D$	Yield, calcd. on PCl_3, %
10	CH_3[b]	71	5.5	1.4179	40
11	i-C_3H_7 and C_2H_5[c]	47	0.7	1.4138	77
12	i-C_3H_7[d]	38.5	0.25	1.4129	21
13	i-C_3H_7[e]	44	0.35	1.4148	62

[a] XVIII (0.5 mole) was prepared in all runs in the usual manner from isopropyl chloride in methylene chloride solution. [b] To XVIII (0.5 mole) in 150 cc. of solvent was added dropwise 64 g. (2 moles) of absolute methanol. After the addition of about 0.5 mole of methanol, a white solid began to precipitate. The alcoholysis mixture was refluxed for 4 hr. after the addition of the methanol was completed. The addition of 300 cc. of water to the mixture resulted in the formation of a gelatinous emulsion which was broken by centrifuging. [c] Described in detail in the Experimental part. [d] XVIII in 200 cc. of solvent was refluxed for 6 hr. with 2 moles of isopropyl alcohol. The white solid precipitate, formed upon the addition of 300 cc. of water, was dissolved by adding 100 cc. of concentrated sulfuric acid. In addition to the product, 33 g. of liquid distillation residue was obtained; on attempted distillation of the residue, decomposition occurred. [e] XVIII in 600 cc. of solvent was first treated with 18.4 g. (0.4 mole) of absolute ethanol in 50 cc. of solvent, refluxed for 1 hr., treated with 80 g. (1.33 moles) of isopropyl alcohol, refluxed for an additional 5 hr. and hydrolyzed at −10° with 110 cc. of water by method B. overnight. About 200 cc. of the solvent was then removed by distillation at atmospheric pressure; the remainder was evaporated under reduced pressure, leaving a pale yellow, crystalline mass which weighed 93.5 g. The product which did not fume in air was pulverized to a light, crystalline powder. Recrystallization from methylene chloride after decolorizing with Norit yielded the complex VIII as a white, microcrystalline powder, m.p. 140–150° (not sharp). The complex VIII could be distilled without decomposition at a pressure of 5 mm.; at 242–245° a liquid distilled which solidified immediately in an attached air condenser.

Anal. Calcd. for CH_3AlCl_5OP: C, 4.5; H, 1.1; Al, 10.1; Cl, 66.6; P, 11.6. Found: C, 5.0; H, 1.6; Al, 9.6; Cl, 63.0; P, 11.6.

Reaction of Methylphosphonyldichloride with Aluminum Chloride.—To a solution of 25 g. of methylphosphonyldichloride in 150 cc. of methylene chloride was added 25 g. of aluminum chloride in portions. A vigorous exothermic reaction occurred keeping the solvent refluxing. After the initial reaction had subsided, the mixture was refluxed for an additional 30 minutes. The light brown solution was filtered to remove a small amount of solid and the filtrate was refrigerated overnight. The resulting deposit of fine, colorless crystals was filtered off, washed on the filter with a small amount of cold methylene chloride and dried in a vacuum desiccator; 93.9% yield.

Anal. Calcd. for CH_3AlCl_5OP: Al, 10.1; Cl, 66.6; P, 11.6. Found: Al, 10.3; Cl, 66.6; P, 12.8.

Reaction of $[CH_3PCl_3][AlCl_4]$ with Two Moles of Methanol.—To a suspension of 107 g. (0.33 mole) of VII in 250 cc. of methylene chloride was added dropwise in the course of 3 hr. a mixture of 21.0 g. (0.66 mole) of absolute methanol and 50 cc. of methylene chloride. After standing overnight, the solvent was removed from the clear, pale yellow solution under reduced pressure leaving 89.5 g. of a pale yellow, crystalline residue. The solid material was kept in a vacuum desiccator for 65 hr.; the loss of weight during this time was 9.5 g. The remaining 80 g. (91.9%) of product was recrystallized from methylene chloride to yield the complex $[CH_3P(O)OCH_3][AlCl_4]$ as colorless crystals.

Anal. Calcd. for $C_2H_6AlCl_4O_2P$: C, 9.2; H, 2.3; Al, 10.3; Cl, 54.2; P, 11.8. Found: C, 9.0; H, 2.4; Al, 10.4; Cl, 52.3; P, 11.9.

Preparation of Samples for NMR Spectra.—Solid V (0.3 mole) was dissolved with stirring at room temperature in 150 cc. of methylene chloride and a 2-cc. aliquot removed for determination of the NMR spectrum. The bulk of the solution was then treated with 13.8 g. (0.3 mole) of absolute ethanol in the usual fashion and refluxed for a period of 6 hr. The mixture, containing complex X, was cooled and another 2-cc. sample of the solution removed for NMR analysis. The alcoholysis was continued in two steps by adding each time a 0.3-mole portion of absolute ethanol and withdrawing at each step a sample for spectral analysis.

The solution used for the determination of the NMR spectrum of the complex $[C_2H_5P(O)(OC_2H_5)_2 \cdot AlCl_3]$ was prepared in the following manner. To a solution of diethyl ethylphosphonate (37 g., 0.22 mole) in 100 cc. of methylene chloride was added, after cooling to −78°, 30 g. (0.22 mole) of anhydrous aluminum chloride in two portions. An exothermic reaction took place upon each addition, but the temperature of the reaction mixture was maintained below 0° by cooling. The mixture was stirred below 0° until the aluminum chloride was dissolved and the stirring continued for an additional 2 hr. at room temperature. The trace amounts of insoluble material were allowed to settle by standing undisturbed overnight and an aliquot of the clear supernatant solution of the desired complex was removed for NMR analysis.

The spectra of III, VI, IX and the liquid complex XVI were determined without solvent.

Table I contains the chemical shifts exhibited by the various ethyl complexes and their phosphorus-containing components.

Monoesters and Ester-amidates of Aromatic Phosphonic Acids

BY ALFRED BURGER AND JAMES J. ANDERSON[1]

RECEIVED JANUARY 30, 1957

Reaction of phosphonic acids with dicyclohexylcarbodiimide yields pyrophosphonic acids, $[RPO(OH)]_2O$, which with alcohols or phenol furnish the respective alkyl or phenyl hydrogen phosphonate esters. These in turn with dicyclohexylcarbodiimide give dialkyl pyrophosphonates, $[RPO(OR)]_2O$, which react with amines to render alkyl N-substituted phosphonamidates. The monoesters and ester-amidates of *p*-aminophenylphosphonic acid exhibited only negligible bacteriostatic activity. The biological observations are discussed in the light of ionization theories of analogous bacteriostatically active sulfanilamide derivatives.

In the course of their studies about the dependence of bacteriostatic activity of sulfanilamide derivatives on the relative negative character of the SO_2 group in these compounds, Bell and Roblin[2] expressed the view that the principles outlined by them should apply to any substance of the type p-$H_2NC_6H_4XO_2R$, provided its activity is inhibited by *p*-aminobenzoic acid. If the properties of the aromatic amino group are constant, activity in such compounds should be expressed by the negativity

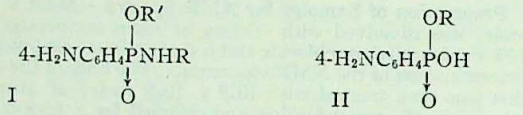
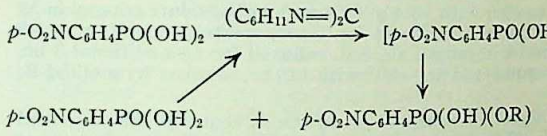
of the XO_2 group. Among compounds predicted to conform with this hypothesis were substances where X is phosphorus.

Since phosphanilic[3,4] and *p*-aminobenzenephosphonous acid[5] as well as phosphanilamide[4] show bacteriostatic activity and the effect of the first two compounds is antagonized by *p*-aminobenzoic acid,[3,5,6] Bell and Roblin's prediction seems to be borne out for these compounds. Moreover, several diamides of phosphanilic acid [$H_2NC_6H_4PO(NHR)_2$] are more highly bacteriostatic than the parent acid,[7] and here the inductive effect of the PO should be equally divided between both NHR groups. It appeared promising to synthesize alkyl N^1-substituted P-(4-aminophenyl)-phosphonamidates (I)[8] because the ionization of the hydrogen of the NHR group could be altered by a change in the electronegativity of one or both R radicals, and this would permit the design of variants with a



range of pK_a values and activities as predicted by Bell and Roblin. In the related, more strongly acidic alkyl hydrogen 4-aminophenylphosphonates (II), acid strength might be manipulated to some extent by varying the structure of the ester group.

Only few monoesters of phosphonic acids have been reported. The methods for their preparation[9–15] include such procedures as the partial alcoholysis of phosphonochloridates or the partial alkaline hydrolysis of dialkyl phosphonate esters and are not generally applicable.[12] The reaction of pyrophosphonic acids [$RPO(OH)]_2O$ with alcohols or phenols should lead to monoesters, but little is known about such anhydrides.[13] It has now been found that the method of Khorana and Todd[16] for the preparation of esters of diphosphoric acids can be extended to the synthesis of alkyl- and arylpyrophosphonic acids. Dehydration of phosphonic acids with one-half molar equivalent of dicyclohexylcarbodiimide in tetrahydrofuran solution quickly furnishes a precipitate of insoluble dicyclohexylurea, and the filtrate contains the desired anhydride. Several phosphonic acids were treated with dicyclohexylcarbodiimide; *n*-hexylphosphonic acid yielded a crystalline pyrophosphonic acid, $[C_6H_{13}PO(OH)]_2O$, while other anhydrides were obtained as viscous oils which we were unable to crystallize. Nevertheless, the tetrahydrofuran solution of the pyrophosphonic acids reacted smoothly with primary or secondary alcohols, or with phenol, to furnish the corresponding monoesters, $RPO(OH)OR'$. Inevitably, one-half of the phosphonic acid used was recovered from this step, and its separation from the acidic monoester proved difficult. In the case of 4-nitrophenylphosphonic acid, which is obtained by a relatively laborious process,[17] the unavoidable recovery of valuable starting material posed the need of recycling in order to increase the yield of monoesters. These obstacles were overcome by dissolving the phosphonic acid and the alcohol or phenol in tetrahydrofuran and slowly adding *one molar* equivalent of dicyclohexylcarbodiimide. The phosphonic acid recovered from the alcoholysis of the resulting pyrophosphonic acid was thus reconverted to the anhydride *in situ*, and the latter was recycled to more monoester. Excellent yields of monoesters were realized by this procedure (Table I).



When dicyclohexylcarbodiimide was added slowly to a solution of an alkyl hydrogen *p*-nitrophenylphosphonate and an amine, the latter was converted to the corresponding N,N′-dicyclohexyl-N″-alkylguanidine derivative [$C_6H_{11}NHC(NH)=NC_6H_{11}$]. Although the addition of amines to carbodiimides had been known,[18,19] the failure of phosphonate monoesters to form anhydrides which in turn could react with amines was surprising, since in an analogous case the addition of dicyclohexylcarbodiimide to a cold solution of two amino acids yielded peptides.[20] The synthesis of alkyl P-(*p*-nitrophenyl)-N-substituted phosphonamidates did succeed when the alkyl hydrogen *p*-nitrophenylphosphonates were converted to the corresponding dialkyl pyrophosphonates, $[p\text{-}O_2NC_6H_4PO(OR)]_2O$, dicyclohexylurea was filtered, and the filtrate containing the anhydride was heated with an amine. The resulting ester-amidates (Table II) could be separated readily from the salts of the monoesters by extraction into ether.

The alkyl or aryl N-substituted P-(*p*-nitrophenyl)-phosphonamidates as well as the alkyl hydrogen *p*-nitrophenylphosphonates were hydrogenated over Raney nickel catalyst to the corresponding *p*-amino derivatives in good yields.

Experimental[21]

Materials.—4-Nitrophenylphosphonic acid was prepared according to Doak and Freedman.[17] Dicyclohexylcarbodi-

imide was obtained by the directions of Schmidt, *et al.*,[22] except that commercial 5.25% sodium hypochlorite solution was used. The compound distilled at 117–120° (0.5 mm.) and melted at 34–35°.

2-Aminopyridine, 2-aminothiazole and 2-aminopyrimidine were supplied generously by Dr. Gilmer T. Fitchett, American Cyanamid Co. 3,4-Dimethyl-5-aminoisoxazole was donated by Hoffmann–LaRoche Co.

General Directions. (a) **Monoesters of Phosphonic Acids.**—A solution of 0.01 mole of the phosphonic acid and 0.01 mole of phenol, or the respective alcohol, in 25 ml. of dry tetrahydrofuran was heated to boiling, and a solution of 0.011 mole of dicyclohexylcarbodiimide in 10 ml. of the same solvent was added over a period of 2.5–3 hr. N,N′-Dicyclohexylurea separated out and was filtered after the mixture had been heated for another 8–10 hr. and allowed to stand at 37° for several hours. The solvent was evaporated under reduced pressure, the resulting pale-brown viscous oil was dissolved in 25 ml. of warm 1 *N* ammonium hydroxide, the solution was filtered and acidified with 6 *N* hydrochloric acid. The viscous oily esters crystallized on scratching to colorless solids which were recrystallized from mixtures of butanone and isopropyl ether, except phenyl hydrogen phenylphosphonate which crystallized from dilute ethanol.

t-Butyl alcohol did not react by this procedure. Data on the monoesters are collected in Table I.

(b) **Ester-amidates of 4-Nitrophenylphosphonic Acid.**—A solution of 22 mmoles of dicyclohexylcarbodiimide in 10 ml. of dry tetrahydrofuran was added slowly with stirring to a solution of 20 mmoles of the respective monoester of 4-nitrophenylphosphonic acid in 40 ml. of dry tetrahydrofuran at 25°. N,N′-Dicyclohexylurea precipitated out immediately. After the mixture was allowed to stand for 30 minutes, the N,N′-dicyclohexylurea was filtered, the filtrate heated to boiling and 22 mmoles of the respective amine was added. Refluxing was continued for 10 hr., and the solvent then evaporated under reduced pressure. The residual light brown tar was extracted with 75 ml. of boiling ether. The undissolved crystalline amine salt of the starting ester was filtered and the ether removed. When the remaining oil was taken up in the minimum amount of ethanol and the solution was diluted with a little water, a viscous oil precipitated which crystallized on scratching. The crude ester-amidates crystallized from isopropyl ether, or from mixtures of isopropyl ether and ethanol or butanone. Data on ester-amidates are listed in Table II. 3,4-Dimethyl-5-aminoisoxazole did not react by this procedure.

(c) **Monoesters and Ester-amidates of 4-Aminophenylphosphonic Acid.**—The derivatives of *p*-nitrophenylphosphonic acid (0.01 mole) were dissolved in 100 ml. of absolute methanol and hydrogenated with the aid of Raney nickel catalyst at 3 atm. and 25° in 2–3 hr. The catalyst was filtered, the solvent evaporated under reduced pressure, the crystalline or viscous residue was taken up in butanone and treated with isopropyl ether. In some cases a sparingly soluble amino compound precipitated during the hydrogenation; it had to be dissolved by addition of a few drops of ammonium hydroxide before the catalyst could be filtered, and the amine was reprecipitated by adjustment of the filtrate to *p*H 5–6. The colorless amino compounds obtained by this procedure are recorded in Table III.

P,P′-(Di-*n*-hexyl) Dihydrogen Pyrophosphonic Acid.—A solution of 1.13 g. (0.055 mole) of dicyclohexylcarbodiimide in 5 ml. of dry ether was added slowly with stirring to a solution of 1.66 g. (0.01 mole) of *n*-hexylphosphonic acid in 50 ml. of dry ether. N,N′-Dicyclohexylurea precipitated immediately and quantitatively. It was filtered and the filtrate concentrated to 5 ml. On cooling, 1 g. (65%) of colorless crystals precipitated which after recrystallization from ligroin melted at 64–66°.

Anal. Calcd. for $C_{12}H_{28}O_5P_2$: C, 45.85; H, 8.98. Found: C, 45.57; H, 9.11.

Determination of pK_a Values.—The apparent pK_a values for the compounds listed in Table IV were determined by measuring the *p*H of a solution containing equimolar concentrations of the acidic material and its salt, prepared by adding 0.2–0.7 mmole of the compound to 50–100 ml. of water followed by addition of the exact amount of standard base to neutralize one-half of the acidic substance.

[a] Recrystallized from methanol. [b] Purified by reprecipitation from dilute hydrochloric acid. [c] Recrystallized from butanone. [d] Recrystallized from butanone–isopropyl ether, dried at 110° (1 mm.). The presence of 0.5 mole of isopropyl ether of crystallization is based on the analytical values only, since infrared absorption shows all major peaks for ether oxygen where NH_2 may be expected to absorb. The compound contained nitrogen, phosphorus, sulfur and fluorine (small amounts in qualitative test) and exhibited a strong absorption band at 3 μ in the infrared.

A Beckman model G *p*H meter equipped with a glass electrode in conjunction with a saturated calomel electrode was used. From control experiments with known acids, the accuracy was judged to be ±0.1 for pK_a values of 4 to 10, while for higher values a drift of 0.1–0.3 was observed. For values below 3.8, see Table IV.

[a] For pK_a values below 3.8 the accuracy is 0.2. Calculated by equation (252), S. Glasstone, "Textbook of Physical Chemistry," 2nd Ed., Van Nostrand Co., Inc., New York, N. Y., 1946. The other values were calculated by the Henderson equation.

Infrared Absorption Spectra.—Major assigned characteristic absorptions of *p*-nitro- and *p*-aminophenylphosphonic acid monoesters and ester-amidates were observed as follows: CF_3 at 9.2 μ[23]; NH_2 at 2.9 and 2.98 μ[23]; *p*-disubstituted phenyl at 12.1 μ[23]; NO_2 at 7.4 μ[23]; thiazole at 6.12 and 6.6 μ[24]; P–O–C aliphatic at 9.7–9.9 μ[25]; P=O at 7.8 μ.[25] In addition, all these compounds absorbed in the region of 10.2–10.4 μ which may be considered characteristic for many phosphorus compounds including phosphonates.[25]

The infrared data indicate that the ester-amidate derivatives of phosphanilic acid contain a free amino group and most probably do not exist as zwitterions. Thus the pK_a values should express the dissociation of the phosphonamidate group. In the case of monoalkyl hydrogen phosphanilates, no bond appears in the region of 3 μ. This implies that the amino group is associated and the pK_a values of these compounds represent probably the dissociation of the inner salt, p-$H_3N^+C_6H_4P(O)(OR)O^-$.

Discussion of Bacteriostatic Activity

The *in vitro* bacteriostatic activities of ethyl N¹-(2-pyridyl)-P-(*p*-aminophenyl)-phosphonamidate, the corresponding N¹-(2-pyrimidyl) and N¹-(2-thiazolyl) derivatives and the lower methyl N¹-(2-thiazolyl) homolog, as well as those of methyl and ethyl N¹-(2-pyridyl)- and N¹-(2-thiazolyl)-P-(*p*-nitrophenyl)-phosphonamidates were measured by the agar diffusion method in the Microbiology Section of Smith, Kline and French Laboratories. Also included in this series were methyl and ethyl hydrogen *p*-nitrophenylphosphonate and methyl hydrogen *p*-aminophenylphosphonate. The organisms employed were *Pseudomonas sp.*, *Escherichia coli*, *Micrococcus pyogenes* var. *aureus*, *Mycobacterium smegmadis*, and *Diplococcus pneumoniae* Type I. Only *D. pneumoniae* was inhibited slightly by all but two of the compounds tested in a 2 × 10^{-4} % solution, and *M. aureus* responded equally slightly to the four *p*-nitrophenylphosphonamidates. The relatively most active derivative, ethyl N¹-(2-pyridyl)-P-(*p*-aminophenyl)-phosphonamidate, did not protect mice against pneumococcus infection at 100 and 800 mg./Kg.

These disappointing findings are not easily fitted into the framework of the Bell and Roblin theory. The lack of correlation between bacteriostatic values and acid dissociation data points to

the influence of other factors which are not so pronounced in the sulfonamide series. Apparently the SO_2 and PO groups cannot compete equally for the negative charge left by the dissociation of the proton of the amide. In the bacteriostatically ineffective alkyl hydrogen *p*-aminophenylphosphonates the PO_2^- carries a formal negative charge as does the CO_2^- in the *p*-aminobenzoate ion, and the pK_a (3.8 to 4.0) of these esters approaches that of PABA (4.68). The effects of solubility, steric influences, etc., may outweigh those of acid dissociation; alkyl N^1-heterocyclically substituted P-(*p*-aminophenyl)-phosphonamidates are uniformly more soluble in base than the corresponding sulfonamide drugs. The valence requirements of the phosphonamidates place an alkyl group on one of the oxygens whereas this is absent in the sulfonamides. While it is conceivable that the extra group could interfere with the fit at an essential receptor site, the bacteriostatic activity of *p*-aminophenylphosphonamidates containing two relatively bulky substituents in the amidate group[7] cannot readily be reconciled with this view.

Synthesis of Peptides of Arginine Related to Arginine-vasopressin[1]

BY DUANE T. GISH[2] AND VINCENT DU VIGNEAUD

RECEIVED MARCH 7, 1957

The preparation of L-prolyl-L-arginylglycinamide dihydrobromide and S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide dihydrobromide, peptides containing sequences that are found in arginine-vasopressin, is described.

As a result of degradation studies on purified preparations of arginine-vasopressin, the principal pressor and antidiuretic hormone of the beef posterior pituitary gland, the sequence of amino acids in arginine-vasopressin was obtained[3] and a structure was postulated.[4,5] For the purpose of investigating synthetic routes to arginine-vasopressin, the peptides L-prolyl-L-arginylglycinamide dihydrobromide (I) and S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide dihydrobromide (II) were desired. The preparation of these peptides and their intermediates are described in this paper.

N^{α}-*p*-Nitrobenzyloxycarbonyl-L-arginylglycinamide hydrochloride (III) was prepared by the method of Gish and Carpenter[6] and the peptide derivative was isolated as the crystalline picrate IV. The picrate IV was cleaved with acetic acid saturated with hydrogen bromide to give L-arginylglycinamide dihydrobromide (V) as an amorphous solid. The dipeptide amide V was characterized as its crystalline dipicrate VI. The dihydrobromide V was converted to the monohydrobromide and the monohydrobromide was condensed with carbobenzoxy-L-proline by the tetraethyl pyrophosphite method[7] to give carbobenzoxy-L-prolyl-L-arginylglycinamide hydrobromide (VII). The tripeptide amide derivative VII was purified by countercurrent distribution and then treated with acetic acid saturated with hydrogen bromide to give L-prolyl-L-arginylglycinamide dihydrobromide (I). The amorphous product was converted to the crystalline diflavianate for characterization.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteine was converted to its acid chloride and then condensed with proline benzyl ester to give S-benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline benzyl ester (VIII) and with proline methyl ester to give the corresponding methyl ester IX. The esters VIII and IX were obtained as oils, but could be converted to the crystalline hydrazide in high yield. Saponification of these esters yielded S-benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline (X). Yields of 50–85% were obtained on various runs of the saponification of the benzyl ester of the *p*-nitrobenzyloxycarbonyl derivative of this dipeptide, whereas a yield of 52% was obtained in the saponification of the methyl ester. Saponification of S-benzyl-N-carbobenzoxy-L-cysteinyl-L-proline methyl ester (XI), prepared in a manner similar to that used for the preparation of IX, gave consistent yields of about 85%. No difficulties had been encountered previously during the saponification of *p*-nitrobenzyloxycarbonyl derivatives of peptides.[6,8] The dipeptide derivative X was condensed with L-arginylglycinamide monohydrobromide by the tetraethyl pyrophosphite method to give the S-benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-prolyl-L-arginylglycinamide hydrobromide (XII). The crude product was purified by countercurrent distribution and the tetrapeptide amide derivative was characterized as its crystalline picrate XIII. Treatment of the purified tetrapeptide amide derivative XII with acetic acid saturated with hydrogen bromide gave S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide dihydrobromide (II) as an amorphous solid. Countercurrent distribution of this material in the system 2-butanol–0.1% acetic acid revealed a single peak and the tetrapeptide amide dihydrobromide

was generally used for further work directly following the cleavage in acetic acid–hydrogen bromide without further purification except for precipitation from methanol with ether in order to remove acetic acid and excess hydrogen bromide.

Experimental[9,10]

Nα-*p*-Nitrobenzyloxycarbonyl-L-arginylglycinamide Picrate.—Nα-*p*-Nitrobenzyloxycarbonyl-L-arginyl chloride hydrochloride was prepared as previously described[6] from 3.53 g. (0.01 mole) of Nα-*p*-nitrobenzyloxycarbonyl-L-arginine. To the acid chloride was added a cold solution of 1.11 g. (0.01 mole) of glycinamide hydrochloride[11] and 3.0 ml. (0.0215 mole) of triethylamine in 15 ml. of dimethylformamide. The mixture was stirred for one hour in the cold. The precipitate of triethylamine hydrochloride was filtered off, washed with a few ml. of cold dimethylformamide and the washings were added to the filtrate. The product was precipitated with chloroform and the sticky solid was collected on a Buchner funnel and washed with chloroform. The material was dissolved in 25 ml. of warm water and 2.6 g. (1.1 moles) of picric acid dissolved in 25 ml. of warm ethanol was added. The crystalline picrate separated as the solution cooled to room temperature. The mixture was not cooled below room temperature since further cooling caused the separation of an oily product. The picrate was collected, washed with 50% ethanol and dried over P_2O_5 *in vacuo*. The yield was usually 60–65%, m.p. 148–158°. For further work the material was twice recrystallized from 50% ethanol to give an over-all yield of 50%, m.p. 165–168°. For analysis a sample was further recrystallized from 50% ethanol, m.p. 165–168°, and dried over P_2O_5 *in vacuo* at 75°; $[\alpha]^{22}D$ −3.8° (*c* 1, acetone–water (4:1)).

Anal. Calcd. for $C_{16}H_{23}O_6N_7 \cdot C_6H_3O_7N_3$: C, 41.38; H, 4.10; N, 21.94. Found: C, 41.40; H, 4.17; N, 21.82.

Sometimes during crystallization of this material a crystalline product of m.p. 110–120° was obtained. This was presumably a hydrate and could be converted to the material of m.p. 165–168° by seeding a warm solution with crystals of m.p. 165–168°.

L-Arginylglycinamide Dihydrobromide.—Nα-*p*-Nitrobenzyloxycarbonyl-L-arginylglycinamide picrate (10 g.) was suspended in 75 ml. of acetic acid which had been saturated with hydrogen bromide in the cold. The mixture was warmed to 50–55° for 1.25 hours. Ether was then added to the cooled mixture to precipitate the dihydrobromide as a white amorphous solid. The material was collected and washed with ether. To free the product from excess hydrogen bromide and acetic acid it was precipitated several times from methanol with ether. The yield was quantitative. The product was easily soluble in water, alcohol and dimethylformamide and insoluble in the usual organic solvents. The material was hygroscopic. Titration of a sample with standard alkali, using the Model G Beckman *p*H meter, gave the expected titration curve, showing the absence of any free carboxyl group and the presence of an α-amino group with a pK' of 7.3. The electrodes used did not permit titration of the guanido group. For titration of the α-amino group, 0.0620 g. requires 1.58 ml. of 0.0998 *N* NaOH. Found: 1.56 ml.

In order to characterize this hygroscopic compound it was converted to its crystalline dipicrate. The dihydrobromide (0.94 g., 2.4 mmoles) was dissolved in 5 ml. of warm water and 1.32 g. (20% excess) of picric acid dissolved in 10 ml. of hot ethanol was added. The crystalline dipicrate separated from the cooled mixture; yield 1.21 g., m.p. 206–207°. The material was recrystallized from water–ethanol (8:1), m.p. 209–210°; $[\alpha]^{24}D$ +15.9° (*c* 1, acetone–water (1:1)). A sample was dried *in vacuo* over P_2O_5 at 56° for analysis.

Anal. Calcd. for $C_8H_{18}O_2N_6 \cdot 2C_6H_3O_7N_3$: C, 34.89; H, 3.51; N. 24.42. Found: C, 34.95; H, 3.62; N, 24.31.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteine.—This was prepared from 21.13 g. (0.1 mole) of S-benzyl-L-cysteine[12] according to procedure A previously described.[13] The yield was 34.75 g. (89%), m.p. 127–133°. One recrystallization from 1600 ml. of 50% acetic acid gave 31.5 g., m.p. 134–135°. Further recrystallization did not raise the melting point. For analysis a sample was dried *in vacuo* over P_2O_5 at 75°; $[\alpha]^{22}D$ −47.0° (*c* 1, 95% ethanol).

Anal. Calcd. for $C_{18}H_{18}O_6N_2S$: C, 55.37; H, 4.65; N, 7.18; S, 8.21. Found: C, 55.42; H, 4.88; N, 7.19; S, 8.08.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline Benzyl Ester.—S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteine (7.8 g., 0.02 mole) was suspended in 100 ml. of dry absolute ether and the mixture was cooled in an ice-salt bath. To the mixture was added 4.6 g. (10% excess) of phosphorus pentachloride and the mixture was stirred for 1.25 hours. The solution was filtered free of excess phosphorus pentachloride and the ether was evaporated at reduced pressure, with a bath temperature less than 20°. The acid chloride crystallized from the concentrated solution. The product was washed with cold hexane by decantation and then collected on a Buchner funnel and washed on the funnel with cold hexane. The acid chloride was added to 100 ml. of cold ether (almost all dissolved) and a cold solution of proline benzyl ester, prepared from 5.8 g. (0.024 mole) of proline benzyl ester hydrochloride,[14] and 2.8 ml. of triethylamine in ether was added. (The free ester was prepared by dissolving the hydrochloride in 30 ml. of chloroform, adding 3.4 ml. of triethylamine and evaporating the solution to a small volume. Dry ether (75 ml.) was added, triethylamine hydrochloride was filtered off, washed with ether and the washings were added to the filtrate. The ethereal solution of the free ester was kept cold until used and triethylamine equivalent to the acid chloride was added just before use.) The reaction mixture was stirred in the cold for about 15 minutes and then at room temperature for 1.5 hours. The triethylamine hydrochloride was removed by filtration and washed with ethyl acetate, the washings being added to the filtrate. The solution was washed successively with *N* hydrochloric acid, water, *N* sodium bicarbonate and saturated sodium chloride and dried over magnesium sulfate. The solvent was removed *in vacuo* and the oil was washed with hexane and then dried *in vacuo* over concentrated sulfuric acid and paraffin. The yield varied from 89–98%. This compound could not be crystallized.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline.—The ester was saponified by stirring a dioxane solution with a 5% excess of *N* sodium hydroxide for 2–3 hours. The mixture was acidified and the product was extracted into ethyl acetate–ether (1:1). The organic solution was washed with *N* hydrochloric acid and water and the product was then extracted into *N* sodium bicarbonate. The bicarbonate solution was washed with ethyl acetate–ether and acidified and extracted with ethyl acetate. The organic solution was washed with *N* hydrochloric acid, water and saturated sodium chloride and dried over magnesium sulfate. The solvent was removed *in vacuo* and the oil was dried over concentrated sulfuric acid *in vacuo*. The yield generally varied from 50–85% and gave a product with a neutral equivalent within a few per cent. of the calculated value.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline Methyl Ester.—This compound was prepared in the same manner as that described for the benzyl ester. The yield varied from 73 to 80%.

Saponification of the methyl ester, carried out as described for the benzyl ester, gave, in a yield of 52%, a product with a neutral equivalent within 3% of the calculated value.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline Hydrazide.—The conversion of both the methyl and benzyl ester to the hydrazide was slow and required more drastic conditions than usually employed. The methyl ester (5.54 g.) was refluxed for one hour with 15 ml. of ethanol and 1.5 ml. of hydrazine hydrate (99–100%). The solution was then stored at about 37° for three weeks. The solution was filtered and crystallization was then induced. The hydrazide was filtered from the cooled mixture and

(9) Corrected capillary melting points are reported.

(10) The analyses were performed by Mr. Joseph Albert of this Laboratory.

(11) Prepared essentially as described by Yang and Rising (THIS JOURNAL, **53**, 3183 (1931)) using glycine ethyl ester hydrochloride as the starting material; yield 40%, m.p. 195–200° with decomposition.

washed with cold ethanol. The yield was 5.06 g. (91%), m.p. 149–151°. Recrystallization was from ethanol, m.p. 150–151°; $[\alpha]^{24}D$ −51.6° (*c* 1, dimethylformamide). A sample was dried *in vacuo* over P_2O_5 at 75° for analysis.

Anal. Calcd. for $C_{23}H_{27}O_6N_5S$: C, 55.08; H, 5.43; N, 13.96; S, 6.39. Found: C, 55.16; H, 5.57; N, 13.64; S, 6.30.

S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-proline Methyl Ester.—This preparation was carried out in the same manner as that used for the preparation of the *p*-nitrobenzyloxycarbonyl derivative. The yield was 69%.

S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-proline.—The saponification was carried out as described above for the *p*-nitrobenzyloxycarbonyl derivative except that 1.5 hours was required for complete saponification. The yield was 85%. Neutral equivalent: Calcd. for $C_{23}H_{26}O_5N_2S$: 442.5. Found: 450.

S-Benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-prolyl-L-arginylglycinamide Hydrobromide.—L-Arginylglycinamide dihydrobromide (1.18 g., 0.003 mole) was dissolved in 5 ml. of dimethylformamide, 0.47 ml. of triethylamine was added, the mixture was stirred for a few minutes and the monohydrobromide was then precipitated by addition of chloroform. The gummy material was washed with chloroform, then ether, and was dried over P_2O_5 *in vacuo*. The material was dissolved in 5 ml. of diethyl phosphite, 1.46 g. (0.003 mole) of S-benzyl-N-*p*-nitrobenzyloxycarbonyl-L-cysteinyl-L-proline and 1.55 g. (100% excess) of tetraethyl pyrophosphite were added and the mixture was heated at 100° with stirring for 30 minutes. The mixture was cooled and the product, along with unreacted L-arginylglycinamide, was precipitated by the addition of ethyl acetate. The amorphous solid was collected on a Buchner funnel, washed with ethyl acetate and ether and dried *in vacuo* over P_2O_5 and sodium hydroxide pellets. The crude material weighed 1.78 g. The material was purified by countercurrent distribution in the system 2-butanol–0.1% acetic acid. One hundred and twenty transfers were sufficient to obtain complete separation of the tetrapeptide (K = 1.1) from unreacted dipeptide (K = 0.2). The distribution curves were obtained by use of the Sakaguchi reaction.[15] The solvent from the tubes containing the tetrapeptide was concentrated on the flash evaporator[16] and lyophilized to yield a white amorphous solid, weight 1.38 g. (59%). The material was easily soluble in water, alcohol and dimethylformamide and insoluble in the usual organic solvents. For the purpose of characterization the amorphous tetrapeptide was converted to its crystalline picrate. The purified tetrapeptide (175 mg.) was dissolved in 5 ml. of warm water and 55 mg. of picric acid in 5 ml. of warm ethanol was added. The picrate crystallized from the cooled solution; yield 184 mg. (88%), m.p. 155–160°. Recrystallization from 50% ethanol gave 153 mg., m.p. 181.5–184.5°; $[\alpha]^{22}D$ −47.7° (*c* 1, acetone–water (4:1)). A sample was dried over P_2O_5 *in vacuo* at 75° for analysis.

Anal. Calcd. for $C_{31}H_{41}O_8N_9S \cdot C_6H_3O_7N_3$: C, 47.84; H, 4.77; N, 18.10. Found: C, 47.78; H, 4.95; N, 17.73.

S-Benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide Dihydrobromide.—The cleavage of the *p*-nitrobenzyloxycarbonyl derivative was carried out in the same manner as for N^{α}-*p*-nitrobenzyloxycarbonyl-L-arginylglycinamide picrate except that warming was at 50° for 45 minutes. The product was freed from excess hydrogen bromide and acetic acid as before. The yield was nearly quantitative. The white amorphous solid was hygroscopic and was easily soluble in water, alcohol and dimethylformamide and insoluble in the usual organic solvents. The tetrapeptide amide dihydrobromide was titrated using the Model G Beckman *p*H meter. No free carboxyl group was detectable. The pK' of the α-amino group was 6.7. For titration of the α-amino group, 0.035 g. requires 0.52 ml. of 0.100 *N* NaOH; found, 0.52 ml. When subjected to countercurrent distribution up to 200 transfers in the system 2-butanol–0.1% acetic acid this material gave a single peak. The distribution constant was about 0.2 but varied with concentration. As a result the distribution curve (the Sakaguchi reaction was used as before) was sharp on the leading edge but skewed to the rear, as expected.[17]

Carbobenzoxy-L-prolyl-L-arginylglycinamide Hydrobromide.—Carbobenzoxy-L-proline[18] (0.5 g., 0.002 mole, m.p. 74.5–76.5°), L-arginylglycinamide monohydrobromide, prepared from 0.78 g. (0.002 mole) of the dihydrobromide as described above, 3 ml. of diethyl phosphite and 1.0 g. (100% excess) of tetraethyl pyrophosphite were heated at 100° for 30 minutes with stirring. Ether was added to the cooled mixture to precipitate the product along with unreacted arginylglycinamide. The amorphous solid was collected, washed with ether and dried over P_2O_5 and sodium hydroxide pellets. The crude material was purified by countercurrent distribution in the system 2-butanol–0.1% acetic acid. One hundred and fifty transfers were sufficient for complete separation. The distribution constant of the tripeptide was 0.6. The Sakaguchi reaction was used for preparation of the distribution curve. From concentration and lyophilization of the solvent containing the tripeptide was obtained 0.80 g. (74%) of a white amorphous solid. Yields from other preparations varied from 65–75%.

L-Prolyl-L-arginylglycinamide Dihydrobromide.—The carbobenzoxy group was removed by warming the carbobenzoxy derivative in acetic acid saturated with hydrogen bromide for one hour at 40–45°. The white amorphous product was freed from excess hydrogen bromide and acetic acid in the manner described for L-arginylglycinamide dihydrobromide. The yield of the hygroscopic dihydrobromide varied from 80–84%. It was easily soluble in water, alcohol and dimethylformamide and insoluble in the usual organic solvents. The pK' of the imino group was 8.5. To characterize this compound it was converted to its crystalline diflavianate. The dihydrobromide (0.36 g., 0.74 mmole) was dissolved in 2 ml. of warm water and 0.51 g. of flavianic acid in 1.5 ml. of warm water was added along with 0.5 ml. of ethanol. The diflavianate crystallized from the cooled mixture; yield 0.58 g. (80%), m.p. 173° (opaque melt). After recrystallization from water–ethanol (3:1) the diflavianate hydrate was allowed to dry in air for analysis, m.p. 180° (forms opaque melt), $[\alpha]^{24}D$ −18.2° (*c* 1, acetone–water (1:1)).

Anal. Calcd. for $C_{13}H_{25}O_3N_7 \cdot 2C_{10}H_6O_8N_2S \cdot 1^1/_2H_2O$: C, 40.32; H, 4.10; N, 15.68; H_2O, 2.75. Found: C, 40.63; H, 4.16; N, 15.38; H_2O, 2.43.

Acetylium Perchlorate-catalyzed Preparation of Ketones. The Use of Sodium Perchlorate–Acetyl Chloride Mixture in the Ring Acetylation of Phenol Ethers

BY K. B. L. MATHUR, J. N. SHARMA, K. VENKATARAMANAN AND H. G. KRISHNAMURTY

RECEIVED NOVEMBER 23, 1956

Sodium perchlorate and acetyl chloride taken in glacial acetic acid together work as satisfactorily as acetylium perchlorate or perchloric acid for ring acetylations. In the presence of acetic anhydride and using the above mixture certain monohydric, dihydric and trihydric phenol ethers have been found to undergo catalytic ring acetylations. A 30–50% conversion of the ethers into the acetophenones can generally be brought about at 40–60° in 4–6 hr., depending on the reactivity of the ethers. The acetyl group enters a position *para* to the ether grouping and, when this is not free, *ortho* substitution also can occur. Except for anisole, the perchlorate-catalyzed acetylations with various phenol ethers have been studied for the first time.

Several workers have studied the ring acetylations of aromatic hydrocarbons and phenol ethers in the presence of catalysts, *e.g.*, trifluoroacetic acid[1a] or its anhydride[1b], chloroacetic acid at high temperatures,[1c] phosphorus pentoxide,[1d] polyphosphoric acid,[1e] sulfuric acid[1f,10b] and sundry other inorganic substances[1g,3a] all of which are different from the usual catalysts of the Friedel and Crafts type.[2a–c,8a] In this connection the use by Burton and Prail[3a] of perchloric acid or of acetylium perchlorate seems to be of greater practical importance.[3b] Thus, acetylium perchlorate, acetic acid, anisole and acetic anhydride when used in the molecular proportion 1:2:4:3 or 1:8:4:3 easily give 1.46 and 1.02 moles of *p*-methoxyacetophenone,[3c] respectively. It is, however, found that solvation with larger proportions of acetic acid or using larger proportions of acetic anhydride seriously lowers the yield of the ketone. The above workers minimized the side reactions, *e.g.*, formation of a certain amount of phenol, diketones, colored pyrrilium salts and tar by keeping the temperature low (0–5°) and limiting the reaction time to 45 minutes. Remarkably *p*-methoxyacetophenone is said to be obtainable in identical yields[4] whether acetylium perchlorate or perchloric acid be used as the catalyst. No systematic study, however, has so far been made of the perchlorate-catalyzed acetylations of phenol ethers other than anisole. Even in the latter case Burton and Prail's own work[3a] was directed more to the elucidation of reaction mechanism. In the present investigation the acetylations of the above type of some monohydric, dihydric and trihydric phenol ethers have been undertaken from a preparatory point of view and by a modified technique.

The modification relates to the use of an equivalent amount of anhydrous sodium perchlorate and acetyl chloride in glacial acetic acid solution, and this solution has been found to work as satisfactorily as acetylium perchlorate or perchloric acid. The amount of acetic acid used as the solvent is limited to what will not cause much of its harmful effect on the yield of the ketones. In the first instance four acetylation mixtures containing sodium perchlorate, acetyl chloride, acetic acid, the phenol ether and acetic anhydride in the mol. proportion 1:1:8:*x*:3 (x = 1, 2, 3 or 4) have been examined with anisole. It is seen (*vide* Table III) that a greater conversion of the ether to the ketone takes place when only one or two (x = 1, 2) mol. proportions of it are used. But in these cases losses—mechanical, as well as those due to side reactions[3a]—are proportionately greater than when acetylation is done with a mixture of composition 1:1:8:4:3. The latter has, therefore, been chosen for acetylation because in most cases it is easy to remove the unchanged ether by vacuum distillation at low temperatures. However, in those cases where the separation is not so easy and the ethers are reactive, acetylation with a 1:1:8:2:3 or even 1:1:8:1:3 mixture may be done. Using the acetylation mixtures (x = 4 or 2), the ethers listed in Table I have been successfully acetylated to give in each case an acetophenone

$$(CH_3O)_nRH + \frac{(CH_3CO)_2O}{NaClO_4,\ CH_3COCl,\ CH_3COOH} (CH_3O)_nRCOCH_3 + CH_3COOH$$

n = 1, 2 or 3

in which the acetyl group is found to be present in a position *para* to the ether grouping. When the *para* position is not free, the acetyl group enters the *ortho* position but the yields then are poor.

Adams, THIS JOURNAL, **46**, 1889 (1924); (c) N. M. Cullinane, S. J. Chord and D. M. Layshon, *J. Chem. Soc.*, 376 (1952).

(3) (a) H. Burton and P. F. S. Prail, *J. Chem. Soc.*, 2036 (1950), and earlier and later papers; (b) *cf.* also R. E. Foster, U. S. Patent 2,496,786; *C. A.*, **44**, 4930c (1950); (c) it is, however, also reported[3b] that the perchloric acid-catalyzed acetylation of anisole results in the formation of both *o*- and *p*-methoxyacetophenone, the yield of the *o*-isomer being half as much (7.3%) as that of the *p*-isomer (14.7%).

(4) It is suggested[3a] that in these reactions, acetylium ions CH_3CO^+, or their solvated form $(CH_3CO)_2OH^+$, are mainly concerned in bringing about acetylation. The reaction becomes catalytic if acetic anhydride is also present, the whole mechanism in the case, *e.g.*, of acetylium perchlorate and anisole is then represented thus:

$$AgClO_4 + CH_3COCl \longrightarrow CH_3CO^+ClO_4^- + AgCl \quad (i)$$

$$CH_3CO^+ClO_4^- \rightleftharpoons CH_3CO^+ + ClO_4^- \quad (ii)$$

$$CH_3CO^+ + C_6H_5OCH_3 \longrightarrow CH_3CO\cdot C_6H_4\cdot OCH_3 + H^+ \quad (iii)$$

$$H^+ + (CH_3CO)_2O \longrightarrow CH_3CO^+ + CH_3COOH \quad (iv)$$

When perchloric acid is the catalyst, the hydrogen ion available from this strong acid is supposed to initiate the reaction iv after which reactions iii and iv occur in sequence as above.

TABLE I

YIELDS OF THE KETONES UNDER OPTIMUM CONDITIONS

Phenol ether	Moles	No.	Ketone[c] formed	Yield, Mol.[a] prop.	Yield, Per cent.[b]
Anisole	4	1	4-Methoxyacetophenone	2.0	50
o-Cresol methyl ether	4	2	3-Methyl-4-methoxyacetophenone	1.8	45
m-Cresol methyl ether	4	3	2-Methyl-4-methoxyacetophenone	2.2	55
p-Cresol methyl ether	4	4	3-Methyl-6-methoxyacetophenone	0.68	17
Phenetole	4	5	4-Ethoxyacetophenone	1.83	45.8
1-Naphthol methyl ether	4	6	1-Acetyl-4-methoxynaphthalene	1.76	44
2-Naphthol methyl ether	4	7	1-Acetyl-2-methoxynaphthalene	1.48	37
Methylenedioxybenzene	4	8	3,4-Methylenedioxacetophenone	1.2	30
Pyrogallol trimethyl ether	4	9	2,3,4-Trimethoxyacetophenone	0.67	16.8
Phloroglucinol trimethyl ether	2	10	2,4,6-Trimethoxyacetophenone	0.68	34
Phloroglucinol dimethyl ether	4	11	2-Hydroxy-4,6-dimethoxyacetophenone	0.64	16
Catechol dimethyl ether	2	12	3,4-Dimethoxyacetophenone	1.02	50.6
Resorcinol dimethyl ether	2	13	2,4-Dimethoxyacetophenone	1.23	62
Hydroquinone dimethyl ether	2	14	2,5-Dimethoxyacetophenone	0.58	30

[a] Moles of ketone formed per 4 or 2 moles of the ether. [b] Calculated on the ether used. [c] Obtainable in a fair degree of purity even by the first distillation; the ketones 1, 5–8 and 10–13 also have been obtained in the pure solidified forms, in spite of the low m.p. of some of them.

In separating the ketones no earlier[3b,3c] or later ketonic fraction containing the acetyl group in a position different from the above has been obtained. Considering the purity of the ketones and the homogeneity of their derivatives, there does not seem to be any possibility of isomeric ketones present in the recovered ketone fractions either. As regards the yields, it will be noted from Table I that any one of the two acetylation mixtures chosen, a 30–50% conversion of the ether to the ketone generally occurs under optimum conditions, though it may be less in an ether of low reactivity. An idea about the reactivities of the ethers can be obtained from Table II in which results for the extent of acetylation undergone by some of the representative phenol ethers at 40° in 2 hr. are compiled together. *m*-Cresol methyl ether, 1-naphthol methyl ether can thus be considered to be very reactive; phenetole, *o*-cresol methyl ether, anisole fairly reactive and pyrogallol trimethyl ether, *p*-cresol methyl ether, methylenedioxybenzene, 2-naphthol methyl ether less reactive. In the case of the reactive ethers the maximum yield of the ketones (*vide* Tables IV and V) can be obtained by heating at 40–45° for 4 hr. and in those of medium or low reactivity by heating at 60° for 4–6 hr. Higher temperatures (*cf.* expt. on *p*-cresol methyl ether at 70°) or a longer time of reaction (*cf.* expt. on 2-naphthol methyl ether for 8 hr.) either produce more residue or because of side reactions do not improve the yield of the ketone materially.

TABLE II

EXTENT OF KETONE FORMATION AT 40° IN 2 HOURS

Ether	Ketone formed mol. proportion	
m-Cresol methyl ether	1.88	Very reactive
1-Naphthol methyl ether	1.76	
Phenetole	1.05	Reactive
o-Cresol methyl ether	0.83	
Anisole	0.44	
Pyrogallol trimethyl ether	0.67 (4 hr.)	Less reactive
p-Cresol methyl ether	0.40	
Methylenedioxybenzene	0.20 (4 hr.)	
2-Naphthol methyl ether	Traces	
o-Bromoanisole	Nil	

At low temperatures (0–5°) very little acetylation is found to occur in the case of anisole. With ethers more reactive than anisole, yields comparable to those obtained by heating at 40–60° are had by keeping the reaction mixture at room temperature (15–22°) for 24 hr. or more. In fact, acetylation in the cold is the better procedure for the preparation of 3,4-dimethoxy- and 2,4-dimethoxyacetophenones from catechol and resorcinol dimethyl ethers. Remarkably for a 50% conversion to the ketones, resorcinol dimethyl ether requires only 0.75 hr., whereas catechol dimethyl ether takes 24 hr. at room temperature.

Partial methyl ethers of polyhydric phenols can be acetylated too. Phloroglucinol dimethyl ether gives 2-hydroxy-4,6-dimethoxyacetophenone. But resorcinol monomethyl ether gives a mixture of 2-hydroxy-4-methoxyacetophenone and 2-methoxy-4-hydroxyacetophenone. Here acetylation seems to have occurred both *para* and *ortho* to the methoxy group. This is rather unusual as in all other cases only one product has been isolated, *i.e.*, the one in which the acetyl group comes *para* or *ortho* to the ether group.

In connection with the identification of the various ketones, 2,3,4-trimethoxyacetophenone (gallacetophenone trimethyl ether) has also been characterized by its oxidation to 2,3,4-trimethoxybenzoic acid by the iodoform reaction. The semicarbazone and picrate of 1-acetyl-2-methoxynaphthalene have been described for the first time. The m.p. of the picrate of 1-acetyl-4-methoxynaphthalene has been corrected.

As for the mode of working of the acetylation mixture, an initial change, *e.g.*

$$CH_3COCl + NaClO_4 \longrightarrow CH_3CO^+ClO_4^- + NaCl$$

can be visualized to occur first in the acetic acid solution[5a,b] after which through the suggested se-

(5) (a) Potassium perchlorate does not work for acetylations, and its inability to do so has been traced to its insolubility in acetic acid. (b) We have tried a different modification also, *viz.*, using perchloric acid liberated *in situ* by mild heating of equivalent amount of sodium perchlorate and concd. sulfuric acid together. This modification, however, does not seem to be as expedient and efficient as using the sodium perchlorate–acetyl chloride mixture.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

quence of changes involving acetylium ion,[4] the ketone formation would occur. However, it is found that by using lesser proportions of the catalyst mixture, proportionately lesser yields of 4-methoxyacetophenone are obtained. The catalyst mixture therefore acts like acetylium perchlorate or perchloric acid only in the sense that a given amount of the mixture can enable the acetylation of more phenol ether than is stoichiometrically possible on the amount of the perchlorate used.

Compared to the Friedel and Crafts reactions, where possibilities of side reactions and dealkylations in the ketone formed are greater,[2a,b,12b,13a,18b] acetylations of phenol ethers have been found to go smoothly by the use of sodium perchlorate–acetyl chloride mixture as the catalyst. The latter technique is also superior to the use of perchloric acid or acetylium perchlorate—obtainable from the hygroscopic silver perchlorate, in that the sodium salt is convenient to handle and its purity can be depended upon. A further advantage is that the reaction conditions do not require excessive cooling or heating. The sodium perchlorate–acetyl chloride mixture can be used successfully for the ring acetylation of phenol ethers.

Experimental

Anhydrous sodium perchlorate was obtained by heating the monohydrate at 135–140° for 4 hr. It was found to be appreciably soluble in warm acetic acid (24 g. in 100 g. of acetic acid at 60°). Potassium perchlorate, however, was insoluble even in hot acetic acid and was ineffective as a catalyst.

Acetic acid, acetyl chloride and acetic anhydride were Merck pure reagents. Anisole, *p*-cresol methyl ether, *m*-cresol methyl ether, *p*-cresol methyl ether and phenetole were used from stock. 2-Naphthol methyl ether, methylenedioxybenzene, pyrogallol trimethyl ether, catechol dimethyl ether, resorcinol dimethyl ether, hydroquinone dimethyl ether and phloroglucinol trimethyl ether were prepared by standard methods described in literature. Phloroglucinol dimethyl ether, b.p. 185° (16 mm.), and resorcinol monomethyl ether, b.p. 240–242°, were obtained as reported by Robinson, *et al.*[6] The m.p. or b.p. of the ethers stated in Tables IV and V are those recorded in literature and were also checked. 2-Naphthol methyl ether was found to have b.p. 132–134° (10 mm.). 1-Naphthol methyl ether could be obtained better by methylation of 1-naphthol with dimethyl sulfate and alkali.

The following account is given as typical of the process of acetylation, being done with anisole under optimum conditions.

Acetylation of Anisole, Taking Sodium Perchlorate, Acetyl Chloride, Acetic Acid, Anisole and Acetic Anhydride in the Molecular Proportion 1:1:8:4:3.—Anhydrous sodium perchlorate (3.1 g., 0.025 mole) was dissolved at 60° in acetic acid (12 g., 0.2 mole) and, when cold, acetyl chloride (2.0 g., 0.025 mole) was added. Slight turbidity was produced. Anisole (10.8 g., 0.1 mole) and acetic anhydride (7.7 g., 0.75 mole) were then added and the reaction mixture warmed under reflux at 60° for 4 hr. There was gradual development of color which became deep brown toward the end. The reaction mixture was then poured over crushed ice. The aqueous liquor which contained the oily reaction product was extracted with ether (50 ml., thrice). The ether layer, separated from the aqueous layer,[7a] still contained a suspension of an orange-red solid and was therefore filtered. The filtered ether extract was washed successively with aq. sodium carbonate, 2 *N* caustic soda solution and finally with water. The residue from the dried (Na_2SO_4) ether extract was fractionally distilled. Unchanged anisole (3.5 g.) admixed with little of the ketone came over at 45–47° (6–8 mm.). The ketone fraction came over at 119–120° (6–8 mm.) and solidified upon refrigeration giving m.p. 37° (4-methoxyacetophenone is reported[3b] to have b.p. 117° (6 mm.) and m.p. 37°); 2,4-dinitrophenylhydrazone, m.p. and mixed m.p. 221°[7b]; oxime,[8a] m.p. and mixed m.p. 88°; yield 7.5 g. (moles of ketone formed per 4 moles of the ether, *i.e.*, mol. prop. = 2); non-volatile residue, 1.7 g. The amount of the ketone formed corresponds to 50% conversion of the ether into 4-methoxyacetophenone. The latter could be obtained in equivalent yields by using hydrated sodium perchlorate $NaClO_4 \cdot H_2O$; the proportion of the sodium perchlorate, acetyl chloride, acetic acid, anisole and acetic anhydride then was 1:1:6:4:4.

When in these experiments acetyl chloride was not included in the acetylation mixture no acetylation took place, but when the acetic anhydride was omitted, there was some acetylation—4-methoxyacetophenone being obtained in poor yields (1.7 g. at 40° in 4 hr.). The results of acetylation of anisole, using different amounts at 60° in 4 hr., as well as those for the yield of the ketone at different temperature and time and with decreasing amount of the catalyst are incorporated in Table III.

TABLE III

ACETYLATION OF ANISOLE UNDER DIFFERENT CONDITIONS

Temp., 60° $NaClO_4$:AcCl:AcOH:Anisole:Ac_2O Mol. proportion	Anisole used, g.	Time, 4 hours Yield[a] 4-methoxyacetophenone, %	Ether recovd., g.
1:1:8:1:3	2.7	60	0.25
1:1:8:2:3	5.4	58	0.75
1:1:8:3:3	8.1	52	1.90
1:1:8:4:3	10.8	52[b,c]	3.50
1:1:8:4:4	10.8	48[d]	3.40

[a] Calculated on the anisole used. [b] At other temperatures and time the amount of the ketone formed was: 0–5°/72 hr. or 45°/4 hr., 3 g.; at 40°/2 hr., 1.7 g. (mol. prop. with anisole, 0.44). [c] AcOH, anisole and Ac_2O remaining the same (8:4:3), at diminished mol. concentration of the catalyst mixture ($NaClO_4$ + AcCl), the amount of the ketone was: 0.25 mole/1.9 g., 0.5 mole/3.4 g., 0.75 mole/5.0 g., the first figures being those for the catalyst mixture. [d] With concentrations greater than 3 moles, Ac_2O is utilized more in promoting side reactions (ref. 3a).

Acetylation of Various Phenol Ethers.—Further experiments were conducted with other ethers at different temperature and time in the manner described for anisole. The results are listed in Tables IV and V. Experiments relating to the ketones a–f in Table IV and c and d in Table V were conducted with an acetylation mixture of composition 1:1:8:4:3 and those for e–h in Table V with one of composition approximating 1:1:8:2:3. The actual amount of the ether is mentioned in the first column, the amount of the other constituents being adjusted accordingly. Distillation of the final reaction products under reduced pressure (as indicated) gave a forerun composed of the unchanged ether and containing also, in some cases, a little of the ketone fraction. After a sudden rise of 40–65°, the main ketone fraction came later at temperatures stated in the tables. Only in a few cases was a second distillation necessary to improve the purity of the ketones. The latter have been characterized through suitable derivatives (*vide* literature cited, Tables IV and V). In the case of 1-acetyl-4-methoxy- and 1-acetyl-2-methoxynaphthalene, their identity has been further confirmed by comparison with authentic samples of the ketones and of their derivatives. The purification of 2,4,6-trimethoxyacetophenone (phloroacetophenone trimethyl ether) was done by crystallization. In all cases, losses entailed during the working of the reaction mixture as well as those due to side reactions were inevitable, but considering together the weights of the ketone fraction, forerun and residue (*cf.*

[a] Reported[8a] b.p. 145–146° (14 mm.); oxime, m.p. 101–102°, reported[8a] 101–102.5°; semicarbazone, m.p. 206–207°, reported[8b] 206–207°. [b] Reported[8a] b.p. 140–141° (14 mm.); semicarbazone, m.p. 194–196°, reported[8a] 194–195°. [c] Reported[2b] b.p. 120.5° (7 mm.); oxime m.p. 89–91°, reported[8a] 89–90°; semicarbazone, m.p. 176–177°, reported[8b] 176–177°. [d] Reported[1d] b.p. 131° (6 mm.). After redistillation and refrigeration solidified, m.p.[9a] 36–37°. Upon oxidation[9b] (with $KMnO_4$ and aq. K_2CO_3) gave *p*-ethoxybenzoic acid, m.p. 195–196°. [e] Reported[10a] b.p. 224–225° (15 mm.). Solidified on keeping. Crystals (from alcohol and then petroleum ether) gave m.p. and mixed m.p. with authentic sample[10b] 70–71°. Semicarbazone, m.p. and mixed m.p. 221–222°. (*Anal.* Calcd. for $C_{14}H_{15}N_3O_2$: N, 16.34. Found: N, 15.91.) Picrate, m.p. and mixed m.p. 129–130° (*Anal.* Calcd. for $C_{19}H_{15}N_3O_9$: C, 53.14; H, 3.49. Found: C, 53.2; H, 3.6). Schneider and Kunau[10b] had reported m.p. of the picrate to be 119–121°. [f] Reported[2b] b.p. 158° (2 mm.). Solidified on keeping to give crystals m.p. and mixed m.p. with authentic sample[2b] 59–60°. Semicarbazone, m.p. and mixed m.p. 234–235°. (*Anal.* Calcd. for $C_{14}H_{15}N_3O_2$: N, 16.34. Found: N, 16.64.) Picrate m.p. and mixed m.p. 134–135°. (*Anal.* Calcd. for $C_{19}H_{15}N_3O_9$: C, 53.1; H, 3.19. Found: C, 52.7; H, 3.57.) [g] Fractionation in the case of the reaction products from these two ethers was done under 8–10 mm. pressure.

Tables IV and V), these losses are not found to be more than 1.5–2.5 g. With 0.1-mole quantities of the ethers, this weight might account for the fate of 15–25% of the phenol ether used.

Acetylation of Resorcinol Monomethyl and Phloroglucinol Dimethyl Ether.—Resorcinol monomethyl ether (12.4 g., 0.1 mole) was acetylated at 60° for 4 hr. using the acetylation mixture of composition 1:1:8:4:3. The reaction mixture was made alkaline and refluxed for 1 hr. to hydrolyze the O-acetyl group if any. It was then acidified and extracted with ether. The ether layer was filtered from suspended matter (0.5 g.) and the ether removed. The residual liquid mass was steam distilled till no more emulsion came over. The steam distillate upon ether extraction yielded an oil (5 g.) which did not solidify but contained 2-hydroxy-4-methoxyacetophenone (peonol); semicarbazone, m.p. 219–221°, reported[17a] 221–222°. Four tenths gram of the oil gave 0.13 g. of semicarbazone, indicating it to contain 25–30% peonol (total *ca.* 1.3 g.), the rest being the unused ether. The colored solid left behind after steam distillation was extracted with ether, the extract treated with animal charcoal and filtered. After removing the ether and crystallizing the residue (1 g., m.p., crude, 120–125°) from alcohol, pure 2-methoxy-4-hydroxyacetophenone (isopeonol) was obtained, m.p.[17b] 137–138°; 2,4-dinitrophenylhydrazone, m.p. 219–220°, reported[17c] 216–217°.

The experiment with phloroglucinol dimethyl ether (7.7 g., 0.05 mole) was done in the same way. The steam distillate gave 2-hydroxy-4,6-dimethoxyacetophenone (1.6 g., mol. prop. 0.64); m.p. and mixed m.p. 84–85° with an authentic sample of m.p. 85°. The m.p.'s of this ketone are variously reported, *e.g.*, 80°,[13a] 85–88°,[18b] 86–87°,[18a] etc. The sample gave with nitric acid[12b] a blue color turning green on making alkaline and an intense violet color with ferric chloride in alcoholic solution.[18b]

Acetylations Using Perchloric Acid Liberated *in situ*.—Anhydrous sodium perchlorate (1.54 g., 0.0125 mole) and concd. sulfuric acid (1.22 g., 0.0125 mole) were heated together at 100–110° for 0.5 hr. The heated mass was cooled and extracted with glacial acetic acid (2 g., 0.034 mole). The extract was filtered through glass wool which was pressed to squeeze out the extract. Acetic anhydride (4.1 g., 0.0 mole) and anisole (5.4 g., 0.05 mole) were then added. This mixture was maintained at 50° for 4 hr. The reaction

	5–10	0.75		49.4		2.1	1.1
	22	0.75		62		1.4	0.7
			2,5-Dimethoxyacetophenone[h]				
Hydroquinone dimethyl ether,[i] b.p. 109° (20 mm.), 6.5 g., 0.047 mole	50	4	156–158	22.4	120–121	..	..
	60	4		30		..	..

[a] Composition of the acetylation mixture was 1:1:8:4:3, in others it was 1:1:8:2:3. [b] Perchloric acid, from $NaClO_4$ + H_2SO_4 (*v. infra*), was the catalyst. [c] Solidified upon refrigeration. After recrystallization from benzene, m.p.[11a,b] 87°; oxime, from hydroxylamine hydrochloride and sodium acetate, m.p. 155–156°, reported[11c] 156–157°; phenylhydrazone, m.p. 115°, reported[11a] 114°. Semicarbazone, m.p. 238–240°, reported[11b] 241–242°. [d] The ketone fraction did not solidify; reported[12a] m.p. 14–15°, b.p. 165° (12 mm.). Semicarbazone, m.p. 168–169°. (*Anal.* Calcd. for $C_{12}H_{17}N_3O_4$: N, 15.73. Found: N, 15.49.) Oxidation with iodine and alkali[12c] gave iodoform, m.p. 119°, and 2,3,4-trimethoxybenzoic acid, m.p. 98° (reported 100°). [e] The reaction product was first decolorized with animal charcoal in 20% alcohol (40 ml.) at 80° and the extract filtered. The residue was then further extracted with alcohol (10 ml. thrice). The combined extracts on concentration and cooling deposited the crude product (3.2 g.), representing a 34% conversion of the ether. The crude product upon recrystallization from alcohol gave crystals, m.p.[13a,13b] 99–100°. The latter gave a blue color with nitric acid.[13b] In a similar experiment, using 5.7 g. of ether and doing the acetylation at 70° for 4 hr., the yield of the crude ketone was 2.4 g., showing 33% conversion of the ether. [f] Reported[14a] b.p. 158° (9 mm.). After redistillation and refrigeration, m.p.[14b] 48–49°; oxime,[14a] m.p. 140°; semicarbazone,[14a] m.p. 211°. [g] Reported[2b] b.p. 157.5° (7 mm.) and[15a] 163–165° (12 mm.). After redistillation and refrigeration solidified to give m.p.[15a] 40°; oxime,[15b] m.p. 125°. At higher reaction temperature considerable colored and tarry material was also produced. [h] Reported[16a] b.p. 156–158° (11 mm.); semicarbazone,[16b] m.p. 181–182°. [i] Fractionation was done under 10–12 mm. pressure.

mixture was then worked as described before for anisole. 4-Methoxyacetophenone isolated weighed 2 g. The amount was 2.5 g. by the sodium perchlorate–acetyl chloride method. The yields of ketones obtained from *m*-cresol methyl ether and pyrogallol trimethyl ether when sodium perchlorate–sulfuric acid was used approached the yields obtained using the sodium perchlorate–acetyl chloride method (*cf.* Table V). In other cases (*e.g.*, phenetole, 1-naphthol methyl ether, phloroglucinol dimethyl ether) the yields were less. Similar results were obtained when the experiments were conducted at room temperatures.

The authors wish to thank Prof. T. R. Seshadri, Dean of the Science Faculty and Head of the Chemistry Department, University of Delhi, for his interest in this work and for facilities.

Cortical Steroid Analogs. II. The Synthesis of Open-chain Dihydroxyacetones from 2,3-Butanedione[1]

BY GARDNER W. STACY, RICHARD A. MIKULEC, STEPHEN L. RAZNIAK AND LAURENCE D. STARR[2]

RECEIVED DECEMBER 29, 1956

The synthesis of 1,3-dihydroxy-3-methyl-2-pentanone (V), an open-chain or acyclic dihydroxyacetone derivative which had resisted prior attempts at synthesis, has been accomplished. The synthetic scheme employed appears to have rather general potentialities for the preparation of a series of such dihydroxyacetone derivatives with 2,3-butanedione (I) as the starting point. It has been demonstrated that from I it is possible to prepare conveniently by reaction with appropriate organocadmium reagents a number of representative acetylcarbinols similar to II, these latter substances being key compounds in the synthesis of dihydroxyacetones. Biological evaluation of V and its corresponding 1-acetate IV has revealed that neither substance has significant anti-inflammatory or glucocorticoid activity.

Syntheses of alicyclic analogs of cortisone have been reported,[3] and studies in the same direction also have been carried out in this Laboratory.[1,4] It now has been decided to investigate the synthesis and possible biological activity of open-chain (acyclic) analogs because of the number of compounds of lesser structural complexity that might possibly be synthesized. A survey of the literature revealed that apparently no acyclic dihydroxyacetone derivatives with a tertiary hydroxyl group had been prepared previously, although an attempted synthesis of such compounds had been reported by Diels and Johlin.[5]

A synthetic scheme, similar to that attempted by Diels and Johlin[5] and employed more recently with success in respect to steroid[6] and analog syntheses,[3] was undertaken. Accordingly, this resulted in the successful preparation of 1,3-dihydroxy-3-methyl-2-pentanone (V), one of the compounds that Diels and Johlin[5] previously had failed to obtain and a representative example of the type of acyclic analog that may be derived from 2,3-butanedione (I).

Acetylcarbinols such as II are the key intermediates for the synthesis of acyclic analogs (V) in respect to the scheme outlined. A method of readily obtaining a series of such acetylcarbinols, where one alkylcarbinol substituent remained constant as a methyl group, suggested itself. It seemed quite possible to derive such a series from 2,3-butanedione (I) by reaction of this substance with an appropriate organometallic reagent. The use of Grignard reagents appeared to be unsatisfactory, for it had been reported that such a reaction results in bis addition to the very reactive twin carbonyl grouping of I to yield pinacols.[7] Although Lapkin and Golovkova[8] more recently had observed that Grignard reagents involving radicals of large size will react under the proper conditions to give acetylcarbinols, a procedure more general in scope was desired for the present application. Since it had been noted that organocadmium reagents, which are relatively unreactive with isolated carbonyl groups, react readily with the twin carbonyl group of α-keto esters to form α-hydroxy esters,[9] it appeared likely that a similar reaction would occur in the case of organocadmium reagents and 2,3-butanedione. This hope was indeed realized, and a number of acetylcarbinols were prepared in yields of 38–70% (Table I). It was found that a 0.5 equivalent excess of organocadmium reagent in respect to the 2,3-butanedione gave optimum results. For example, when an equivalent amount of diethylcadmium was used in the preparation of II, a 28% yield was obtained; however, when the excess was used the yield was 68%. With one exception, the acetylcarbinols were characterized as semicarbazones (Table II).

$C_6H_5CH_2CH_2$	94	185–186[f]	$C_{13}H_{19}N_3O_2$	62.63	62.67	7.68	7.95	16.86	16.87

[a] Yields were based on the weight of crude product. [b] M.p. of analytical sample. All samples were recrystallized from aqueous ethanol unless otherwise stated. [c] In addition to the derivatives listed in the table, the following known semicarbazones were prepared for purposes of comparison: R = C_6H_5, 82% yield, m.p. 187°; Wegmann and Dahn (ref. *a*, Table I) reported m.p. 183–184°. R = C_2H_5, 69% yield, m.p. 150.5–151°; Kapron and Wiemann (ref. *a*, Table I) reported m.p. 148.5–149.5°. R = n-C_4H_9, 63% yield, m.p. 152–153°; Leers (ref. *a*, Table I) reported m.p. 152°. [d] Recrystallized from aqueous acetone. [e] Recrystallized from 95% ethanol. [f] In this instance purification was difficult; the crude product, m.p. 93.5–114°, was recrystallized five times, twice from aqueous ethanol and three times from 2-propanol.

The acetylcarbinol derived from 1-naphthylmagnesium bromide was converted to a picrate and to a 2,4-dinitrophenylhydrazone. Extension of the study to R = n-$C_{16}H_{33}$ and R = n-$C_{18}H_{37}$ gave products which could not be purified. In the case of R = n-$C_{16}H_{33}$, however, it was possible to prepare a pure semicarbazone from the crude acetylcarbinol.

In some instances small amounts of hydrocarbons, formed as coupling products from the organocadmium reagents, were observed in the reaction mixture. For example, eicosane and tetracosane were isolated from the reaction mixtures involving the C_{10}- and C_{12}-organocadmium reagents, respectively. To confirm the structure of the acetylcarbinols obtained from I by the method just described, II was prepared by hydration of the ethynylcarbinol (VI). The identity of these compounds prepared by the two different methods was established through comparison of semicarbazones by a mixture melting point determination. As a result of the study of this procedure involving the reaction of organocadmium reagents with 2,3-butanedione, it is to be concluded that it constitutes a useful supplement to the ethynylcarbinol hydration for the preparation of acetylcarbinols, particularly where the prerequisite ethynylcarbinols are not readily available.

In continuation of the description of the synthesis of the dihydroxyacetone derivative V, the intermediate bromo ketone III was obtained in yields of about 60% by addition of bromine to a chloroform solution of the acetylcarbinol II. Although III seemed stable when kept in chloroform solution in the crude state, attempts at distillation under reduced pressure by ordinary procedures led to decomposition. The product always rapidly discolored, the colorless liquid turning brown as it was collected in the receiver. Catch and co-workers[10] had observed that bromoacetone exhibited a similar instability, but by storing this bromo ketone over magnesium oxide, they were able to keep samples indefinitely in a purified state. Application of this principle led to solution of the distillation problem just described, and our bromo ketone was obtained as a colorless liquid when it was distilled from magnesium oxide into a receiver containing magnesium oxide. Although the bromo ketone III failed to yield typical carbonyl derivatives, a solid derivative in the form of a 2-naphthyl ether could be prepared in low yield.

The intermediate acetate IV was formed by a modification of the procedure of Rosenkranz, *et al.*,[11] in yields ranging from 24 to 33%, as based on the acetylcarbinol II (it was unnecessary to isolate and purify the unstable bromo ketone). Finally, the desired dihydroxyacetone derivative V was obtained in yields of 41–43% by the reaction of IV with methanolic potassium bicarbonate. A molecular distillation of this substance gave a colorless product, which reduced both Benedict

solution and Tollens reagent. The infrared absorption spectrum was compatible with a dihydroxy ketone structure. There was no sign of an absorption band corresponding to the carbon–hydrogen stretching frequency that might be related to an aldehyde group. Therefore, an aldose type structure isomeric with V did not seem probable for the product obtained. Attempts to characterize V by solid derivatives were not at first successful. Using standard procedures, we were unable to prepare common carbonyl derivatives (semicarbazone, thiosemicarbazone, phenylhydrazone, osazone, 2,4-dinitrophenylhydrazone, *p*-nitrophenylhydrazone, or oxime). By way of comparison, it was interesting to note that the very similar acetylcarbinol II formed a semicarbazone easily in excellent yield. The timely appearance of an article by Reich and Samuels[12] on the preparation of derivatives of dihydroxyacetone resolved the difficulty. When the procedures of these authors were employed, it was possible to prepare both a 2,4-dinitrophenylhydrazone and a 2,4-dinitrophenylosazone of V, although the yields of pure derivative in each instance were relatively low.

In relation to bromination of acetylcarbinols, one is confronted with difficulties which may detract from the yield of the desired bromo ketone. In addition to the well-known ease of reaction of a tertiary hydroxyl group with hydrobromic acid, tertiary alcohols react with bromine to form dibromides.[13] It was thought that such problems might be advantageously circumvented by proceeding through an intermediate where the tertiary hydroxyl group was protected by conversion to an ester. One type of ester that was of particular interest was an oxalate because of the prospective ease with which this group might be reconverted to the hydroxyl group under mild conditions. Accordingly, the ethoxalyl derivative VII was obtained in a 72% yield by reaction of II with ethoxalyl chloride in the presence of pyridine. A bromination product was obtained in a 62% yield, and it was interesting to note that the bromo ketone obtained showed a much lesser tendency to discolor on standing than III. In the treatment of the bromo ketone with potassium acetate in acetone, not only was the bromo group displaced by an acetate group but also the ethoxalyl group was removed to give the acetate IV in a 31% yield. These experiments demonstrated the ease with which the ethoxalyl group is removed and its possible use in analog synthesis as a protective device for the hydroxyl group. However, the method has not yet proved to be advantageous from the standpoint of over-all yield.

Biological Evaluation.—1,3-Dihydroxy-3-methyl-2-pentanone (V) and the corresponding 1-acetate (IV) were investigated for possible biological activity. These compounds revealed no significant anti-inflammatory activity in the granuloma pouch assay[14] in rats; the compounds were applied locally at a level of 1 mg. In comparison, hydrocortisone is very active at a level of 300 μg., so that the activity, if any, is less than 20% of hydrocortisone.

In the glycogen deposition assay for glucocorticoid activity,[15] these compounds were inactive at levels of 300 mg./kg. subcutaneously in fasted, adrenalectomized rats, and even at higher dosage levels of 1 g./kg., no increase in the weight of liver glycogen over the controls was to be observed.

Experimental[16]

Preparation of Acetylcarbinols.—The procedure for the preparation of the acetylcarbinol where R = *n*-$C_{12}H_{25}$ will serve to illustrate the general method used in all cases. Di-*n*-dodecylcadmium was obtained by reaction of a Grignard reagent, prepared from 7.30 g. (0.30 gram atom) of magnesium turnings in 200 ml. of absolute ether and 74.8 g. (0.30 mole) of *n*-dodecyl bromide in 50 ml. of absolute ether, with 27.5 g. (0.15 mole) of anhydrous cadmium chloride in 100 ml. of absolute ether.[17] After formation of the organocadmium reagent was shown to be complete by a negative Gilman test, 17.2 g. (0.20 mole) of 2,3-butanedione in 50 ml. of absolute ether was added dropwise.[18] After the addition was complete, the reaction mixture was heated under reflux with vigorous stirring for 11 hr. The complex then was decomposed by the slow addition of cold 1 *N* hydrochloric acid. The water phase was separated and in turn was extracted with four 100-ml. portions of ether. The ether extracts and the original ether phase were combined and washed with a saturated sodium bicarbonate solution and then with a saturated sodium chloride solution. The ether solution was dried over anhydrous sodium sulfate. The ether was removed under reduced pressure, and as the solution cooled during the evaporation of the ether, material, which by melting point appeared to be tetracosane, crystallized from solution. As much of the substance as possible was removed by filtration, the remainder of the ether was removed and the residue was fractionally distilled to yield 20.1 g. (39%) of the acetylcarbinol (Table I). The residue, remaining after the distillation had been completed, crystallized and was combined with the material previously removed by filtration. This was recrystallized from toluene–ethanol to give 4.45 g., m.p. 48–50° (tetracosane is reported[19] to melt at 51°).

Semicarbazones (Table II) were prepared according to standard procedures.[20]

3-Hydroxy-3-(1-naphthyl)-2-butanone 2,4-Dinitrophenylhydrazone.—This derivative was prepared[20] from 500 mg. (2.3 mmoles) of the corresponding acetylcarbinol. Two recrystallizations from an ethanol–water–ethyl acetate mixture gave 430 mg. (47% yield) of orange needles, m.p. 193.5–194.5° (uncor.).

Anal. Calcd. for $C_{20}H_{18}N_4O_5$: C, 60.91; H, 4.60; N, 14.21. Found: C, 61.14; H, 4.69; N, 14.05.

3-Hydroxy-3-(1-naphthyl)-2-butanone Picrate.—This picrate was prepared from 100 mg. (0.46 mmole) of the acetylcarbinol, dissolved in 1 ml. of ethanol, and 3 ml. of a saturated ethanolic solution of picric acid.[20] The product was recrystallized twice from 95% ethanol and washed with a small amount of anhydrous ether to yield fine yellow needles, m.p. 133–135°.

Anal. Calcd. for $C_{20}H_{17}N_3O_9$: C, 54.18; H, 3.86; N, 9.48. Found: C, 54.20; H, 4.00; N, 9.45.

(16) All melting points are corrected unless otherwise stated, and boiling points are uncorrected. The microanalytical work was performed by Galbraith Laboratories, Knoxville, Tenn., and Weiler and Strauss Laboratories, Oxford, England. Infrared absorption spectra were determined on pure liquid samples using a Perkin-Elmer double beam infrared spectrometer, model 21.

(17) For a more detailed procedure for the preparation of organocadmium reagents see ref. 9a.

(18) Since the reaction mixture many times becomes viscous and difficult to stir, it is advisable to use a heavy-duty stirrer and motor for this operation. We used a Hershberg-type stirrer constructed from one-quarter-inch nickel rod and No. 15 chromel wire and a "Power-Stir" motor, manufactured by Eberbach and Son Co., Ann Arbor, Mich.

3-Hydroxy-3-methyl-2-pentanone (II) from VI.[21]—To a mixture of 380 ml. of water, 16 ml. of concd. sulfuric acid and 10 g. of red mercuric oxide[21] heated to 60° was added dropwise 78.5 g. (0.80 mole) of 3-hydroxy-3-methyl-1-pentyne[22] over a 1-hr. period. The product was distilled through a 20-cm. column packed with glass helices to give 79.5 g. (86%) of II, b.p. 74–78° (50 mm.), $n^{25}D$ 1.4205 (see footnote, Table I).

The infrared absorption spectrum showed bands that were assignable to OH stretching frequency (3450 cm.$^{-1}$, s), *t*-OH (1350 cm.$^{-1}$, s; 1170 cm.$^{-1}$, s) and C=O (1705 cm.$^{-1}$, s).

A mixture melting point determination of a semicarbazone prepared from this material and that derived from the organocadmium procedure showed no depression.

1-Bromo-3-hydroxy-3-methyl-2-pentanone (III).—To a solution of 20.0 g. (0.17 mole) of II in 800 ml. of chloroform was added dropwise over a 3.5-hr. period 28.9 g. (0.18 mole) of bromine in 400 ml. of chloroform. The reaction mixture was washed with 190 ml. of ice-cold 5% sodium hydroxide solution and two 100-ml. portions of water. The organic layer was separated and dried over 100 g. of anhydrous sodium sulfate, to which had been added 0.1 g. of magnesium oxide.[10] After the solvent had been removed, the product was fractionally distilled under nitrogen from magnesium oxide using as short a pathway of distillation as possible (fraction cutter directly attached to distilling flask). Seven fractions were collected amounting to 20.4 g. (61%), b.p. 49–56° (0.1–0.15 mm.), $n^{25}D$ 1.4790–1.4847. The first four fractions distilled as a colorless liquid and turned tan to brown as collected. The third fraction was subjected to molecular distillation at 43–45° (oil-bath temperature) (0.005 mm.) from magnesium oxide and collected in a receiver containing magnesium oxide.[23] The sample submitted for analysis ($n^{25}D$ 1.4831) was stored over magnesium oxide.

Anal. Calcd. for $C_6H_{11}BrO_2$: C, 36.94; H, 5.69; Br, 40.97. Found. C, 36.75; H, 5.84; Br, 41.20.

The infrared absorption spectrum showed bands that were assignable to OH stretching frequency (3485 cm.$^{-1}$, s), *t*-OH (1375 cm.$^{-1}$, s; 1175 cm.$^{-1}$, s) and C=O (1720 cm.$^{-1}$, s).

A 2-naphthyl ether[20] was prepared from 2.00 g. (0.01 mole) of III, which had been obtained by a molecular distillation. One recrystallization from petroleum ether (b.p. 90–120°) gave 330 mg. (13%) of fine colorless needles, m.p. 114.5–115°.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02. Found: C, 74.27; H, 7.12.

1,3-Dihydroxy-3-methyl-2-pentanone 1-Acetate (IV).—A mixture of 54.3 g. of glacial acetic acid and 86.2 g. of potassium bicarbonate in 516 ml. of acetone was heated under reflux with stirring for 30 minutes.[11] Crude III, obtained from 20.0 g. (0.17 mole) of II, in 70 ml. of acetone was added dropwise with stirring to the acetone–potassium acetate suspension. The resulting mixture was heated under reflux for 12 hr. and then was allowed to stand for 2 days. The reaction mixture was cooled for 1 hr. in an ice-bath to precipitate dissolved potassium acetate, filtered and dried over 50 g. of anhydrous potassium carbonate. After the acetone had been removed, the residue was distilled under nitrogen through a 15-cm. Vigreux column to give four fractions of IV amounting to 10.0 g. (33%), b.p. 75–77° (0.1 mm.), $n^{25}D$ 1.4400–1.4410. A portion of a middle fraction was subjected to molecular distillation[23] at 55–60° (oil-bath temperature) (0.025 mm.) to give a colorless analytical sample, which was stored under nitrogen; $n^{25}D$ 1.4403, d_4^{25} 1.0933.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.10; *M*D, 42.34. Found: C, 55.32; H, 8.25; *M*D, 42.02.

The infrared absorption spectrum showed bands that were assignable to OH stretching frequency (3470 cm.$^{-1}$, s), *t*-OH (1355 cm.$^{-1}$, s; 1165 cm.$^{-1}$, m) and C=O (1725 cm.$^{-1}$, s).

A semicarbazone was prepared from 1.00 g. (5.7 mmoles) of IV. Recrystallization from water afforded 690 mg. (52%) of colorless needles, m.p. 174.5–175.5°.

Anal. Calcd. for $C_9H_{17}N_3O_4$: C, 46.75; H, 7.40; N, 18.17. Found: C, 46.95; H, 7.30; N, 18.24.

1,3-Dihydroxy-3-methyl-2-pentanone (V).—A mixture of 12.6 g. (0.072 mole) of IV and 52.7 g. of potassium bicarbonate in 275 ml. of methanol was stirred under nitrogen for 48 hr. at room temperature.[3b] The mixture was filtered and was concentrated by distilling the solvent under reduced pressure through a 20-cm. Vigreux column. The residual mixture was dissolved in 500 ml. of water, which then was saturated with sodium chloride. The solution was continuously extracted with ether for 2 days. Then the ether phase was separated and dried over 100 g. of anhydrous sodium sulfate. After the ether was removed by distillation, the residue was fractionally distilled through a 15-cm. Vigreux column to give three fractions of product; yield 4.20 g. (44%), b.p. 51–58.5° (0.1–0.25 mm.), $n^{25}D$ 1.4548. Molecular distillation[23] of a small portion of this material at 25° (0.005 mm.) gave a colorless, analytical sample, $n^{25}D$ 1.4537, d^{25}_4 1.0998.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.52; H, 9.16; *M*D, 32.97. Found: C, 54.48; H, 9.19; *M*D, 32.52.

The infrared absorption spectrum showed bands that were assignable to OH stretching frequency (3400 cm.$^{-1}$, s), *t*-OH (1350 cm.$^{-1}$, m; 1160 cm.$^{-1}$, s) and C=O (1710 cm.$^{-1}$, s).

A 2,4-dinitrophenylhydrazone was prepared[12] by heating under reflux for 22 hr. a mixture of 132 mg. (1.0 mmole) of V, 200 mg. (1.0 mmole) of 2,4-dinitrophenylhydrazine and 5 ml. of absolute ethanol. The reaction mixture was concentrated to a small volume from which was obtained 42 mg. (13%) of product, m.p. 140.5–144°. Two recrystallizations from aqueous ethanol gave 22 mg. (7%) of yellow needles, m.p. 147.5–148°.

Anal. Calcd. for $C_{12}H_{16}N_4O_6$: C, 46.15; H, 5.16; N, 17.94. Found: C, 46.32; H, 5.02; N, 17.74.

A 2,4-dinitrophenylosazone also was prepared[12] by heating under reflux for 1 hr. a mixture of 132 mg. (1.0 mmole) of V, 790 mg. (4.0 mmoles) of 2,4-dinitrophenylhydrazine and 200 ml. of 2 *N* hydrochloric acid. The reaction mixture was allowed to stand overnight; yield 412 mg. (84%), m.p. 256–258° dec. Six recrystallizations from ethylene chloride gave 168 mg. (34%) of bright-red, microscopic prisms, m.p. 269.5–270° dec.

Anal. Calcd. for $C_{18}H_{18}N_8O_9$: C, 44.08; H, 3.70; N, 22.85. Found: C, 44.18; H, 3.50; N, 22.74.

3-Ethoxaloxy-3-methyl-2-pentanone (VII).—To a mixture of 81.3 g. (0.70 mole) of II and 119.5 g. (0.875 mole) of ethoxalyl chloride[24] in 140 ml. of absolute ether was added 69.2 g. (0.875 mole) of anhydrous pyridine in 140 ml. of absolute ether with stirring at such a rate as to produce moderate reflux (85 minutes). The reaction mixture was stirred for an additional 10 minutes, was allowed to cool and was filtered. The filter cake (pyridine hydrochloride) was washed with three 70-ml. portions of anhydrous ether. The combined ether filtrates were washed with two 50-ml. portions of saturated sodium chloride solution and were dried over sodium sulfate. The ether was removed under reduced pressure through a 15-cm. helices-packed column, and the residue was distilled; yield 108.1 g. (72%), b.p. 102–106° (3 mm.), $n^{25}D$ 1.4342, d^{25}_4 1.0859.

Anal. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46; *M*D, 51.71. Found: C, 55.32; H, 7.35; *M*D, 51.88.

1,3-Dihydroxy-3-methyl-2-pentanone 1-Acetate (IV) from VII.—A solution of 21.6 g. (0.10 mole) of VII in 320 ml. of chloroform was treated with 0.6 ml. of 30% hydrobromic acid in acetic acid. The mixture was heated to 50° and, with stirring, a solution of 16.8 g. (0.105 mole) of bromine in 120 ml. of chloroform was added dropwise over a period of 2.5 hr. After the solvent was removed under reduced pressure, the residue was distilled through a 15-cm. Vigreux column to give 18.4 g. (62%) of an intermediate bromo ketone, b.p. 94–98° (0.07 mm.), $n^{25}D$ 1.4645–1.4740.

To a solution of 17.9 g. of the crude bromo ketone in 630 ml. of acetone was added 143 mg. of potassium iodide, 40.0 g. of potassium acetate and 6.3 ml. of glacial acetic acid.[25]

(21) This preparation is similar to one previously reported for 1-acetylcyclopentanol (ref. 1). A modification of the original procedure which was employed here to advantage involved sprinkling the mercuric oxide on the surface of the sulfuric acid solution with stirring; this greatly facilitated the dissolving of the material.

The mixture was heated under reflux with stirring for 16 hr., filtered and the filter cake washed well with acetone. The acetone was removed by distillation, and the dark-brown residue was distilled through a 15-cm. Vigreux column; yield 5.17 g. (31%), b.p. 79–105° (0.2–0.5 mm.), $n^{25}D$ 1.4422–1.4435.

A sample of semicarbazone of this substance was prepared in a 48% yield, m.p. 174.5–175.5°, and when admixed with a sample of semicarbazone as derived above (III→IV), no depression in melting point was observed.

Acknowledgments.—This investigation was supported in part by a research grant (A-253, C-C3) and in part by a predoctoral fellowship to R.A.M. (AF-5336) from the National Institute of Arthritis and Metabolic Diseases, Public Health Service. For the biological evaluations, we wish to extend our thanks to Mr. S. C. Lyster and Mr. L. E. Barnes, Department of Endocrinology, The Upjohn Co., Kalamazoo, Michigan. For determination and aid in interpretation of infrared absorption spectra, we wish to thank Mr. George D. Wagner of the Division of Industrial Research of the State College of Washington and Dr. J. L. Johnson and Mrs. Anne E. Fonken of the Department of Physics of The Upjohn Co.

Preparations of Synthetic Estrogens. VIII.[1a] New Syntheses of 1,1,2-Tri-*p*-anisylethylene and Diethylstilbestrol

BY KEIITI SISIDO, KÔITI OKANO, MINORU SINDÔ AND HITOSI NOZAKI[1b]

RECEIVED FEBRUARY 9, 1957

1,1,2-Tri-*p*-anisylethylene (VI) has been obtained by the condensation of α-chloro-*p*-methoxyacetophenone (I) with 2 moles of anisole in the presence of titanium tetrachloride. A similar condensation of α-chloroacetophenone (VII) with 2 moles of anisole gave 1,2-di-*p*-anisyl-1-phenylethylene (VIII). When these condensations were carried out with sulfuric acid or aluminum chloride as a catalyst, 1,1,1,2- and 1,1,2,2-tetra-*p*-anisylethanes as well as 1,1-di-*p*-anisylethylene were obtained instead of triarylethylenes. 2,3-Di-*p*-anisylbutene-2 (X) and diethylstilbestrol dimethyl ether (XII) were prepared by the condensation of 3-chlorobutanone (IX) and 4-chlorohexanone-3 (XI) with 2 moles of anisole in the presence of titanium tetrachloride.

In the previous paper[1a] it was reported that the treatment of *p*-methoxy-α,α-di-*p*-anisylacetophenone with phosphorus pentachloride effected simultaneous chlorination and dehydrochlorination giving 1,1,2-tri-*p*-anisyl-2-chloroethylene. The usual preparation[2] of 1,1,2-tri-*p*-anisyl-2-chloroethylene is the chlorination of tri-*p*-anisylethylene (VI) with chlorine in carbon tetrachloride. Recent studies in this Laboratory have given a new preparation of the key intermediate, tri-*p*-anisylethylene (VI), using a Grignard reaction between α-chloro-*p*-methoxyacetophenone (I) and *p*-anisylmagnesium bromide.[1] It has now been discovered that the condensation of α-chloro-*p*-methoxyacetophenone (I) with 2 moles of anisole in the presence of titanium tetrachloride gives tri-*p*-anisylethylene (VI) in a 53% yield. This method, in which the use of a Grignard reaction is avoided, seems to be suitable for large scale preparation.

The condensation of α-haloketones with phenol in the presence of an acidic catalyst has been studied by Lippmann.[3] Zaheer, *et al.*,[4] have reported recently that the reaction between chloroacetone and phenol or its ether in the presence of sulfuric acid or aluminum chloride as a catalyst gives 4,4′-dihydroxy- or -dialkoxy-α-methylstilbene, respectively. They have reported further that the similar condensation of 4-chlorohexanone-3 (XI) with anisole gives 3,3,4-tri-*p*-anisylhexane in addition to 1,1-di-*p*-anisyl-2-ethylbutene-1, and that phenol reacts with 1,3-dichloroacetone only at its carbonyl group to give 1,3-dichloro-2,2-di-*p*-hydroxyphenylpropane.[5] It was observed in the present experiments, in which sulfuric acid or aluminum chloride was used, that anisole reacted with α-chloro-*p*-methoxyacetophenone (I) to give various condensation products, among which, however, the desired tri-*p*-anisylethylene (VI) could not be found. The treatment of the chloroketone I with 2 moles of anisole in the presence of concentrated sulfuric acid in glacial acetic acid solution resulted in almost quantitative recovery of the starting materials. Essentially the same result was obtained in a reaction without the solvent, but further experiments in which the chloroketone I was dissolved in a large excess of anisole gave 1,1,1,2-tetra-*p*-anisylethane (III) and 1,1,2,2-tetra-*p*-anisylethane (IV).

$$\underset{\text{I}}{\text{ClCH}_2\text{COC}_6\text{H}_4\text{OCH}_3\text{-}p} + \underset{\text{II}}{3\text{C}_6\text{H}_5\text{OCH}_3} \xrightarrow{\text{concd. } H_2SO_4} p\text{-CH}_3\text{OC}_6\text{H}_4\text{CH}_2\text{C}(\text{C}_6\text{H}_4\text{OCH}_3\text{-}p)_3 + (p\text{-CH}_3\text{OC}_6\text{H}_4)_2\text{CHCH}(\text{C}_6\text{H}_4\text{OCH}_3\text{-}p)_2$$

III IV

As to the mechanism of the initial step of the condensation of chloroketone with phenol, Zaheer, *et al.*, postulated either a Friedel–Crafts type removal of the chlorine atom involving combination of phenol at that position,[4a] or an addition of one mole of phenol at the carbonyl group and a subsequent rearrangement involving a dehydrochlorina-

tion and a migration of an aromatic nucleus.[4b] The latter mechanism seems to be more plausible, as they suggested,[4c] since in the chloroketone the chlorine atom is attached firmly by the effect of the electron-attracting carbonyl group and the Friedel–Crafts type reaction, in which the chlorine atom must be taken off as an anion, would not be expected to occur.

In either route, however, desoxyanisoin may be formed at the first step of this reaction, being followed by attacks of second and third molecules of anisole to give 1,1,1,2-tetra-*p*-anisylethane (III) *via* 1,1,2-tri-*p*-anisylethanol. The unsymmetrical tetraanisylethane may partly be isomerized to the symmetrical one because of excessive crowding in III.

When the chloroketone I was treated with a large excess of anisole in the presence of aluminum chloride as a catalyst, 1,1-di-*p*-anisylethylene (V) and a resinous product were obtained. The mechanism of the production of this material is presumed to involve the removal of the chlorine atom by means of the reducing action of aluminum chloride at the first step and the subsequent addition of one mole of anisole at the carbonyl group followed by a dehydration. Similar removal of the chlorine atom has been observed in the reaction of acetyl chloride and cyclohexene in the presence of aluminum chloride.[6] It seems that 1-acetyl-2-chlorocyclohexane

$$\text{I} + \text{II} \xrightarrow{AlCl_3} CH_2{=}C(C_6H_4OCH_3\text{-}p)_2$$

$$\text{I} + \text{II} \xrightarrow{TiCl_4} p\text{-}CH_3OC_6H_4CH{=}C(C_6H_4OCH_3\text{-}p)_2$$

$$\underset{\text{VII}}{ClCH_2COC_6H_5} + \text{II} \xrightarrow{TiCl_4} p\text{-}CH_3OC_6H_4CH{=}\underset{\text{VIII}}{C(C_6H_5)C_6H_4OCH_3\text{-}p}$$

is formed at the first step of the reaction but is reduced to acetylcyclohexane by means of aluminum chloride.

This specificity of catalytic action of individual Lewis acids in this condensation stimulated the trial of titanium tetrachloride, which was reported[7] recently to be an advantageous catalyst in Friedel–Crafts reactions. When the chloroketone I was treated with a large excess of anisole in the presence of 2 moles[7a] of titanium tetrachloride at 35–37°, 1,1,2-tri-*p*-anisylethylene (VI) was obtained in a 53% yield. Higher reaction temperature decreased the yield of VI, *i.e.*, 35% at 50° and only resinous product resulted above 60°. Treatment of the reaction mixture at 0–35° gave 1,1,1,2-tetra-*p*-anisylethane (III) besides a small quantity of 1,1,2-tri-*p*-anisylethylene (VI). If carbon disulfide was used as a solvent instead of an excess of anisole, only starting materials were recovered, and if chloroacetyl chloride was used as a reactant instead of I, 1,1,2-tri-*p*-anisylethylene (VI) and I were obtained in very poor yield.

It was found furthermore that the condensation of α-chloroacetophenone (VII) with 2 moles of anisole in the presence of titanium tetrachloride at 0° gave two forms of 1,2-di-*p*-anisyl-1-phenylethylene (VIII), m.p. 105.5–107° and 92–94°[8] in 61% yield. Prolonged reaction time decreased the yield of VIII and phenyl-tri-*p*-anisylethane was obtained as a by-product.

Attempted condensations with stannic chloride or polyphosphoric acid failed. Thus treatment of the α-chloro-*p*-methoxyacetophenone (I) with anisole in the presence of these Lewis acids afforded only a non-crystallizable resin.

In addition to these reactions, it was also discovered that the condensations of 3-chlorobutanone (IX) and 4-chlorohexanone-3 (XI) with 2 moles of anisole in the presence of titanium tetrachloride at 0° gave 2,3-di-*p*-anisylbutene-2 (X) and 3,4-di-*p*-anisylhexene-3 (XII), so-called diethylstilbestrol dimethyl ether, in 32 and 19% yields, respectively. As described above, Zaheer, *et al.*,[5] were unable to prepare 3,4-di-*p*-anisylhexene-3 (XII) by the condensation of 4-chlorohexanone-3 (XI) with anisole in the presence of sulfuric acid or aluminum chloride. It was found that the reaction with titanium tetrachloride gave an oil, presumably the *cis* form of 3,4-di-*p*-anisylhexene-3 (XII), in a 51% yield, and that when the oil was treated with iodine in chloroform solution[9] the stilbestrol ether (XII) was obtained in crystalline form.

$$\underset{\text{IX}}{CH_3COCHClCH_3} + 2CH_3OC_6H_5 \xrightarrow{TiCl_4} \underset{\text{II}}{} p\text{-}CH_3OC_6H_4C(CH_3){=}\underset{\text{X}}{C(CH_3)C_6H_4OCH_3\text{-}p}$$

$$\underset{\text{XI}}{C_2H_5COCHClC_2H_5} + 2CH_3OC_6H_5 \xrightarrow{TiCl_4} \underset{\text{II}}{} p\text{-}CH_3OC_6H_4C(C_2H_5){=}\underset{\text{XII}}{C(C_2H_5)C_6H_4OCH_3\text{-}p}$$

An attempted condensation of 4-chlorohexanone-3 (XI) with phenol under the same conditions, however, failed to afford 3,4-di-*p*-hydroxyphenylhexene-3. A considerable quantity of starting materials besides a small amount of tar was recovered.

Experimental[10]

Tetra-*p*-anisylethane (III and IV).—To a solution of 10.0 g. (0.054 mole) of α-chloro-*p*-methoxyacetophenone (I) in 150 g. of anisole (II), 100 g. of concentrated sulfuric acid was added dropwise with stirring. The addition required about 40 minutes, during which the temperature was maintained below 0°. The stirring was continued for an additional six hours at 20° and the mixture was allowed to stand overnight. Ice-cold water was then added and the product was extracted with benzene. The benzene solution was washed with dilute sodium hydroxide solution and water. After distilling off the solvent the residue was subjected to steam distillation in order to remove excess anisole. The residue was taken up in benzene, dried over anhydrous sodium sulfate, the solvent was removed on a water-bath, and the residue was recrystallized from ethanol. Distillation of the crystals gave 2.4 g. of unchanged chloroketone I and 1.9 g. of 1,1,2,2-tetra-*p*-anisylethane (IV) boiling at 265–272° (3 mm.), which melted at 190°[11] after a single recrystallization from glacial acetic acid.

Anal. Calcd. for $C_{30}H_{30}O_4$: C, 79.27; H, 6.65. Found: C, 79.14; H, 6.78.

On the other hand, distillation of the mother liquor of the recrystallization gave 1.3 g. of I and 1.8 g. of 1,1,1,2-tetra-*p*-anisylethane (III) boiling at 265–275° (3 mm.) which melted at 149–150°[12] after several recrystallizations from glacial acetic acid.

Anal. Calcd. for $C_{30}H_{30}O_4$: C, 79.27; H, 6.65. Found: C, 79.15; H, 6.52.

1,1-Di-*p*-anisylethylene (V).—To a solution of 10.0 g. (0.054 mole) of α-chloro-*p*-methoxyacetophenone (I) in 150 g. of anisole (II), 14.6 g. (0.109 mole) of anhydrous aluminum chloride was added below 10° in small portions, and the mixture was heated at 92–94° for five hours, during which time a vigorous evolution of hydrogen chloride was observed. After cooling, the reaction mixture was poured into ice-cold dilute hydrochloric acid. The product was taken up as usual and the distillation gave 1 g. of 1,1-di-*p*-anisylethylene (V) boiling at 167–180° (4 mm.) and 3 g. of a brown resinous product boiling at 261–263° (4 mm.). The former product melted at 139–141° after several recrystallizations from ethanol and showed no depression when admixed with an authentic specimen.[13] The latter fraction could not be crystallized.

1,1,2-Tri-*p*-anisylethylene (VI).–A solution of 10.0 g. (0.054 mole) of α-chloro-*p*-methoxyacetophenone (I) in 150 g. of anisole (II) was cooled with an ice–salt-bath and 20.9 g. (0.110 mole) of titanium tetrachloride was added dropwise with stirring at a rate sufficient to maintain the temperature at about −3°. After the addition was completed, the mixture was heated at 35–37° for five hours. An evolution of hydrogen chloride took place in the initial stage of the reaction. The dark-brown sticky product was poured into a mixture of 200 g. of crushed ice and 20 ml. of concentrated hydrochloric acid and the precipitated oil was extracted with benzene. The benzene solution was washed with dilute sodium hydroxide solution and water. After distilling off the solvent the residue was subjected to steam distillation. The residue was taken up in benzene and dried over calcium chloride. After removing the solvent, distillation of the residue gave 2.5 g. of unchanged chloroketone I followed by the product boiling at 245–260° (4 mm.) which was crystallized from glacial acetic acid. A single recrystallization from glacial acetic acid gave 10.0 g. (53%) of 1,1,2-tri-*p*-anisylethylene (VI), m.p. 97–99°,[14] which showed no depression when admixed with the product prepared by the Grignard reaction in the previous paper.[1]

When this reaction mixture was treated at 0–35° for 6 hours, the evolution of hydrogen chloride was not vigorous and 2.0 g. of 1,1,1,2-tetra-*p*-anisylethane (III) boiling at 260–275° (4 mm.) was obtained, which melted at 149° after a single recrystallization from glacial acetic acid. In addition 0.8 g. of 1,1,2-tri-*p*-anisylethylene (VI) also was isolated from the mother liquor of the recrystallization.

1,2-Di-*p*-anisyl-1-phenylethylene (VIII).—To a solution of 10.0 g. (0.065 mole) of α-chloroacetophenone (VII) in 150 g. of anisole (II), 24.7 g. (0.130 mole) of titanium tetrachloride was added dropwise below 0°. The addition required about 40 minutes, after which time the mixture was immediately poured into ice-cold dilute hydrochloric acid. The product was taken up as usual, and the distillation gave 15.5 g. of a resinous product boiling at 235–243° (4 mm.), which was crystallized to yield 12.4 g. (61%) of 1,2-di-*p*-anisyl-1-phenylethylene (VIII) by the treatment with ethanol. Fractional recrystallization from ethanol gave nearly the same quantity of two crystalline products which were considered to be *cis* and *trans* isomers. The less soluble one melted at 105.5–107° (VIIIa), while the substance isolated from the mother liquor melted at 92–94° (VIIIb).[8] Each mixed melting point with the products prepared by the use of the Grignard reaction between α-chloroacetophenone (VII) and *p*-anisylmagnesium bromide showed no depression.

When the stirring was continued for an additional 2.5 hr. at 0° after the addition was completed, 8.2 g. (40%) of 1,2-di-*p*-anisyl-1-phenylethylene (VIII) boiling at 230–240° (5 mm.) and 4.0 g. of 1,1,2-tri-*p*-anisyl-1- or -2-phenylethane boiling at 245–260° (5 mm.), which melted at 113–114° after a single recrystallization from ethanol, were obtained.

Anal. Calcd. for $C_{29}H_{28}O_3$: C, 82.05; H, 6.65. Found: C, 82.23; H, 6.64.

2,3-Di-*p*-anisylbutene-2 (X).—To a stirred mixture of 5.3 g. (0.050 mole) of 3-chlorobutanone (IX)[15] and 10.8 g. (0.100 mole) of anisole (II), 19.0 g. (0.100 mole) of titanium tetrachloride was added dropwise during 1.5 hr. at 0–5°, and the mixture was allowed to stand for five hours at the same temperature. The product was poured into ice-cold hydrochloric acid and was extracted with ether. The extract was washed with dilute sodium hydroxide solution and water and dried over anhydrous sodium sulfate. Distillation gave 4.3 g. (32%) of 2,3-di-*p*-anisylbutene-2 (X) boiling at 180–200° (5 mm.), which melted at 129–130° after a single recrystallization from methanol and the mixed m.p. with an authentic sample[16] showed no depression.

3,4-Di-*p*-anisylhexene-3 (XII).—To a mixture of 17.5 g. (0.15 mole) of propionoin and 18.0 g. (0.15 mole) of dimethylaniline, 18.3 g. (0.15 mole) of thionyl chloride was added at 0–5° with vigorous stirring. The addition required about 1.5 hr., during which the mixture almost solidified. The mixture was slightly heated until the semi-solid was dissolved, poured into water and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. Distillation gave 8.0 g. (39%) of 4-chlorohexanone-3 (XI) boiling at 42–43° (8 mm.).

A mixture of 8.0 g. of (0.059 mole) of 4-chlorohexanone-3 (XI) and 12.8 g. (0.118 mole) of anisole (II) was treated with 22.6 g. (0.119 mole) of titanium tetrachloride below 0° in the manner described above and the product was worked up as usual. Distillation gave 9.0 g. (51%) of yellow viscous oil boiling at 196–200° (8 mm.) which could not be crystallized. When the oil was treated with 1.0 g. of iodine in 190 ml. of chloroform,[9] 3.3 g. (19%, based on XI) of 3,4-di-*p*-anisylhexene-3 (XII) was obtained. A single recrystallization from petroleum ether gave colorless plates melting 123–124°, which showed no depression when admixed with an authentic specimen.[16]

D-Homo Rearrangement of 11-Oxygenated 17α-Hydroxy-20-ketosteroids

BY EUGENE P. OLIVETO, CORINNE GEROLD, RICHARD RAUSSER AND E. B. HERSHBERG

RECEIVED JANUARY 18, 1957

Reaction of 11-oxygenated 17α-hydroxy-20-ketopregnanes with refluxing acetic anhydride was found to produce D-homo rearrangement products rather than the expected 17α-acetoxy-20-ketosteroids.

Two methods are claimed to be satisfactory for the preparation of 17α-acetates from a 17α-hydroxy-20-ketone: reaction of the ketol with an acylating agent and an acid catalyst at room temperature,[1,2] or with refluxing acetic anhydride alone.[2]

By this last procedure 3α-acetoxy-17α-hydroxypregnane-11,20-dione (II) was reported to be converted into its diacetate XIV in good yield.[2] We attempted to prepare the same compound XIV from 3α,17α-dihydroxypregnan-11,20-dione (I). The use of acetic anhydride, either redistilled or not, gave no isolable XIV but a different compound. This was identified as a D-homo rearrangement product, since it was identical with the compound obtained from I upon reaction with boron trifluoride in acetic acid–acetic anhydride. With the 3-acetate II and refluxing acetic anhydride, however, we did obtain the expected 3,17-diacetate but in lower yield than the previous workers. The diacetate also was obtained from II if the acetic anhydride contained acetic acid.

Our studies were then extended to other 11-oxygenated 17α-hydroxy-20-ketosteroids. Both 3α,-11β,17α-trihydroxypregnan-20-one 11-acetate (III) and 3α,11α,17α-trihydroxypregnan-20-one 3,11-diacetate (IV) were converted to D-homo rearrangement products VI and X identical with those obtained by reaction with boron trifluoride. With all three starting materials, acetic anhydride gave at least as good yields as boron trifluoride.

The rearrangement products were all submitted to lithium aluminum hydride and sodium–alcohol reductions. Reaction of X with either reducing agent gave the same tetrol XIII. Reduction of IX and VI with lithium aluminum hydride gave two different tetrols (which we formulate as XI and XII) while reduction of IX with sodium gave the same tetrol XIII which had been obtained from X. These results suggest that the D-ring structures of IX and X are similar, while those of IX and VI are different. Unfortunately the yields in most of the reduction experiments were too low to permit positive conclusions to be drawn. However, further evidence was obtained from a study of the Zimmerman reaction on VI, IX and X, and by a comparison of molecular rotation differences.

The Zimmerman test for active methylene groups[3] was strongly positive with compound VI (derived from III) and essentially negative with IX (from I) and X (from IV),[4] indicating that IX and X have the 17a keto structures. In addition, the molecular rotation changes (ΔM_D) for the transformations II → IX and IV → X are in good agreement with the values reported by Fukushima[3] for the conversion of a 17α-hydroxy-20-ketosteroid to a 17α-hydroxy-17a-keto-D-homo-steroid, and the molecular rotation change for the transformations XV → VIII and III → VII are also in fair agreement with the expected value. However, the ΔM_D for the change XV → VI is far from the published figure (Table I).

TABLE I

MOLECULAR ROTATION DIFFERENCES

	$[\alpha]_D$	M_D	ΔM_D
3α,17α-Dihydroxypregnane-11,20-dione 3-acetate (II)	+50.3	+196	+276
3α,17α-Diacetoxy-17β-methyl-D-homoetiocholane-11,17a-dione (IX)	+109.4	+472	
ΔM_D (17α-OH,20-C=O → 17-OAc,17a-C=O) ~ + 290			
3α,11α,17α-Trihydroxypregnan-20-one 3,11-diacetate (IV)	− 7.7	− 33	+128
3α,11α,17α-Triacetoxy-17β-methyl-D-homoetiocholan-17a-one (X)	+19.9	+ 95	
ΔM_D (17α-OH, 20-C=O → 17-OH,17a-C=O) ~ + 135			
3α,11β,17α-Trihydroxypregnane-20-one 11-acetate (III)	+35.6	+140	− 15
11β-Acetoxy-3α,17aα-dihydroxy-17aβ-methyl-D-homoetiocholan-17-one (VII)	+32.5	+125	
3α,11β,17α-Trihydroxypregnane-20-one 3,11-diacetate (XV)	+62.6	+271	− 35
3α,11β-Diacetoxy-17aα-hydroxy-17aβ-methyl-D-homoetiocholan-17-one (VIII)	+54.2	+235	
ΔM_D (17α-OH,20-C=O → 17a-OH,17-C=O) ~ −70			
3α,11β-17α-Trihydroxypregnane-20-one 3,11-diacetate (XV)	+62.6	+271	−271
3α,11β,17aα-Triacetoxypregnane-17aβ-methyl-D-homoetiocholan-17-one (VI)	0.0	0	
ΔM_D (17α-OH,20-C=O → 17a-OAc,17-C=O) ~ + 40			

No simple explanation is immediately apparent to explain the fact that I, III and IV give D-homo products, and II the normal diacetate.[5] Pending

(1) R. Turner, THIS JOURNAL, 75, 3489 (1953).

(2) Huang-Minlon, E. Wilson, N. Wendler and M. Tishler, *ibid.*, 74, 5394 (1952).

(3) *Cf.* D. Fukushima, S. Dobriner, M. Heffler, T. Kritchevsky, F. Herling and G. Roberts, *ibid.*, 77, 6585 (1955).

(4) The 12-methylene group of IX adjacent to the 11-ketone is apparently sufficiently hindered so that only a faint color is obtained in the Zimmerman reaction. The same faint color is obtained with I.

(5) It is, of course, quite possible that *mixtures* of D-homo and normal products are obtained which we have made no particular attempt to separate. However, one would presume that the fastest reaction of I with hot acetic anhydride would be formation of the 3-acetate II, and that therefore I and II should give the same isolable

further investigation, it would seem that the use of refluxing acetic anhydride to prepare 17α-acetates is not as satisfactory as room temperature acylations with an acid catalyst.

Experimental[6]

3α,11β,17aα-Triacetoxy-17aβ-methyl-D-homoetiocholan-17-one (VI). A.—A solution of 1.0 g. of 3α,11β,17α-trihydroxypregnan-20-one-11-acetate (III) in 35 ml. of acetic acid, 2 ml. of acetic anhydride and 2 ml. of boron trifluoride–ether complex was allowed to stand overnight at 25°. The mixture was poured into water, the solid removed by filtration and triturated with ether to give 0.08 g. of VI, m.p. 235–255°. One crystallization from methanol raised the m.p. to 258–262°.

B.—A solution of 10.0 g. of 3α,11β,17α-trihydroxypregnan-20-one in 100 ml. of C.P. acetic anhydride was refluxed for 12 hours. The solvent was removed under reduced pressure, and the crystalline residue sludged with 75 ml. of ether to yield 4.96 g. of VI, m.p. 260–263°. Two crystallizations from methanol raised the m.p. to 267–268°, $[\alpha]_D$ 0.0°.

Anal. Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 67.82; H, 8.62.

The use of acetic anhydride which had been freshly distilled through a glass-packed column gave the same compound, but in somewhat lower yield (0.2 g. from 1 g.). The infrared spectra of the two compounds prepared in (A) and (B) were identical, and did not match the spectrum of 3α,11β,17α-triacetoxypregnan-20-one. Both also gave strong Zimmerman tests.

11β-Acetoxy-3α,17aα-dihydroxy-17aβ-methyl-D-homoetiocholan-17-one (VII).—A mixture of 1.0 g. of VI, 0.5 g. of potassium carbonate, 40 ml. of C.P. methanol and 4 ml. of water was refluxed for 2.5 hours. The excess carbonate was then neutralized with acetic acid, the methanol removed under reduced pressure, and the residue diluted with water to precipitate 0.79 g. of crude material, m.p. 131–143°. The analytical sample, crystallized twice from ether–hexane, melted at 173–174°, $[\alpha]_D$ +32.5°.

Anal. Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.47; H, 9.31.

3α,11β-Diacetoxy-17aα-hydroxy-17aβ-methyl-D-homoetiocholan-17-one (VIII).—A solution of 130 mg. of VII in 4 ml. of pyridine and 1 ml. of acetic anhydride was allowed to stand 17 hours at 25°. The solution was then poured into ice and water containing excess hydrochloric acid to give 120 mg. of solid. Crystallization from ether–pentane gave 70 mg. of VIII, m.p. 197–201°, $[\alpha]_D$ +54.2°.

Anal. Calcd. for $C_{25}H_{38}O_6$: C, 69.09; H, 8.81. Found: C, 68.85; H, 8.54.

3α,17α-Diacetoxy-17β-methyl-D-homoetiocholane-11,17a-dione (IX). A.—A solution of 1.0 g. of 3α,17α-dihydroxypregnane-11,20-dione (I) in 35 ml. of acetic acid, 2 ml. of acetic anhydride and 2 ml. of boron trifluoride–ether complex was allowed to stand overnight at 25°. Addition of water precipitated 1.15 g., m.p. 105–145°. Trituration with ether, followed by recrystallization from aqueous methanol, gave 0.38 g., m.p. 169–171°; lit.[7] m.p. 167–168.5°.

Anal. Calcd. for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39. Found: C, 69.62; H, 8.54.

B.—A solution of 1.0 g. of I in 25 ml. of C.P. acetic anhydride was refluxed for 12 hours. The solvent was removed under reduced pressure, the residue taken up in methylene chloride, the organic layer washed with dilute sodium carbonate solution, twice with water, dried and evaporated to yield 1.24 g. of a pale yellow resin which crystallized on the addition of methanol. Trituration with ether, followed by recrystallization from aqueous methanol, gave 0.51 g. of IX, m.p. 163–167°, $[\alpha]_D$ +109.4°. The use of acetic anhydride freshly distilled through a glass-packed column gave the same compound in slightly lower yield.

The infrared spectra of either sample was identical with that of the compound obtained by means of boron trifluoride, and was not identical with the spectrum of 3α,17α-diacetoxy pregnane-11,20-dione.

Treatment of 3α,11β,17α-triacetoxypregnan-20-one or 3α,17α-diacetoxypregnane-11,20-dione with refluxing acetic anhydride for 12 hours as described above resulted in almost quantitative recovery of starting material in both cases.

(6) All m.p.'s are corrected. All rotations were taken in a one dm. tube in chloroform at a concentration of *ca.* 1% and at 25°. Analyses and optical data were obtained by the Microanalytical and Physical Chemistry Departments of these laboratories.

3α,11α,17α-Triacetoxy-17β-methyl-D-homoetiocholan-17a-one (X). A.—A solution of 1.0 g. of 3α,11α,17α-trihydroxypregnan-20-one 3,11-diacetate (IV) in 35 ml. of glacial acetic acid was combined with 2 ml. of acetic anhydride and 2 ml. of boron trifluoride etherate. After standing for 16 hours at 30–35°, the reaction was poured into water, yielding 1.07 g. of a gel. Crystallization from hexane gave 0.94 g. of needles, m.p. 184–186°. The analytical sample, crystallized once more, melted at 186–189°, $[\alpha]_D$ +19.9°.

Anal. Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 68.23; H, 8.82.

B.—A solution of 1.0 g. of IV in 25 ml. of acetic anhydride was refluxed for 12 hours. The solvent was removed under reduced pressure, leaving a crystalline residue. Crystallization from aqueous methanol yielded 0.93 g. of X, m.p. 187–190°. A mixture melting point with the boron trifluoride product showed no depression, and the infrared spectra of the two were identical.

Lithium Aluminum Hydride Reductions. A.—A solution of 1.0 g. of IX in 45 ml. of tetrahydrofuran was added dropwise with stirring to a suspension of 2.0 g. of lithium aluminum hydride in 15 ml. of tetrahydrofuran. The suspension was stirred overnight at 25°, the excess hydride was decomposed by the addition of 10 ml. of ethyl acetate followed by 5 ml. of water, and the mixture poured into ice-water containing 25 ml. of concentrated hydrochloric acid. This was extracted with methylene chloride, the extracts washed with dilute sodium bicarbonate and water, dried and evaporated to give 0.65 g. of a crystalline residue. Two recrystallizations from ethyl acetate yielded 0.22 g. of XII, m.p. 260–275°. The infrared spectrum disclosed the absence of carbonyl or acetate groups.

Anal. Calcd. for $C_{21}H_{36}O_4$: C, 71.55; H, 10.30. Found: C, 71.29; H, 10.65.

B.—The identical procedure was used for the reduction of 1.0 g. of VI; there was obtained 0.12 g. of XI, m.p. 260–270°. This material also did not possess any acetate or carbonyl groups, but its infrared spectrum was not identical with that of XII.

Anal. Calcd. for $C_{21}H_{36}O_4$: C, 71.55; H, 10.30. Found: C, 71.52; H, 10.62.

C.—A solution of 1.0 g. of X in 30 ml. of tetrahydrofuran was added dropwise to a stirred suspension of 2.0 g. of lithium aluminum hydride in 50 ml. of anhydrous ether. The mixture was refluxed for 17 hours, then allowed to stand with stirring at room temperature for 48 hours. The reaction was cooled in an ice-bath, and the excess reagent destroyed by the addition of 2 ml. of water, 2 ml. of 15% sodium hydroxide and 6 more ml. of water. The resulting suspension was allowed to warm up to room temperature and stir for 20 minutes. The solids were removed by filtration and washed thoroughly with tetrahydrofuran and methylene chloride. The solids were stirred with 200 ml. of ice-water containing 20 ml. of concentrated sulfuric acid. Filtration gave 0.27 g. of crystals, m.p. 265–272°.

The original filtrate was evaporated to dryness to yield 0.50 g. of a gum; triturating with acetone gave 0.29 g. of crystals, m.p. 235–275°.

The two crystalline fractions were combined and recrystallized from ethanol–hexane to give 0.34 g. of XIII, m.p. 292–300°. The analytical sample, crystallized once more, melted at 300–307°.

Anal. Calcd. for $C_{21}H_{36}O_4$: C, 71.55; H, 10.30. Found: C, 71.37; H, 10.13.

Sodium–Alcohol Reductions. A.—Ten portions of sodium totalling 2 g. were added to a refluxing solution of 0.50 g. of IX in 75 ml. of isopropyl alcohol; the total reaction time was 5 hours. The solution was then poured onto ice and 10 ml. of acetic acid was added to lower the *p*H to *ca.* 7. The solution was then extracted with methylene chloride, and the organic extracts were washed with water, dried and evaporated to yield 0.45 g. of a crystalline residue. Trituration with ethyl acetate left 0.17 g. Recrystallization from aqueous methanol gave 85 mg. of XIII, m.p. 230–237° with bubbling. Its infrared spectrum was identical with that of the $LiAlH_4$ reduction product of X.

B.—A similar sodium reduction of 0.50 g. of X gave 95 mg. of XIII, m.p. 265–278° with bubbling, identical in its infrared spectrum with the two other samples of XIII. The wide variation in m.p. between the three samples of compound XIII might possibly be due to varying degrees of solvation, but this could not be proven definitely.

3α,17α-Diacetoxypregnane-11,20-dione (XIV). A.—A solution of 2.0 g. of 3α,17α-dihydroxypregnane-11,20-dione-3-acetate (II) in 40 ml. of C.P. acetic anhydride was refluxed for 12 hours. The excess anhydride was decomposed at reflux by the slow addition of water, the solution poured into ice and water and the resulting precipitate filtered and dried: 1.67 g., m.p. 160–180°. Crystallization from methanol yielded 0.66 g., m.p. 195–199°, and 0.20 g. m.p. 192–197°.

B.—Repetition of the above experiment, with 1.2 g. of acetic acid added, gave 0.80 g. of XIV, m.p. 196–199°, $[\alpha]_D$ +50.4°; lit.[2] m.p. 203–204°, $[\alpha]_D$ +46.7° ($CHCl_3$).

Some Transformation Products of Cortisone Acetate

BY EUGENE P. OLIVETO, CORINNE GEROLD AND E. B. HERSHBERG

RECEIVED JANUARY 22, 1957

Addition of HOBr to cortisone acetate, followed by treatment with potassium acetate, gave the 4,5α- and 4,5β-epoxides III and IV. Reaction of either of these with HBr, or warming the intermediate bromohydrins with acetic acid, gave 4-bromocortisone acetate (V). 4-Chlorocortisone acetate (VI) was prepared by the action of HCl on the β-epoxide. Compound VI was also the main product from the addition of HOCl to cortisone acetate. Opening the β-epoxide with acid gave the 4,5-glycol IX.

Relatively simple changes in the structure of cortisone have resulted in marked increase in corticoid activity. For example, introduction of a 9α-fluorine atom increases the glucocorticoid activity by a factor of about 9 with an even greater enhanced mineralocorticoid activity.[1] Even more startling, the introduction of an added double bond to produce 1-dehydrocortisone enhances the glucocorticoid activity three- to fourfold, without increasing the salt-retaining properties.[2] It seemed desirable, therefore, to prepare other simple derivatives of cortisone.

Addition of hypobromous acid (N-bromoacetamide and perchloric acid) to the 4,5-double bond of cortisone acetate, followed by treatment with potassium acetate, resulted in the formation of two epoxides: The major one had m.p. 224–227°, $[\alpha]_D$ +142°, and the minor product, m.p. 248–255°, $[\alpha]_D$ +34.9°. In order to help assign configurations, 4-cholesten-3-one was converted to its two epimeric epoxides; the β-epoxide[3] had $[\alpha]_D$

$+123.8°$, and the α-epoxide (prepared from cholestenone with H_2O_2 and an acid resin) had $[\alpha]D$ $-33.4°$. The lower-melting epoxide with a more positive rotation derived from cortisone acetate is therefore assigned the β-configuration, and the higher-melting, lower-rotation epimer the α-configuration. Recently, Ringold, *et al.*,[4] prepared the $4\alpha,5\alpha$-epoxide of cortisone by alkaline hydrogen peroxide treatment of the 3-keto-Δ^4-system and reported m.p. 235–237°, $[\alpha]D$ $-13°$. This is in agreement with our assignment of the α-configuration to our acetate of m.p. 248–255°, $[\alpha]D$ $+34.9°$.

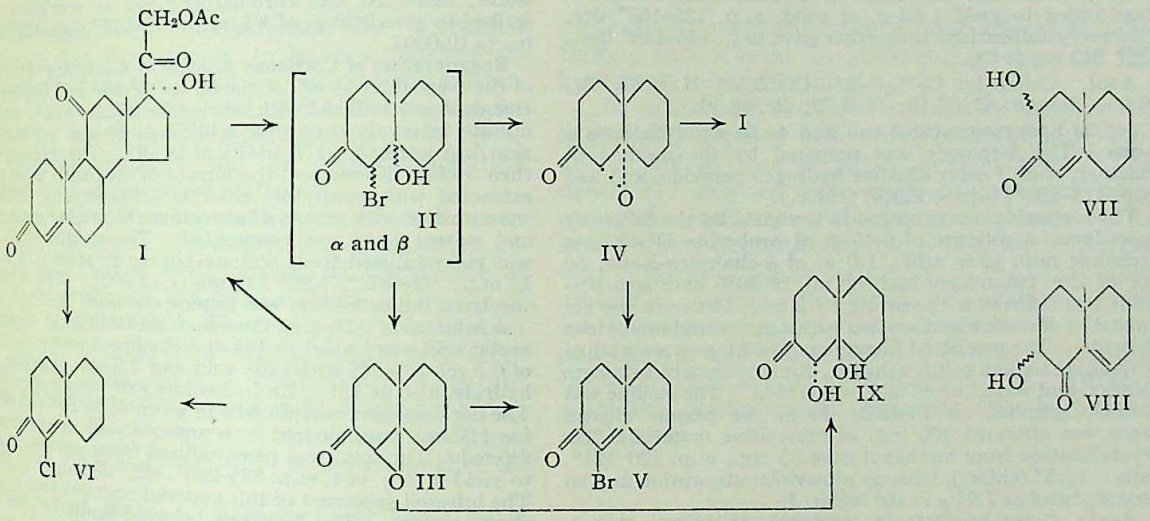
The intermediate bromohydrins could not be isolated in pure state, but treatment of the crudes with hydrogen bromide in acetic acid at room temperature, or warming with acetic acid alone, produced 4-bromocortisone acetate, λ_{max}^{EtOH} 260 mμ (ϵ 11,200). This latter compound could be prepared from either epoxide by reaction with hydrogen bromide in acetic acid. Debromination by vigorous treatment with zinc and acetic acid regenerated cortisone acetate.

Addition of hypochlorous acid (N-chlorosuccinimide and perchloric acid) to cortisone acetate, followed by potassium acetate treatment, gave, as the main product, 4-chlorocortisone acetate (VI) rather than either epoxide. Compound VI was also prepared readily by the action of hydrogen chloride in acetic acid on the β-epoxide.

Reaction of either epoxide with hydriodic acid in acetic acid readily regenerated cortisone acetate. Zinc dust treatment of the β-epoxide also gave cortisone acetate but in an impure state.

Opening of the β-epoxide with aqueous perchloric or trifluoroacetic acid gave a glycol, which, if our formulation of the epoxide is correct, must be the $4\alpha,5\beta$-diol. The α-epoxide, however, on treatment with trifluoroacetic acid failed to react. These results differ from those obtained with the two epoxides derived from testosterone.[5] In this latter case, the β-epoxide with dilute sulfuric acid in acetone rearranged to 2α-hydroxytestosterone, while the α-epoxide with the same reagent gave the $4\beta,5\alpha$-diol.

In one reaction with the β-epoxide and perchloric acid, the reaction time was extended from 18 to 72 hr., and a small amount of a second product was obtained with an ultraviolet maximum at 236 mμ (ϵ 13,200) and with an analysis corresponding to $C_{23}H_{30}O_7$. Two possible structures for this compound are VII and VIII: The first might arise by rearrangement and the second by dehydration of the 5-hydroxyl with a hydrogen at C-6, followed by a keto–enol shift. Unfortunately, not enough material was available for further study.



Experimental[6]

$4\beta,5\beta$-Epoxypregnane-17α,21-diol-3,11,20-trione 21-Acetate (IV) and $4\alpha,5\alpha$-Epoxyallopregnane-17α,21-diol-3,11,20-trione 21-Acetate.—A suspension of 20.0 g. of cortisone acetate (I) in 1 liter of tetrahydrofuran and 100 ml. of water was chilled in an ice-bath, and 100 ml. of 1 *N* aqueous perchloric acid and 13.8 g. of N-bromoacetamide were added. The ice-bath was removed after the reaction was homogeneous (*ca.* 1 hr.) and then stirred and protected from light for 72 hr. at 25°. At the end of this time, a starch–iodide test was either negative or very weak. The solution was diluted with water containing a small amount of sodium sulfite and extracted with methylene chloride. The combined organic extracts were washed with dilute sodium bicarbonate solution and water, dried over magnesium sulfate and concentrated to dryness under reduced pressure. The resinous residue was taken up in 1 liter of acetone, 40 g. of potassium acetate added and the mixture refluxed with stirring for 5 hr. Water was added, the mixture extracted with methylene chloride, and the organic extracts were washed with water, dried and concentrated under reduced pressure. The crystalline residue was reacetylated by reaction with 100 ml. of pyridine and 15 ml. of acetic anhydride for 1 hr. The excess anhydride was destroyed by the addition of 40 ml. of water and the mixture poured into excess dilute sulfuric acid and ice, then extracted with methylene chloride. The residue obtained from the organic extracts was chromatographed on Florisil. Elution with 50% methylene chloride–benzene yielded a crystalline mixture of the α- and β-epoxides.

Crystallization from acetone–hexane yielded 2.32 g. of α-epoxide, m.p. 240–247°; concentration of the mother liquor yielded 4.40 g. of β-epoxide, m.p. 224–229°. The former was purified by three additional crystallizations from acetone, m.p. 248–255°, $[\alpha]D$ $+34.9°$ (chlor.).

Anal. Calcd. for $C_{23}H_{30}O_7$: C, 66.01; H, 7.23. Found: C, 66.15; H, 7.33.

The β-epoxide was crystallized from acetone–hexane, m.p. 224–227°, $[\alpha]D$ +142.2° (chlor.).

Anal. Calcd. for $C_{23}H_{30}O_7$: C, 66.01; H, 7.23. Found: C, 65.74; H, 7.16.

Further elution of the Florisil column with methylene chloride, and methylene chloride–methanol gave fractions having increasing ultraviolet absorption at 238 mμ.

Instead of perchloric acid, either trifluoroacetic acid or Amberlite IR-120 ion exchange resin (free acid form) could be used.

The intermediate bromohydrins could not be obtained pure, because of their instability and the ease with which they were converted to 4-bromocortisone acetate. The resinous bromohydrin from the addition of HOBr to 1 g. of cortisone acetate was dissolved in ether, and pentane was then added to yield 1.02 g. of solid, m.p. 125–150° dec. Two recrystallizations from ether gave m.p. 145–148° dec., λ_{max}^{EtOH} 242 mμ (ε 73).

Anal. Calcd. for $C_{23}H_{31}O_7Br$: C, 55.31; H, 6.26; Br, 16.00. Found: C, 56.18; H, 6.72; Br, 16.16.

4β,5β-Epoxycoprostan-3-one and 4α,5α-Epoxycholestan-3-one.—The β-epoxide was prepared by the method of Plattner, *et al.*,[3] using alkaline hydrogen peroxide, and had m.p. 118–120°, $[\alpha]D$ +123.8° (chlor.).

The α-epoxide was prepared in low yield by the following procedure: A mixture of 0.45 g. of Amberlite IR-120 ion exchange resin (free acid), 1.0 g. of 4-cholesten-3-one, 50 ml. of C.P. chloroform and 3.0 ml. of 30% hydrogen peroxide was refluxed with stirring for 3 hr. The resin was removed by filtration and washed with acetone and methylene chloride. The combined filtrate and washings were washed with dilute sodium sulfite solution, dilute sodium bicarbonate solution and water, dried and evaporated. The residue was chromatographed on Florisil. From the hexane eluates there was obtained 100 mg. of crystalline material. Recrystallization from methanol gave 35 mg., m.p. 120–121°, $[\alpha]D$ −42.5° (chlor.), with no ultraviolet absorption and an epoxide band at 7.91 μ in the infrared.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07. Found: C, 80.62; H, 10.98.

4-Bromocortisone Acetate (V).—The crude bromohydrins obtained from 1 g. of cortisone acetate were dissolved in 10 ml. of acetic acid and heated on the steam-bath for 30 minutes. Dilution with water gave crystals contaminated with a dark oil. The mixture was extracted with methylene chloride, the organic extracts washed with dilute sodium bicarbonate and water, dried and evaporated. The residue was reacetylated in the usual manner, and the resulting 1.02 g. of crystalline material was chromatographed on Florisil. The material eluted with 50% benzene–methylene chloride was recrystallized from acetone–hexane to give 0.22 g. of V, m.p. 170–173° dec., $[\alpha]D$ +196.2° (diox.), λ_{max}^{EtOH} 260 mμ (ε 10,400). Two crystallizations from acetone–hexane gave a m.p. of 178–181° dec.

Anal. Calcd. for $C_{23}H_{29}O_6Br$: Br, 16.60. Found: Br, 16.20.

The crude bromohydrins also could be converted to V by treatment with hydrogen bromide. The resin from the addition of HOBr to 2.5 g. of cortisone acetate was dissolved in 25 ml. of acetic acid, and 5 ml. of acetic acid saturated with hydrogen bromide added. After standing for 1 hr. at 25°, the reaction was diluted with water, extracted and chromatographed in the usual way to give 0.46 g., m.p. 183–185° dec., λ_{max}^{EtOH} 260 mμ (ε 11,200).

Reaction of either epoxide III or IV with HBr in acetic acid by the following procedure also gave V.

A mixture of 0.3 g. of III in 10 ml. of acetic acid was combined with 0.6 ml. of 4 *N* hydrogen bromide in acetic acid. After 1 hr. at 25°, water was added, the precipitated solids were removed by filtration, dried and recrystallized from acetone–hexane to yield 0.23 g. of V, m.p. 189–191° dec. All samples of V were identical in their infrared spectra. The reported[3,7] ultraviolet absorption for 3-keto-Δ⁴-4-bromo-steroids is λ_{max} 258–261 mμ (ε 10–12,000).

4-Chlorocortisone Acetate (VI).—A solution of 0.20 g. of the β-epoxide III in 5 ml. of glacial acetic acid was combined with 1 ml. of glacial acetic acid saturated with hydrogen chloride. The solution was allowed to stand for 1 hr. at 25° and was then poured into water. The resulting white gel (0.18 g.) was recrystallized from acetone–hexane to yield 0.13 g. of VI, m.p. 227–231° dec., $[\alpha]D$ +223.8° (chlor.), λ_{max}^{MeOH} 253 mμ (ε 11,200); lit.[8] m.p. 232–234° dec., $[\alpha]D$ +214° (diox.), λ_{max} 253 mμ (ε 12,900).

The same product, 4-chlorocortisone acetate, was obtained *via* the addition of hypochlorous acid to cortisone acetate. This compound formed with such great ease that it was impossible to obtain any reasonably pure epoxide on potassium acetate treatment of the supposed chlorohydrin. The reaction of 1 g. of cortisone acetate and N-chlorosuccinimide (instead of N-bromoacetamide) gave, after potassium acetate treatment and chromatography, 0.3 g. of VI, m.p. 218–224° dec., λ_{max}^{EtOH} 252 mμ (ε 8,500).

The crude "chlorohydrin" from another 1-g. reaction was taken up in 20 ml. of glacial acetic acid and heated for 30 minutes on the steam-bath. The mixture was diluted with water, extracted and chromatographed as previously described to give 0.26 g. of VI, m.p. 210–222° dec., λ_{max}^{EtOH} 253 mμ (ε 10,000).

Regeneration of Cortisone Acetate.—A mixture of 0.15 g. of the β-epoxide, 15 ml. of glacial acetic acid and 150 mg. of zinc dust was refluxed with stirring for 30 minutes.[9] At 10-minute intervals thereafter additional 80-mg. portions of zinc dust were added (5 additions in all). The mixture was then cooled, filtered and the filtrate diluted with water and extracted with methylene chloride. The organic extracts were washed with water, dilute sodium bicarbonate solution and water, dried and evaporated. The residue (0.13 g.) was recrystallized from acetone–hexane to yield 0.07 g. of I, m.p. 196–202°, λ_{max}^{EtOH} 238 mμ (ε 12,500). The infrared spectrum indicated this was impure cortisone acetate.

A solution of 0.20 g. of the α-epoxide IV in 5 ml. of glacial acetic acid was cooled to 15° and combined with a mixture of 0.5 ml. of 48% hydriodic acid and 2.3 ml. of acetic anhydride, also at 15°. An immediate iodine color appeared. The dark solution was allowed to warm up to 25° and stand for 1.5 hr., then poured into aqueous sodium sulfite and filtered. The solid was recrystallized from acetone–hexane to yield 0.14 g. of I, m.p. 235–240°, λ_{max}^{EtOH} 238 mμ (ε 14,800). The infrared spectrum of this material matched that of cortisone acetate. The β-epoxide behaved similarly with hydriodic acid.

A solution of 0.20 g. of 4-bromocortisone acetate (V) in 20 ml. of ethanol and 5 ml. of glacial acetic acid was brought to reflux with stirring, and eight portions of zinc (200 mg. each) were added, one every 15 minutes. The solids were removed by filtration and washed with methylene chloride. The combined washings and filtrate were diluted with water and the organic extract washed with dilute sodium bicarbonate solution and water, dried and evaporated. Recrystallization of the residue from acetone–hexane yielded 0.12 g. of cortisone acetate (I), m.p. 225–231°, λ_{max}^{MeOH} 238 mμ (ε 13,000), identical in its infrared spectrum with an authentic sample.

4α,5β,17α,21-Tetrahydroxypregnane-3,11,20-trione 21-Acetate (IX).—A solution of 0.50 g. of the β-epoxide, 25 ml. of acetone, 5 ml. of water and 5 drops of trifluoroacetic acid was allowed to stand for 18 hr. at 25°. The solution was diluted with water and extracted with methylene chloride. The combined extracts were washed with dilute sodium bicarbonate solution and water, dried and evaporated. Crystallization of the residue from acetone–hexane gave 0.34 g. of IX, m.p. 228–234°. The analytical sample, crystallized twice more, had m.p. 230–235°, $[\alpha]D$ +203.0° (chlor.).

Anal. Calcd. for $C_{23}H_{32}O_8$: C, 63.28; H, 7.39. Found: C, 63.34; H, 7.12.

An 18-hr. run using perchloric acid as the catalyst and chromatographing the crude reaction product gave the same result. However, a 72-hr. run with perchloric acid followed by chromatography gave, besides the expected glycol, 50 mg. (from 0.50 g. of III) of a second product. Crystallization from acetone yielded 35 mg., m.p. 265–270°, λ_{max}^{MeOH} 236 mμ (ε 13,200). Compounds VII and VIII are possible structures.

Anal. Calcd. for $C_{23}H_{30}O_7$: C, 66.01; H, 7.23. Found: C, 65.91; H, 7.11.

The Effects of Deuterium Substitution on the Rates of Organic Reactions. V. Hydrolysis of α-Deutero Ketals[1]

BY V. J. SHINER, JR., AND SALLY CROSS

RECEIVED FEBRUARY 28, 1957

A study of the effect of deuterium substitution in the α-positions on the rates of hydrolysis of the diethyl ketals of acetone, methyl ethyl ketone, methyl isopropyl ketone and phenoxyacetone has been made. It has been found that the magnitude of the effect is solvent dependent and varies according to the nature of the substituents on the α-carbon atom. This is in general agreement with the results previously obtained for secondary deuterium isotope rate effects on the solvolysis of tertiary alkyl halides, although the rate effects are smaller in the present case. The results are interpreted as indicating that the assumption of Kreevoy and Taft, that the hyperconjugative release of electrons by a C–H bond is independent of the nature of the other substituents on the C-atom, is not quite correct.

The substitution of deuterium for β-situated hydrogen has been shown to have a marked retarding effect on the solvolysis rates of certain tertiary alkyl chlorides and related compounds. This effect has been explained tentatively in terms of hyperconjugation[2] and of hyperconjugation assisted by β-hydrogen solvation.[3]

It has further been shown that the effect is cumulative as the degree of β-deuterium substitution increases and that it is dependent on the nature of the other groups on the carbon which is the site of isotopic substitution.[3] For example, substitution of a deuterium atom for a secondary hydrogen atom in an ethyl group gives a smaller effect than obtains when the tertiary atom of an isopropyl group is replaced. Replacement of a primary hydrogen atom of a methyl group leads to a still smaller effect.

The recent work of Kreevoy and Taft[4] gives some of the best evidence in the literature for the effect of hyperconjugation on reaction rates. These authors were able to correlate the hydrolysis rates of a number of diethyl acetals and ketals with the Taft equation in the form $\log k/k_0 = \rho^*\Sigma\sigma^* + (n-6)h$, where k refers to the hydrolysis rate of any of the ketals or acetals studied, k_0 refers to the hydrolysis rate of diethyl acetonal, ρ^* is a reaction constant, σ^* is a substituent constant characteristic of the substituent on the ketal linkage, n is the number of α-C–H bonds in the acetal or ketal and h is a constant characteristic of the acceleration of the solvolysis rate due to the hyperconjugative effect of one C–H bond. The important thing to note for purposes of the present discussion is that the equation rather successfully correlates a large number of rate constants differing in magnitude over a wide range, with the assumption that each α-C–H bond hyperconjugates the same amount regardless of the nature of its environment in the molecule. Since this leads to a conclusion different from that obtained from the secondary deuterium isotope rate effects, *if* one assumes that the *variations* noted in the latter are due to variations in hyperconjugation, it was of interest to us to locate the apparent discrepancy more precisely by measuring the isotope effects of deuterium substitution in different groups on the hydrolysis rates of ketals.

The deuterated ketals were made by treating the deuterated ketones with ethyl orthoformate, ethanol-*d* and a trace of strong acid catalyst. The deuterated ketones were made by repeated base-catalyzed exchange with deuterium oxide. The ketones were deuterated in the α-position to the extent of 95–97% before being used in the ketal preparation. During the ketal preparations some spurious exchange apparently lowered the deuterium content and the deuterated ketals were not of the same high degree of isotopic purity. Table I gives the deuterium analyses for the deuterated ketals used.

TABLE I

DEUTERIUM ANALYSES OF KETALS

Ketal of	D, %	Atoms D/mole	Deut. of α-pos., %
Acetone	30.56	4.88	81.3
Methyl ethyl ketone	22.46	4.04	80.8
Methyl isopropyl ketone	13.23	2.65	66.2
Phenoxyacetone	21.19	4.24	84.8

The rates of hydrolysis of the ketals of acetone, methyl ethyl ketone and their deuterated analogs were first measured in an acetic acid–sodium acetate buffer in 50% (by weight) aqueous dioxane, the solvent used by Kreevoy and Taft. In order to make the isotope rate effects as large as possible, subsequent measurements on all of the compounds were done in 90% dioxane–10% water solution. The phenoxyacetone ketal hydrolyses were catalyzed by dilute hydrochloric acid and the others by a dichloroacetic acid–sodium acetate buffer.

The rate measurements were mainly made with a dilatometer, although several constants obtained in this way were checked using a spectrophotometric method. The rate constants were calculated by the statistical method for first-order reactions described by DeTar.[5] Fifty to seventy points were used in calculating the results for each run. The computation was programmed for an IBM 650 Magnetic Drum Data Processing Machine. The program yielded the rate constant, the constants a and b and the standard deviations for each. It is important to note that the statistical method successfully overcomes difficulties in reproducing rate constants which are associated with errors in

the zero and infinity readings. As a result the variations in the same rate constants from run to run are of the same order as the standard errors in a given run. The hydrolysis rate for each compound was measured in from two to five different runs and several times with different preparations of the ketals. With a few exceptions all of the reactions in a given solvent type were carried out with solvent from the same master batch. The common impurities encountered in the ketals, the hydrolysis products, ethyl formate and ethyl orthoformate do not affect the observed rates if they are present in only small amounts. Ethyl formate hydrolyzes too slowly and ethyl orthoformate too rapidly. However, the impurities would affect the deuterium analyses, so care was taken to obtain pure compounds. Gas chromatography analyses showed that the deuterated ketals were about 95 mole % pure. More than half of the impurities was accounted for as hydrolysis products which would not strongly affect the deuterium analyses. The constants obtained are summarized in Tables II and III.

Table II

Hydrolysis Rates of Ketals in 90% Dioxane–10% Water at 25°

Diethyl ketal of	k_1, 10^{-4} sec.$^{-1}$	Std. error	No. of runs
Acetone[a]	3.67	0.01	3
Acetone-d_6[a]	3.27	.01	5
Methyl ethyl ketone[a]	2.73	.02	3
Methyl ethyl ketone-d_5[a]	2.37	.01	2
Methyl isopropyl ketone[a]	3.20	.02	3
Methyl isopropyl ketone-d_4[a]	2.89	.01	3
Phenoxyacetone[b]	3.52	.03	3
Phenoxyacetone[b,c]	3.52	.02	2
Phenoxyacetone-d_5[b]	2.80	.01	2

[a] Solution 0.05 N in dichloroacetic acid and 0.02 N in sodium acetate. [b] Solution 0.00786 N in hydrogen chloride. [c] Measured spectrophotometrically.

Table III

Hydrolysis Rates of Ketals in 50% Dioxane–50% Water at 25°

Diethyl ketal of	k_1[a]	[H$^+$]	k_2, l./mole/sec. This work	Ref. 4[b]
Acetone[c]	2.31	3.04×10^{-7}	7.60×10^2	7.52×10^2
Acetone-d_6[c]	2.09	3.04×10^{-7}	6.87×10^2	
Methyl ethyl ketone[c]	2.34	3.04×10^{-7}	7.70×10^2	7.2×10^2
Methyl ethyl ketone-d_6[c]	2.12	3.04×10^{-7}	6.96×10^2	
Phenoxyacetone[d]	4.04	1.28×10^{-3}	0.315	0.350

[a] Units of 10^{-4} sec.$^{-1}$; std. errors are all about 0.01. [b] Data of Kreevoy and Taft, ref. 4. [c] Measured dilatometrically in buffer solutions 0.02 N in sodium acetate and 0.01 N in acetic acid, [H$^+$] calculated by method of Kreevoy and Taft. [d] Measured spectrophotometrically because of low solubility of ketal; solution 0.001283 N in $HClO_4$.

Table III shows that the rate constants obtained in this work for diethylacetonal and diethylbutanonal dilatometrically and for diethylphenoxyacetonal spectrophotometrically agree reasonably well with those obtained spectrophotometrically by Kreevoy and Taft for these compounds. Table II also shows agreement between hydrolysis rate constants obtained in this work for diethylphenoxyacetonal by the spectrophotometric and dilatometric methods. Table IV gives a summary of the isotope rate effects observed for the different compounds in 90% dioxane–10% water at 25°. The observed rate ratios, the changes in free energy of activation due to the amount of deuteration actually obtained (calculated by the formula $\Delta\Delta F_a = RT \ln k_H/k_D$) and the predicted free energy of activation change due to complete deuteration of the α-positions are given. These last figures were obtained from the observed free energy differences and the deuterium analyses given in Table I by a proportional extrapolation.

Table IV

Summary of Isotope Rate Effects Due to α-Deuteration on Hydrolysis of Ketals at 25°

Diethyl ketal of	K_H/K_D (obs.)	$\Delta\Delta F_a$ (obsd.)	$\Delta\Delta F_a$ (cor.)[a]
Acetone[b]	1.12	67.2	82.5
Acetone[c]	1.10		
Methyl ethyl ketone[b]	1.15	83.0	102.6
Methyl ethyl ketone[c]	1.10		
Methyl isopropyl ketone[b]	1.11	61.9	93.5
Phenoxyacetone[b]	1.25	132.0	156.0

[a] Corrected to represent complete α-deuteration; units are calories. [b] In 90% dioxane–10% water. [c] In 50% dioxane–50% water.

Table V shows how the data in the last column of Table IV may be broken down to give the isotope rate effects due to deuteration of the α-position of each group and due to each deuterium atom substituted. This separation is based on the assumption that the free energy of activation effects of deuteration are linearly accumulative and that the methyl group shows a constant effect (for a given reaction) from compound to compound. The available data, obtained in the study of secondary deuterium isotope rate effects on the hydrolysis of tertiary alkyl halides,[3] which test these two assumptions, indicate that they are at least approximately correct. The first three entries in Table V show that the isotope rate effect per α-deuterium atom increases in the series of groups methyl (14 cal.), ethyl (30 cal.), isopropyl (51 cal.) in about the same way that it does in these three groups in the hydrolysis of tertiary alkyl halides where the free energy of activation effects per deuterium atom are, in order, 56, 96 and 156 calories. Thus the two cases are strikingly similar. The isotope effects are smaller in the hydrolysis of ketals because the carbon atom to which the groups are attached develops a smaller degree of unsaturation in the ketal hydrolysis transition state, which forms a carbonium–oxonium ion, than it does in the alkyl chloride solvolysis transition state, which forms a carbonium ion.

Table V

Isotope Rate Effects in Ketal Hydrolyses Due to α-Deuteration of Different Groups

Group deuterated	$\Delta\Delta F_a$/group[a]	$\Delta\Delta F_a$/D atom[a]
Methyl	42.3	14
Ethyl	61.3	30
Isopropyl	51.2	51
Phenoxymethyl	115.0	57

[a] Units are calories.

The last entry in Table V summarizes the data which contribute our present knowledge of the effects

of substituents on secondary isotope rate effects to include the interesting example of the phenoxy group. This substituent increases the isotope rate effect of deuteration more than do two methyl groups. Since the methyl group is an inductive electron releaser while the phenoxy group is an inductive electron attractor, it would seem that the similar effects of the two groups on the isotope rate effect would be related to their conjugative electron-releasing powers which operate in the same direction for both but to a greater extent in the phenoxy group. Thus the group effects on the isotope rate effect might be attributed to the extra stabilization of hyperconjugative canonical forms by resonance (conjugation and hyperconjugation). These effects are viewed as being intrinsically similar to second-order hyperconjugation which shows up, for example, in the alternation effect.[6]

The isotope effects were observed to be larger in 90% dioxane–10% water than in 50% dioxane–50% water. This trend is in the same direction as that already observed for solvent effects on secondary isotope rate effects in the solvolysis of organic halides.[2,3,7]

Using the Taft–Hammett equation and the rate constants obtained in this work for acetonal, methyl ethyl ketone ketal and phenoxyacetonal, values for ρ^* and h can be calculated for the reaction in each of the two solvents used. The calculated value for h is appreciably larger in the less polar solvent, so h and the isotope rate effect apparently show the same gross dependence on solvent composition. Unexpectedly, ρ^* turned out to be slightly smaller in the less polar solvent, but the difference was small and apparently within the experimental error. These values are not given because they are not calculated as averages for a representative number of points and their absolute magnitude is not very significant, but they should be accurate enough to show the correct relationship between the parameters for the two solvents.

In conclusion, it seems that the apparent discrepancy noted in the introduction between the interpretation of the substituent effects on secondary deuterium isotope rate effects as being due to variations in hyperconjugation and the use of the Taft h parameter as a measure of hyperconjugation is inherent in the methods themselves and not in the reaction systems studied. It appears that the Kreevoy–Taft assumption of a constant value of h characteristic of every C–H bond may be an approximation and that the value obtained by the statistical method used is an average one which smooths out the variations among the different cases. Perhaps the remaining deviations of the points from the line are due to variations in h values.

It is not considered that the secondary deuterium isotope rate effects are a direct relative measure of hyperconjugation.[8] At least two other factors, not yet fully investigated, are recognized as influencing the magnitude of these secondary isotope rate effects. The first of these is the solvent effect[3,7] and the second is the isotope effect on the frequency factor of the Arrhenius equation. Carbon–hydrogen bond stretching, presumably resulting from increased hyperconjugation in the transition state, shows up most directly in the activation energy term of the isotope rate effect. The observed rate effect is of course a combination of the activation and frequency factor effects. In the cases where the Arrhenius parameters of the secondary isotope rate effects have been measured, it has turned out that the activation energy effect was present and affected the rate ratios, in the temperature range in which they were observed, in the direction observed. However, this effect was, in each case, partly cancelled by a frequency factor effect in the opposite direction. This suggests that at some temperature the frequency factor and activation energy effects would cancel and no isotope rate effect would be observed. At a higher temperature a negative rate effect would be found. This "cross-over" temperature might be different in different reaction systems. The most fundamental (but more difficulty obtained) experimental quantity is the isotope activation energy effect. In each of the cases that have been measured thus far this has paralleled the isotope rate effect at the temperatures used. This relationship, which will not always hold, is a necessary condition for the isotope rate effects to be relative measures of hyperconjugation. However, in comparing closely related reactions in the same solvent at the same temperature it seems that the isotope rate effect variations are most reasonably attributed to variations in hyperconjugation.

Experimental

Purification of Commercial Chemicals.—The following compounds were purified by distillation through an 88 × 1.9 cm. column packed with $^1/_{32}$″ glass helices: ethyl orthoformate, b.p. 143–144° (740 mm.); methyl ethyl ketone, b.p. 78.5° (740 mm.); and methyl isopropyl ketone, b.p. 92.3° (740 mm.). Dioxane was purified according to the method of Fieser[9] and fractionated through the 88 × 1.9 cm. column. Absolute alcohol was obtained by distilling added benzene from commercial absolute ethanol through a packed column. The ternary azeotrope (b.p. 64.9°), the ethanol–benzene azeotrope (b.p. 68.2°) and a foreshot of ethyl alcohol (b.p. 78.5°) were removed before the material to be used was collected.

Deuterium Oxide.—The deuterium oxide was obtained from the Stuart Oxygen Co. and was specified to be 99.5% isotopically pure.

Phenoxyacetone.—This compound was prepared according to the method of Hurd and Perletz[10] and vacuum distilled. It was then fractionally distilled through a spinning band column and the product collected at 125° (18 mm.), over-all yield 48%. The semicarbazone derivative gave m.p. 175–176°, reported[11] 173°.

Deuteration of Ketones.—Deuteroacetone was made by repeated potassium carbonate catalyzed exchange with deuterium oxide. The deuteroacetone was separated from each exchange by distillation. Methyl ethyl ketone was exchanged by refluxing the ketone with deuterium oxide and a little potassium carbonate for 24 hr. The deuterated methyl ethyl ketone–water azeotrope was separated from the deuterium oxide each time by distillation. Methyl isopropyl ketone was exchanged by refluxing with deuterium

oxide and a little potassium carbonate for three days. Deuterated methyl isopropyl ketone was separated from the deuterium oxide by separation of the layers after cooling. Phenoxyacetone was exchanged by refluxing for 24 hr. with a deuterium oxide–dioxane solution to which had been added several drops of triethylamine. Enough dioxane was used so that all of the deuterium oxide could be distilled from the mixture as the dioxane azeotrope and separation was thus accomplished. The exchanges were carried out each time with 5.0 g. (0.25 mole) of deuterium oxide and enough ketone so as to have an equivalent number of exchangeable (alpha) hydrogen atoms. Several successive ketone samples were run through the same sequence of deuterium oxide samples to increase the efficiency of deuterium transfer. The exchanges were continued until the completely α-deuterated ketones were 95–97% isotopically pure as shown by combustion analysis.

Preparation of Ketals.—The method of Carswell and Adkins[12] was used for the preparation of the ketals. These materials had to be distilled carefully at reduced pressures to prevent decomposition to the enol ethers which was apparently promoted by higher temperatures. The Carswell and Adkins procedure which involves the treatment of the ketone with ethyl orthoformate, ethyl alcohol and a little hydrochloric acid had to be modified for the preparation of the deuterated ketals, to include ethanol-*d* instead of ethanol to prevent loss of the deuterium from the deuterated ketones by exchange. This was accomplished as described in the following procedure for the preparation of deuterated phenoxyacetone ketal. The other deuterated ketals were prepared in a similar way. A 39 × 1.0 cm. fractionating column packed with $^1/_{16}$″ glass helices was cleaned and dried by refluxing ethyl orthoformate through it and removing the low-boiling material. In a 100-ml. round-bottomed flask were placed 57 ml. (0.35 mole) of ethyl orthoformate, 3.9 ml. (0.21 mole) of deuterium oxide and one drop of concentrated hydrochloric acid. The flask was attached to the cleaned column, and 17.2 g. of material was distilled out until the temperature reached 76°; theoretical yield of ethyl formate, 15.8 g. The flask was allowed to cool and 15.75 g. (0.10 mole) of deuterated phenoxyacetone and one drop of concentrated hydrochloric acid were added. The mixture was shaken and allowed to stand at room temperature for 11 days and then distilled through a dry spinning band column. Ethyl formate was distilled over at atmospheric pressure and the ethanol-*d* was distilled at 100 mm. Deuterated phenoxyacetone ketal, 19.5 g. (0.087 mole), was collected at 69–71° (0.1 mm.), yield 87%. Combustion deuterium analysis showed the material to contain an average of 4.24 deuterium atoms per molecule.

The yields of the other deuterated ketals varied from 45 to 65%. The boiling points of methyl isopropyl ketone ketal and ethyl orthoformate are very close together so the product obtained in the preparation of the former compound was subjected to partial hydrolysis with deuterium oxide catalyzed by a drop of glacial acetic acid. Enough deuterium oxide was added to hydrolyze about 33% of the material. This hydrolysis should have preferentially removed any ethyl orthoformate impurity. The hydrolysis reaction mixture was redistilled in the spinning band column. Gas chromatography analysis showed the distillate to be 95 mole % or more pure.

Dioxane–Water Solution.—Solutions 90% dioxane–10% water and 50% dioxane–50% water (by weight) were prepared from the dioxane purified as mentioned above and deionized distilled water. The following solutions were made from the 50% dioxane, placed in brown glass-stoppered bottles and stored in an ice-box for use as needed: (1) 0.02 *N* sodium acetate and 0.01 *N* acetic acid, (2) 0.001283 *N* perchloric acid. The following solutions were made from the 90% dioxane solution and similarly stored: (1) 0.02 *N* sodium acetate and 0.05 *N* dichloroacetic acid, (2) 0.00786 *N* hydrogen chloride.

Deuterium analyses were done using the method previously described.[13]

Kinetic Equipment.—The dilatometer consisted of a 125-ml. spherical mixing chamber connected by a long-handled stopcock to a 100-ml. reaction chamber in the shape of a U-tube approximately 34 cm. long and 15 mm. in diameter. The other end of the U-tube was connected to a precision bore capillary tube 30 cm. long and approximately 0.6 mm. inside diameter. The runs were done in a constant temperature water-bath kept in a room at 22° and heated intermittently by an infrared lamp. The temperature was set at 25.00 ± 0.001° with a Beckman thermometer calibrated against a platinum resistance thermometer. The temperature variations were of the order of ±0.002°.

Kinetic Procedure.—The dilatometer was placed in the 25.00° bath, and 105 ml. of solvent was placed in the mixing chamber. After the solvent had come to the temperature of the bath, approximately 1 ml. of the ketal was pipetted into the solution which was then stirred and degassed. Degassing was accomplished by reducing the pressure in the mixing chamber until the solution boiled. Then the reaction mixture was run into the reaction chamber and allowed about 15 minutes to come to temperature. The meniscus was then allowed, by slow opening of the stopcock, to rise into the bottom part of the capillary tube, and readings by a cathetometer of the meniscus heights with time were begun. The reaction half-lives were of the order of 45 min., and readings were taken through the second half-life or longer. The total capillary rise was usually in the range of 5 to 10 cm.

The rate of hydrolysis of phenoxyacetone ketal was measured in several experiments using a spectrophotometric method based on the change in absorption at 295 mμ which accompanies the reaction. The run was done in a flask in the 25.00° bath, and 3-ml. samples were withdrawn periodically and their optical densities measured at 295 mμ in a Beckman DU spectrophotometer.

Calculation of Rate Constants.—The rate constants were calculated by the statistical method described by DeTar.[4] The basic equation which applies is

$$h_i = a + be^{-kt_i}$$

where k is the first-order hydrolysis rate constant, h_i is the cathetometer reading at time t_i, a is equal to the cathetometer reading at infinity and b is equal to the cathetometer reading at zero time minus the infinity reading. The data are fitted to the equation treating a, b and k as disposable parameters chosen so that $\Sigma(h_i \text{ (observed)} - h_i \text{ (calculated)})^2$ is a minimum. This treatment avoids difficulties in reproducing first-order constants which have traditionally been associated with errors in zero and infinity readings. The solution was programmed for an IBM 650 Magnetic Drum Data Processing Machine. The programming was done in the Bell Laboratories interpretive system. The data, consisting of a series of height and a series of corresponding time readings along with an estimate of the infinity height reading, is fed into the machine on punched cards. The machine calculates a trial rate constant and then calculates corrections for the trial constant and for a and b. It then tests these for size, and if the corrections are 0.1% or more, it recycles to calculate another correction. When the correction is small enough, it then calculates the standard errors, punches a, b and k and their standard errors on output cards and takes in the data for the next run. The program for a seventy point run usually takes five to ten minutes machine time depending on the number of successive corrections (usually two to four) it must calculate. This compares with DeTar's estimate of 4 hr. used by an experienced operator to calculate a single set of corrections and the standard errors for a ten point run using a desk calculator. These calculations would not be practical for runs involving many points without an electronic computing machine.

Gas Chromatography Analyses.—The deuterated ketals used were analyzed for impurities using a Fisher–Gulf Partitioner equipped with an 8 ft. column packed with Carbowax supported on powdered firebrick. The column was thermostated at 100°. Elution times for the ketones and ketals (except phenoxyacetone ketal which was not run) were less than 15 minutes. Ethyl orthoformate seemed to decompose a little on the column but gave a characteristic elution pattern. The deuterated ketals were all 95 or more mole % pure with most of the impurities being accounted for as the ketal hydrolysis products.

Acknowledgment.—The authors are indebted to Professor L. L. Merritt for his help in programming the calculations for the computer.

COMMUNICATIONS TO THE EDITOR

THE CLEAVAGE OF 3-TROPANYL CHLORIDE WITH POTASSIUM CYANIDE

Sir:

When 3-tropanyl chloride[1] (I) was treated with potassium cyanide in alcohol solution a sharp-boiling (b.p. 68–70°, 0.2 mm.) mixture of isomers was obtained whose analysis agreed with the formula $C_9H_{14}N_2$ (I); (*Anal.* Calcd. for $C_9H_{14}N_2$: N, 18.65, N_{AP},[2] 9.33. Found: N, 18.35; N_{AP},[2] 9.38).

The infrared spectrum[3] was characterized by the presence of two cyanide bands at 4.50 μ and an intense band at 6.08 μ. When this oil was treated with phenylmagnesium bromide a liquid (b.p. 69–70°, 0.1 mm.), presumably a mixture of isomers also, was obtained, the analysis of which was compatible with the formula $C_{14}H_{19}N$ (III); (*Anal.* Calcd. for $C_{14}H_{19}N$: C, 83.53; H, 9.51; N, 6.96. Found: C, 83.70; H, 9.81; N, 6.84). The infrared spectrum showed that bands due to the aromatic ring system and the 6.08 μ band were present but the absorption at 4.50 μ had disappeared. This displacement of a nitrile function by the radical of a Grignard reagent is manifested by α-dialkylaminoacetonitriles.[4] The band at 6.08 μ is indicative of a terminal vinyl group (confirmatory bands at 11.00 μ + 3.27 μ). Catalytic hydrogenation resulted in the uptake of one mole of hydrogen and the bases IV (b.p. 111–113°, 0.4 mm.). (*Anal.* Calcd. for $C_{14}H_{21}N$: N, 6.86. Found: N, 6.90) were isolated. The band at 6.08 μ had disappeared. Structures I–IV illustrate the course of the reactions. The mixtures which persisted throughout were due to the formation of *cis* and *trans* pyrrolidine nitriles in the first step.

The bases (IV) were converted to a mixture of methiodides (V), m.p. 126–130°, the most readily purified of which melted at 173–174° after crystallization from acetone (*Anal.* Calcd. for $C_{15}H_{20}IN$: I, 36.1. Found: I, 36.0). Hofmann degradation of the bases corresponding to V furnished an oil VI (b.p. 125–128°, 0.4 mm.). (*Anal.* Calcd. for $C_{15}H_{23}N$: N, 6.46. Found: N, 6.44) which showed typical styrene absorption, $\lambda_{max}^{95\%\ EtOH}$ 253 (log ϵ 4.07).

Reduction in the presence of Adams catalyst furnished 4-dimethylamino-1-phenylheptane, which was independently synthesized from 1-phenyl-4-heptanone via oximation, reduction and methylation. The picrates from both samples melted at 92.5–94° (*Anal.* Calcd. for $C_{21}H_{28}N_4O_7$: N, 12.49. Found: N, 12.23) and were otherwise identical in all respects. The 1-phenyl-4-heptanone (b.p. 96–98°; 0.1 mm.; *Anal.* Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 82.07; H, 9.43) required for this synthesis was prepared from γ-phenylbutyronitrile and propylmagnesium iodide.

THYMIDINE INCORPORATION INTO DEOXYRIBONUCLEIC ACID OF RAT LIVER HOMOGENATES

Sir:

The incorporation of radioactive thymidine into DNA[1] of cell-free extracts of *E. coli* was reported in 1956.[2] Attempts to demonstrate thymidine incorporation in homogenates of chick embryo were unsuccessful,[3] although rabbit thymus nuclei have been reported to be active in this respect.[4] In normal or regenerating rat liver homogenates which actively incorporate radioactive orotic acid into RNA, no radioactivity was found in DNA.[5] The availability[6] of very high specific activity tritium labeled thymidine encouraged us to re-examine DNA synthesis in rat liver homogenates. Our experiments have met with some success, and will be described briefly herein.

(1) These abbreviations are used: DNA, deoxyribonucleic acid; RNA, ribonucleic acid; ATP, adenosine triphosphate; and Tris, tris-(hydroxymethyl)-aminomethane.

Previous work[7] demonstrated that following hepatectomy, no DNA is synthesized or labeled by orotic acid for the first 18 hours following the operation. An experiment was therefore designed in which homogenates were prepared from lobes removed at partial hepatectomy, as well as from liver allowed to regenerate 15 hours, and 24 hours and incubated in the presence of radioactive thymidine. The results presented in Table I show the incorporation observed in these preparations.

TABLE I

INCORPORATION OF THYMIDINE INTO DNA OF RAT LIVER HOMOGENATES

Each 50-ml. flask contained: 2 ml. of 25% rat liver homogenate; approximately 3×10^6 c.p.m. (3 micrograms) of thymidine[b]; 20 μM. each of K fumarate, K glutamate and K pyruvate; 5 μM. disodium ATP; 100 μM. nicotinamide; 12 μM. $MgSO_4$; 12 μM. K phosphate, *p*H 7.6; 10 μM. KCl; 20 μM. Tris:HCl buffer, *p*H 8; and 500 μM. of sucrose in a final volume of 2.55 ml.; incubation, for one hour with shaking, 38°, O_2 in the gas phase. Reaction was stopped by placing the flasks in an ice-bath. Sodium nucleates extracted and DNA purified as described previously.[7] A trace of radioactivity associated with RNA is attributed to slight degradation of radioactive DNA during the mild alkaline hydrolysis required to remove RNA.

Rat no.	Homogenate from	C.p.m./plate (actual[a])	DNA[c] mg./plate	Sp. act.[a] c.p.m./mg. DNA
1	Lobes removed at partial hepatectomy	350	0.35	1,000
2	Lobes removed at partial hepatectomy	270	.32	840
1	Liver 15 hours after operation	360	.30	1,200
2	Liver 24 hours after operation	12,300	.28	44,000
3	Liver 24 hours after operation	4,400	.26	16,900[c]

[a] Tritium was assayed in windowless flow counters. Since approximately the same amount of DNA was placed on each plate no correction has been made for self-absorption. Crude self absorption curves for tritium, using DNA as absorber, indicate a correction of about 2-fold could be applied to the DNA samples. [b] Colorimetric analysis using the Dische diphenylamine reagent. [c] This homogenate aged for 2 hours at 0° before incubation. All others incubated immediately after preparation.

It is apparent that a low level of incorporation is present in the zero hour and 15 hour regenerated preparations, and that the 24 hour regenerating liver shows about a 50-fold increase (Rat no. 2) in ability to incorporate thymidine into DNA. Thus the results with the homogenates are in agreement with previous studies with orotic acid *in vivo*[7] and in rat liver slices.[8]

It is our opionion that the marked incorporation seen in the 24-hour livers and the low incorporation in other samples argues against simple exchange reactions, since in all cases the same amount of tissue was incubated with the labeled precursor under identical conditions. The distribution of tritium in the isolated DNA was examined by hydrolysis with 98% formic acid for 2 hours at 165° and chromatography of the bases in 2-propanol:HCl on S. and S. no. 589 filter paper. The chromatogram showed only one radioactive spot, coincident with an ultraviolet quenching spot, with R_f and spectrum of thymine.[9]

FORMATION OF L-XYLULOSE FROM L-GULONOLACTONE IN RAT KIDNEY

L-Xylulose, a sugar excreted by patients with essential pentosuria, is present normally in urine of man,[1] guinea pig[1] and rat.[2] Conversion of D-glucuronolactone to L-xylulose occurs in man[1,3] and guinea pig.[1] L-Gulonic acid, which is formed from D-glucuronolactone in the rat and guinea pig,[4] has been postulated to be an intermediate in this reaction.[1] This communication reports the presence of an enzyme system in rat kidney which catalyzes the formation of L-xylulose from L-gulonolactone. It has been shown previously that L-gulonolactone is converted to L-ascorbic acid in rats.[5–7]

Carboxyl labeled and uniformly labeled L-gulonolactone[8] were incubated with the soluble fraction of rat kidney (Table I).[9] Carboxyl labeled L-gulonolactone yielded 30 to 60% of the added C^{14} in CO_2.[10] Uniformly labeled L-gulonolactone yielded about one-sixth the amount of C^{14} in CO_2.

TABLE I

DECARBOXYLATION OF L-GULONOLACTONE IN RAT KIDNEY

Expt.	% of added C^{14} found in CO_2[a] Carboxyl labeled L-gulonolactone	Uniformly labeled L-gulonolactone
1	30	4.9
2	51	7.8
3	..	4.6
4	..	7.6
5	60	..
6	35	..

[a] 2.0 mg. of either carboxyl labeled L-gulonolactone (0.05 μc./mg.) or uniformly labeled L-gulonolactone (0.20 μc./mg.) was incubated under air at 37° for 90 minutes in 6.0 ml. of a high speed supernate fraction (100,000 × *g*) equivalent to 600 mg. of tissue, *p*H 7.0, 0.1 *M* phosphate buffer. Cofactor additions were the same as used by Rabinowitz and Sall.[9] The methods used in preparation and assay of samples for C^{14} have been described.[5]

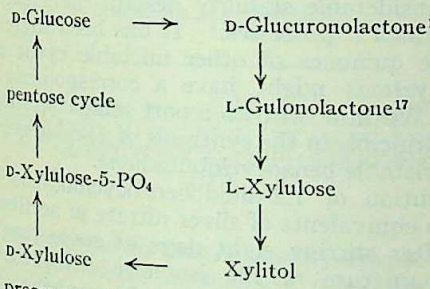
These results indicate that L-gulonolactone is decarboxylated in this system.

Evidence was found for the conversion of at least 15% of the uniformly labeled L-gulonolactone to labeled L-xylulose as follows:[11] 400 mg. of carrier L-xylulose[12] was added to the trichloroacetic acid extract of the incubation mixture and the solution was passed through an Amberlite IR-4B (acetate) column. L-Xylulose, in the effluent, was converted to L-ascorbic acid by the procedure described previously.[13] In brief, this method involved oxidizing L-xylulose to L-xylosone which was converted to imino-L-ascorbic acid by cyanide addition. After hydrolysis, the resulting L-ascorbic acid was purified by ion-exchange chromatography and converted to its 2,4-dinitrophenylosazone derivative which was recrystallized to constant specific activity.[5,14] This procedure does not distinguish between L-xylulose and L-xylose since both isomers are oxidized to L-xylosone. However, identification of the labeled pentose as L-xylulose was established and it was quantitatively determined by the cysteine-carbazole method[15] and a specific enzyme assay.[16]

Finding that L-gulonolactone is converted to L-xylulose suggests the following cyclic pathway for glucose metabolism in animals



The presence of enzyme systems in mammalian tissues for all these steps has been reported by others,[6,18–24] except the conversion of L-gulonolactone to L-xylulose. Evidence for occurrence *in vivo* of such an alternate pathway of glucose metabolism in animals will be presented elsewhere.

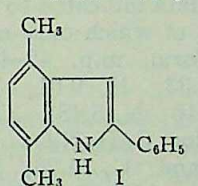
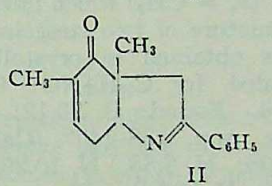
EVIDENCE FOR A HIGH ENERGY INTERMEDIATE IN THE FISCHER INDOLE SYNTHESIS. A NEW CLASS OF HYDROINDOLES

Sir:

When acetophenone 2,6-dimethylphenylhydrazone was heated at 130° in nitrobenzene solution with anhydrous zinc chloride for one hour, five products were isolated, among which 2-phenyl-4,7-dimethylindole (I), 4% yield, and 3a,4,7,7a-tetrahydro-2-phenyl-3a,5-dimethyl(3H)pseudoindolone-4 (II), 33% yield, were the most significant.



I



II

The structure of I, m.p. 65.5–66.5°, (calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.38; N, 6.33. Found: C, 86.69; H, 7.17; N, 6.24) was established by its independent synthesis from acetophenone 2,5-dimethylphenylhydrazone. The structure of II was proven by degrading it to 2-(β-phenylethyl)-2,6-dimethylcyclohexanone (VI), b.p. 143° (1–2 mm.), $n^{20}D$ 1.5205, (Calcd. for $C_{16}H_{22}O$: C, 83.43; H, 9.63. Found: C, 83.20; H, 9.66. Oxime, m.p. 115–116°, calcd. for $C_{16}H_{23}NO$: C, 78.32; H, 9.45; N, 5.71. Found: C, 78.51; H, 9.28; N, 5.64) which was synthesized by treating 2,6-dimethylcyclohexanone with sodamide and then with β-phenylethyl bromide. The infrared spectra of the two samples of VI were identical, and their oximes had the same m.p. and gave no mixed m.p. depression.

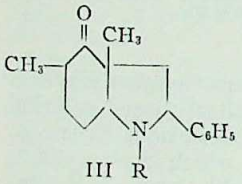
Crystalline II, m.p. 92–101°, was obtained as a hemihydrate (Calcd. for $C_{16}H_{17}NO \cdot {}^1/_2H_2O$: C, 77.39; H, 7.31; N, 5.64. Found: C, 77.46; H, 7.31; N, 5.68.), but the oxime, m.p. 230° (dec.), (Calcd. for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02. Found: C, 75.42; H, 7.25; N, 11.20), picrate, m.p. 224° (dec.), (Calcd. for $C_{22}H_{20}N_4O_8$: C, 56.41; H, 4.30: N, 11.96. Found: C, 56.19; H, 4.02; N, 12.20.), and hydrochloride, m.p. 214° (dec.) (Calcd. for $C_{16}H_{17}NO \cdot HCl$: C, 69.68; H, 6.58; N, 5.08. Found: C, 69.74; H, 6.49; N, 5.16) all crystallized without bound water. The infrared spectrum ($CHCl_3$) of II featured bands at 2.72 μ (water), 6.02 μ (conj. C=O); 6.22 μ (conj. C=N, conj. phenyl) which split into two bands at

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

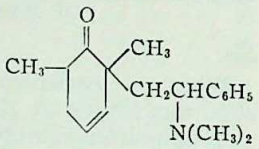
Digitized by Arya Samaj Foundation Chennai and eGangotri

6.12 μ and 6.24 μ in acid solution. The ultraviolet absorption spectrum in ethanol showed a major band at 242 mμ (ϵ, 21,500) which split into two bands in acid solution (λ_1 242 mμ; ϵ_1 10,500; λ_2 273 mμ; ϵ_2, 16,500). Both the infrared and the ultraviolet spectra are characteristic of the conjugated carbonyl and conjugated imine chromophores.[1]

Hydrogenation of II over Adams catalyst in acetic acid afforded stereoisomeric forms of III (R = H), m.p. 56.5–58° and 92.5–93.5° (Calcd. for $C_{16}H_{21}NO$: C, 78.97; H, 8.70; N, 5.76. Found: C, 79.01 and 78.94, resp.; H, 8.80 and 8.86, resp.; N, 5.67 and 5.60, resp.). Oximes, m.p. 162–164° and 177–179°, resp. (Calcd. for $C_{16}H_{22}N_2O$: C, 74.38; H, 8.58; N, 10.84. Found: C, 74.44 and 74.32, resp.; H, 8.40 and 8.39, resp.; N, 10.74 and 10.83, resp.)



III R



IV

Formaldehyde and formic acid converted either stereoisomeric form of III (R = H) to the same III (R = CH_3) which infrared data indicated to be a mixture of two stereoisomers of which only one was obtained in crystalline form, m.p. 42–44° (Calcd. for $C_{17}H_{23}NO$: C, 79.33; H, 9.01; N, 5.44. Found: C, 79.12; H, 9.16; N, 5.48). Oxime, m.p. 138–140° (Calcd. for $C_{17}H_{24}N_2O$: C, 74.96; H, 8.88; N, 10.29. Found: C, 75.26; H, 8.89; N, 10.18). The methiodide of III (R = CH_3) (Calcd. for $C_{18}H_{26}NOI$: C, 54.14; H, 6.56; N, 3.51. Found: C, 54.27; H, 6.65; N, 3.61) was converted to the methohydroxide by passage of its water solution through a column of the hydroxide form of Amberlite IRA-400. Heating the methohydroxide at 120° (1μ) afforded IV (methiodide, m.p. 158–213° (dec.), Calcd. for $C_{19}H_{28}NOI$: C, 55.21; H, 6.83; N, 3.39. Found: C, 55.33; H, 7.18; N, 3.26). Action of 30% hydrogen peroxide on IV gave the amine oxide (picrate, m.p. 133–134.5°, Calcd. for $C_{24}H_{28}N_4O_9$: C, 55.81; H, 5.46; N, 10.85. Found: C, 56.13; H, 5.56; N, 10.95) which decomposed[2] at 100° (15–20 mm.) to V, not obtained analytically pure, (Calcd. for $C_{16}H_{18}O$: C, 84.91; H, 8.02. Found: C, 83.60; H, 7.71). Hydrogenation of V in absolute methanol over Adams catalyst yielded VI.

BENZOCYCLOBUTADIENOQUINONE

Sir:

Although no stable cyclobutadiene has yet been found, the monophenyl derivative of cyclobutadienoquinone has been prepared and appears to have considerable stability despite the great ring strain which it possesses.[1] It has been suggested[1] that the quinones of other unstable cyclic polyolefin systems might have a corresponding stability. We now wish to report some confirmation of this principle in the synthesis of a stable quinone of the unstable benzocyclobutadiene.[2]

A solution of 1,2-diiodobenzocyclobutene[2a] (I) and two equivalents of silver nitrate in acetonitrile gave, after stirring eight days at room temperature, a mixture of the isomeric *cis*-benzocyclobutene-1,2-diol dinitrate (II) and *trans*-benzocyclobutene-1,2-diol dinitrate (III), separable by crystallization from methanol. Isomer A:[3] m.p. 110°. *Anal.* Calcd. for $C_8H_6N_2O_6$: C, 42.48; H, 2.67; N, 12.39. Found: C, 42.50; H, 2.59; N, 12.42. Isomer B:[3] m.p. 55.5–56.5°. *Anal.* Found: C, 42.24; H, 2.88; N, 12.29. Either isomer, when refluxed one hour with 1:1 methylene chloride–triethylamine gave, in 75% yield, the pale yellow 1,2-diketobenzocyclobutene, or benzocyclobutadienoquinone (IV), m.p. 132.5°. *Anal.* Calcd. for $C_8H_4O_2$: C, 72.73; H, 3.05. Found: C, 72.77; H, 3.08; λ_{max}^{EtOH} 271 mμ (log E = 3.45), 277 mμ (log E = 3.83). In the infrared (CS_2 solution), the strained carbonyls absorbed as a doublet at 5.51 and 5.61 μ.

The quinone IV was quite stable thermally and sublimed unchanged at 100° (0.2 mm. pressure). It reacted rapidly with *o*-phenylenediamine (V) to give the first known heterocyclic biphenylene analog, 1,4-diaza-benzo[b]biphenylene (VI), m.p. 238–239°. *Anal.* Calcd. for $C_{14}H_8N_2$: C, 82.33; H, 3.95; N, 13.72. Found: C, 82.21; H, 3.84; N, 13.83.

THE FORMATION OF A CYCLIC DIANHYDRODIADENYLIC ACID (I) BY THE ALKALINE DEGRADATION OF ADENOSINE-5′-TRIPHOSPHORIC ACID (II)[1]

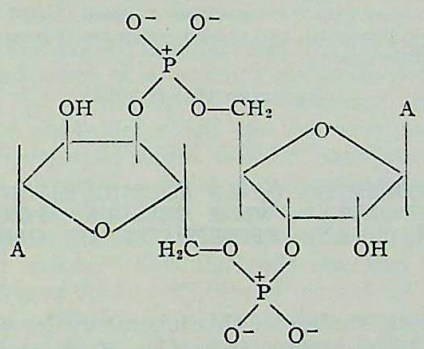
Sir:

It has been shown that barium hydroxide hydrolysis of (II) yields adenosine-5′-phosphoric acid (III) and inorganic pyrophosphate.[2] Hock and Huber[3] recently demonstrated that at least one other product is formed in this reaction.

Experiments in this laboratory show that the degradation of (II) by barium hydroxide is complex and that a number of previously unreported products are formed. One of these (I) exhibits sufficiently unexpected properties to merit description, particularly since it appears to be identical with a recently isolated, naturally-occurring compound.[4] In the preparation of (I), 250 mg. of (II)[5] and 3 ml. of 0.4 *N* barium hydroxide were heated for 30 min. at 100° and then the barium ion was precipitated. The solution was chromatographed on paper using 70% 2-propanol-ammonia as the developing solvent.[6] The fastest-moving substance is adenosine and this is closely followed by (I) (yield *ca.* 5–10%[7]).

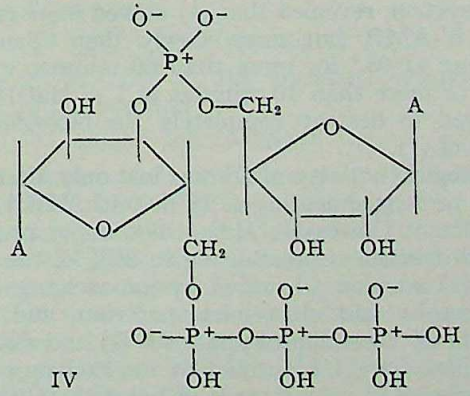
The new compound (I) has the following properties: (1) the molar ratio of adenine:phosphorus is unity; (2) adenosine is slowly formed from it by the action of *Crotalus adamanteus* venom; (3) it is not attacked by prostate phosphomonoesterase; (4) it is not oxidized by periodate; (5) it is deaminated by nitrite to the inosine analog, which also has been prepared from inosine-5′-triphosphoric acid; (6) its electrophoretic mobility on paper[8] relative to (III) is 1.2 at *p*H 3.5 (formate), 0.57 at *p*H 7.2 (phosphate) and 0.49 at *p*H 9.2 (borate); and (7) it is eluted from a Dowex-2 formate column by ammonium formate (*p*H 5.0) after all four known adenine-containing monoribonucleotides and just prior to adenosine-5′-pyrophosphoric acid.

A structural formula for (I) which is in accord with the above data is (A = adenine-9 residue)



There is no evidence at present to indicate that the phosphate ester bonds involve only the 3′, in addition to the 5′, carbon atoms. A study of models indicates, however, that this is the most likely phosphate diester structure and explains the surprising stability of (I) toward alkali. The positions of the phosphorus atoms in (I) are such that the formation of a 2′,3′ cyclic phosphate ester is hindered. The compound also is exceptionally stable toward acid hydrolysis.

The formation of (I) may take place by one of two paths. Two molecules of (II) suitably oriented may react simultaneously at two sites to give (I) directly, or (IV)



and inorganic pyrophosphate may form followed by intramolecular cyclization to give (I). Alternatively, (IV) could yield equivalent amounts of adenosine and 3′(or 2′)-phosphoadenosine-5′-phosphoric acids. The latter, which we have tenta-

tively identified in our hydrolyzates, may be the product NF observed by Hock and Huber.

It is interesting to note that the reactions leading to the formation of (I) are similar in character to two of the enzymatic reactions involved in polynucleotide synthesis.[9,10]

Recently Khorana, *et al.*,[11] described a thymidine derivative analogous to (I) which they prepared by an entirely different procedure.

THE PROPERTIES OF AN ADENINE RIBONUCLEOTIDE PRODUCED WITH CELLULAR PARTICLES, ATP, Mg^{++}, AND EPINEPHRINE OR GLUCAGON

Sir:

Previous studies in this laboratory have shown that a heat-stable factor (formed by particulate fractions of liver homogenates in the presence of ATP, Mg^{++}, and epinephrine or glucagon) stimulated the formation of phosphorylase in supernatant fractions of homogenates.[1] This factor was isolated by ion-exchange chromatography and proved to be an adenine ribonucleotide (I).[1] Similar or identical compounds have been isolated from heart, skeletal muscle and brain. Crystals formed when 2×10^{-2} *M* aqueous solutions of (I) were chilled at acid *p*H. (I) was not attacked by several monoesterases[1] and upon titration with alkali exhibited no buffering capacity between *p*H 5 and *p*H 8. Descending paper chromatography, using an ethanol–ammonium citrate (*p*H 4.4) solvent system, revealed that (I) moved more rapidly than 5′-AMP, but more slowly than adenosine. Heating at 98° for more than 60 minutes in 1 *N* HCl, or more than 40 minutes in 1 *N* NaOH, was required to destroy completely the biological activity of (I).

Biological activity of (I) was lost only after relatively prolonged heating at 98° in 0.05 *N* HCl in the presence of Dowex-50 (H^+). The major products of such treatment, amounting to 85% of the total, were (1) adenine, identified by ion-exchange chromatography and ultraviolet spectrum, and (2) a mixture of ribose-3-phosphate (60%) and ribose-2-phosphate (40%), identified by ion-exchange chromatography in the presence of borate.[2] However, the biological activity of (I) was lost rapidly on incubation with crude or fractionated extracts of heart or brain. In the presence of a partially purified enzyme from heart, (I) was converted quantitatively to 5′-AMP, identified by paper chromatography and dephosphorylation by low concentrations of snake venom.

The biological activity of (I) was not destroyed by incubation with pancreatic ribonuclease or spleen phosphodiesterase.[3] Through private communication with Dr. Leon Heppel, we learned that the structure we had tentatively proposed for (I) was identical with that proposed by Cook, Lipkin and Markham for a product isolated from the $Ba(OH)_2$ digestion of ATP.[4] This knowledge prompted an exchange of information and samples were kindly provided for comparison.[5] These samples were identical with (I) by the following criteria: (1) ultraviolet spectrum, (2) biological activity, (3) paper chromatography, (4) loss of biological activity, when incubated with enzyme fractions from heart or brain, (5) quantitative conversion to 5′-AMP on incubation with a partially purified enzyme from heart, and (6) conversion to adenosine on prolonged incubation with large amounts of *Crotalus adamanteus* venom (although, as reported,[1] moderate amounts of Russell's viper venom did not attack (I)).[6]

The addition of dibromocarbene to 1,4-cyclohexadiene[9] afforded 7,7-dibromonorcar-3-ene (II), m.p. 36.8–37.0°; *Anal.* Calcd. for $C_7H_8Br_2$: C, 33.5; H, 3.2; Br, 63.3. Found: C, 33.0; H, 3.5; Br, 63.0. Oxidation converted (II) into *cis*-3,3-dibromocyclopropane-1,2-diacetic acid (III), m.p. 179.4–181.2°; *Anal.* Calcd. for $C_7H_8O_4Br_2$: C, 26.8; H, 2.5; Br, 50.5; neut. equiv., 158. Found: C, 26.5; H, 2.2; Br, 50.5; neut. equiv., 159. Hydrogenolysis of (III) gave *cis*-cyclopropane-1,2-diacetic acid (IV), m.p. 131–133°; *Anal.* Calcd. for $C_7H_{10}O_4$: C, 53.3; H, 6.4; neut. equiv., 79.4. Found: C, 53.0; H, 6.2; neut. equiv., 79.6. The monomethyl ester chloride of (IV) on treatment with *n*-hexylcadmium followed by alkaline hydrolysis afforded DL-*cis*-6-keto-3,4-methylene-dodecanoic acid which was reduced[10] to DL-*cis*-3,4-methylenedodecanoic acid (V), b.p. 153–154° at 3 mm.; *Anal.* Calcd. for $C_{13}H_{24}O_2$: C, 73.7; H, 11.4; neut. equiv., 213. Found: C, 73.6; H, 11.3; neut. equiv., 208. Conversion of (V) into DL-*cis*-9,10-methyleneoctadecanoic acid (I) was effected by procedures previously described,[8,11] m.p. 38.6–39.6°; *Anal.* Calcd. for $C_{19}H_{36}O_2$: C, 77.0; H, 12.2; neut. equiv., 296. Found: C, 77.0; H, 12.2; neut. equiv., 298. Amide, m.p. 86.4–87.6°; *Anal.* Calcd. for $C_{19}H_{37}ON$: C, 77.2; H, 12.6; N, 4.7. Found: C, 77.0; H, 12.3; N, 5.0. Mixed melting point determinations and comparison of the infrared absorption spectra and X-ray diffraction patterns of (I) and dihydrosterculic acid demonstrated the complete identity of these compounds. The X-ray diffraction patterns of the amide of (I) and of dihydrosterculamide were identical also, and admixture of the amides did not result in a depression of the melting point. These findings establish the structure of dihydrosterculic acid.[12]

In connection with studies on the structure of lactobacillic acid, we have converted *cis*-cyclopropane-1,2-diacetic acid (IV) into DL-*cis*-11,12-methylene-octadecanoic acid (VI), m.p. 31.0–33.6°; Found: C, 76.5; H, 12.0; neut. equiv., 294. Amide, m.p. 84.0–85.2°; Found: C, 77.0; H, 12.6; N, 4.8. Although exhibiting an identical infrared absorption spectrum, the synthetic specimen differed from lactobacillic acid in melting point and X-ray diffraction pattern. The non-identity of lactobacillic acid (which has been shown to represent one of the stereoisomeric forms of 11,12-methyleneoctadecanoic acid[13]) with either *cis*- or *trans*-DL-11,12-methyleneoctadecanoic acids demonstrates clearly that lactobacillic acid must be a distinct optical isomer. Synthetic DL-*cis*-11,12-methyleneoctadecanoic acid exhibits approximately one-half the growth promoting activity of natural lactobacillic acid for *Lactobacillus delbrueckii*. DL-*trans*-11,12-Methyleneoctadecanoic acid fails to support growth of this organism under identical experimental conditions.[14] These observations point to either D- or L-*cis*-11,12-methyleneoctadecanoic acid as the structure for lactobacillic acid.

OXIDATIONS AT MERCURY HALIDE ANODES

Sir:

It is well known in polarography that the anodic potential range of a mercury electrode is severely limited by oxidation of the mercury itself. A mercury electrode which can be used at highly anodic potentials might well be considered a significant advance in polarographic practice. Such an electrode has been developed as a result of chronopotentiometric studies at a mercury pool in chloride media. This electrode operates through formation of an "inert" film of mercurous chloride prior to oxidation of electroactive species in the bulk of solution. This phenomena has not been observed previously since conventional polarography at the dropping mercury electrode does not allow sufficient time for the proper film formation.

The theory of chronopotentiometry has been thoroughly reviewed by Delahay.[1] The equipment used in the present study was conventional in all respects. The background electrolyte was a solution 0.3 M in potassium chloride and 2×10^{-3} M in hydrochloric acid (pH 2.7). The anodic chronopotentiogram of this solution (Hg pool area 1.47 cm.^{2}, current 350 microamperes) shows four small waves at *ca.* +0.07, 0.5, 0.8, and 1.2 v. *vs.* S.C.E. The first wave is due to formation of mercurous chloride. The variation of $E_{1/4}$ for this wave follows closely

$$E_{Hg} = E^0 - 0.059 \log [Cl^-]/2$$

where $E^0 = 0.022$ v., the standard potential vs. S.C.E. of the reaction

$$2Hg^0 + 2Cl^- = Hg_2Cl_2 + 2e^-$$

Further interpretation of these potential–time patterns will be reported in the near future.

The chronopotentiogram of a 2×10^{-3} M solution of N,N′-dimethyl-p-phenylenediamine (DPP) in the same background electrolyte shows an identical first wave for mercurous chloride formation. It is followed by a clearly defined wave for the oxidation of DPP. The $E_{1/4}$ of DPP (*ca.* +0.4 v.) wave is identical with that obtained at a platinum electrode under the same pH conditions. A plot of $\tau^{1/2}$ *vs.* concentration shows excellent linearity between 4×10^{-4} to 3×10^{-3} M DPP.

The anodic oxidations of aniline, *o*-phenylenediamine and hydroquinone, which take place at

(1) P. Delahay, "New Instrumental Methods in Electrochemistry," Interscience Publishers, Inc., New York, N. Y., 1954.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

considerably more positive potentials, also have been studied. Again, plots of $\tau^{1/2}$ *vs.* concentration show the expected linearity for a chronopotentiometric reaction which is proceeding independent of any previous electrode process. Oxidation reactions with potentials as high as +1.0 v. appear possible with the mercury chloride electrode.

The electrode can also be operated in a more conventional polarographic sense. The halide film is formed by application of an anodic potential for a short period of time. The compound to be oxidized is then introduced and the voltage scanned in an increasing anodic direction using a Leeds and Northrup Electrochemograph. With DPP and ferrocyanide, typical quiet pool polarograms[2] are obtained whose peak heights are proportional to concentration. Investigations are in progress to evaluate the effect of stirring and changing scan rate on peak currents as well as application of the technique to the hanging drop electrode.

A detailed report of this work will be published shortly.

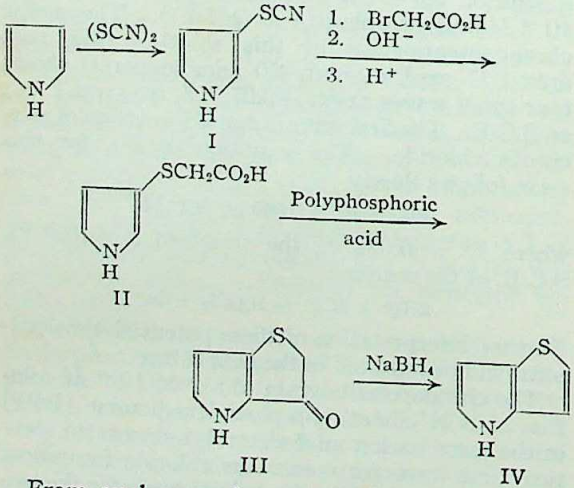
A PRACTICAL SYNTHESIS OF THIENO[3,2-*b*]PYRROLE

Sir:

We have synthesized thieno[3,2-*b*]pyrrole (IV) from pyrrole in four steps. The new synthesis makes this isostere of indole readily available for conversion to various derivatives of biological interest.



From analogous electrophilic substitutions and resonance theory,[1] thiocyanation of pyrrole was expected to occur preferentially at the 2-position. However, recent molecular orbital calculations[2] indicate that the orientation of substitution in the pyrrole nucleus cannot be predicted unambiguously; π-electron localization energy favors 2-substitution but π-electron densities favor 3-substitution. When the reaction was carried out by rapidly mixing cold (−75°) methanolic solutions of pyrrole and thiocyanogen (prepared at −60° from potassium thiocyanate and bromine), the product collected after pouring the reaction mixture onto ice and salt, and amounting to 50% yield after recrystallization from methylene chloride–methylcyclohexane, was 3-thiocyanopyrrole (I), m.p. 40–44°. *Anal.* Calcd. for $C_5H_4N_2S$: C, 48.36; H, 3.25; N, 22.55. Found: C, 48.72; H, 3.15; N, 22.80.

Treatment of a cold methanolic solution of I and bromoacetic acid with an excess of potassium hydroxide in aqueous methanol furnished in 90% yield (3-pyrrolylthio)-acetic acid (II), characterized as the ammonium salt which crystallized when anhydrous ammonia was introduced into a methylene chloride solution of the acid. The salt melted at 127–133° (dec.). *Anal.* Calcd. for $C_6H_{10}N_2O_2S$: C, 41.35; H, 5.78; N, 16.08. Found: C, 41.59; H, 5.73; N, 15.77. Addition of a dilute methylene chloride solution of II over 1 hr. to vigorously stirred polyphosphoric acid at 125°, followed by dilution of the mixture with water, extraction with ethyl acetate and sublimation of the product, yielded 36% of 2H,3H-thieno[3,2-*b*]-pyrrol-3-one (III), m.p. 183–188.5°. The analytical sample, m.p. 187–190°, was prepared by a series of recrystallizations and resublimations. *Anal.* Calcd. for C_6H_5NOS: C, 51.78; H, 3.62; N, 10.07. Found: C, 52.04; H, 3.82; N, 10.14. The infrared spectrum of III (Nujol) contained strong bands at 1635 (C=O) and 3150 cm.$^{-1}$ (NH). The structure of III was proved by desulfurization with Raney nickel catalyst to 2-acetylpyrrole, shown to be identical with an authentic sample[3] by infrared spectra (chloroform), m.p. and mixture m.p. Treatment of III with sodium borohydride in methanol yielded 62% of sublimed thieno[3,2-*b*]-pyrrole (IV), m.p., after further purification, 25–28°. *Anal.* Calcd. for C_6H_5NS: C, 58.50; H, 4.09; N, 11.38. Found: C, 58.60; H, 4.27; N, 11.32. The infrared spectrum of IV (smear) was identical with that[4] of a less pure sample prepared[5] unequivocally from thiophene, except for bands due to a carboxylic acid present as an impurity in the latter sample.

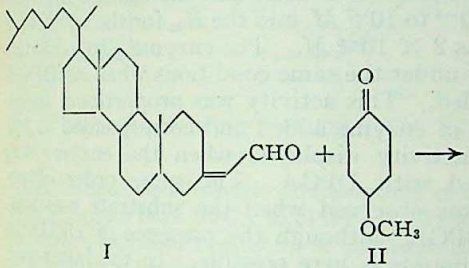
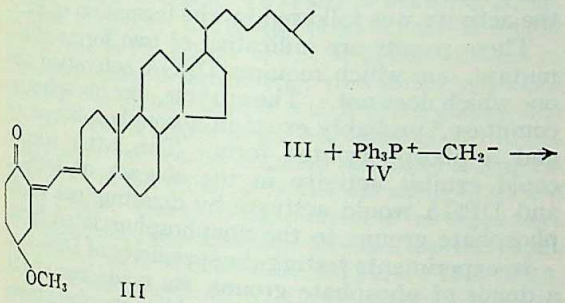
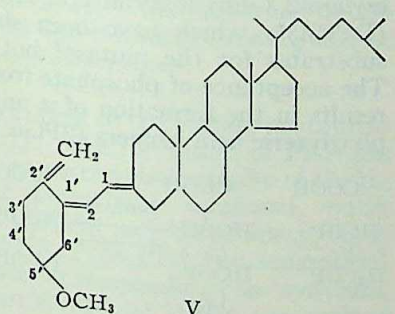
dene)-ethane (V), a homolog of vitamin D, which is biologically active. Following the scheme outlined in previous publication,[1] 7.54 g. of 2-cholestanylideneethan-1-al (I) [m.p. 114–115°. *Anal.* Calcd. for $C_{29}H_{48}O$: C, 84.39; H, 11.72. Found: C, 84.00; H, 11.82; ϵ (244.5 mμ), 30,250 (ethanol); $[\alpha]^{25}D$ −9.38° (chloroform)] was condensed in the dark with 4.7 g. of 4-methoxycyclohexanone (II) in a liter of *t*-butanol containing 4 g. of sodium hydroxide and 10 cc. of water. The mixture was stirred under nitrogen in the dark for 24 hr. A yellowish-brown amorphous product (7.4 g.) was isolated from this reaction and chromatographed in the dark using alumina (Act. III) from which was obtained two fractions: one



I II



III



V

the 2,1′-*trans*-dienone (10%), m.p. 221–224° (dec.). *Anal.* Calcd. for $C_{36}H_{58}O_2$: C, 82.70; H, 11.18. Found: C, 82.73; H, 11.33; ϵ (309 mμ), 30,600 (ethanol); infrared α,β-conjugated >C=O band at 1674 cm.$^{-1}$; $[\alpha]^{25}D$, +86.8° (chloroform). Semicarbazone, m.p. 220–222°. *Anal.* Calcd. for $C_{37}H_{62}N_3O_2$: C, 76.50; H, 10.76; N, 7.23. Found: C, 76.72; H, 10.95; N, 6.94. The other fraction was the 2,1′-*cis*-dienone (12%), m.p. 186°. *Anal.* Calcd. for $C_{36}H_{58}O_2$: C, 82.70; H, 11.18; |═, 2.00. Found: C, 82.71; H, 11.07; |═, 1.85 (Pd.); ϵ (307 mμ), 12,200 (ether); infrared α,β-conjugated >C=O band at 1675 cm.$^{-1}$; $[\alpha]^{25}D$, +40.3° (chloroform).

Reaction of the 2,1′-*cis*-dienone (III) with triphenylphosphinemethylene (IV) in a pressure bottle gave an amorphous solid (23%), m.p. 193° (dec.); ϵ (265 mμ), 20,200 (ether). This was further purified by chromatography in a nitrogen atmosphere and in the dark giving again an amorphous product which had the following analyses.[2] *Anal.* Calcd. for $C_{37}H_{60}O$: C, 85.34; H, 11.61. Found: C, 84.22; 11.55; $[\alpha]^{25}D$, −10.6°; ϵ (267 mμ), 31,300 (ether); principal infrared bands[3] for =CH_2: 3100R, 1641W, 892S cm.$^{-1}$. Principal infrared bands for =CH_2 of vitamin D_3: 3100R, 1645M, 892M cm^{-1}.

An exploratory biological test of this homolog was carried out by Professor Robert S. Harris of the Nutritional Biochemical Laboratories of M.I.T. and he reports that the group of rachitic rats which was fed this homolog showed nearly the same degree of healing as the group which was fed vitamin D_2 at approximately the same concentration. These preliminary results do make it possible to estimate exactly the potency of the 2,1′-*cis*-homolog (V) but indicate quite definitely that its activity may approach that of vitamin D_2.

The 2,1′-*trans*-homolog was also synthesized from the 2,1′-*trans*-dienone and had an ϵ (272 mμ), 34,700 (ether). The *trans*-homolog also was found to be biologically active but very much less so than the *cis*-homolog. Details of this work will be published elsewhere.

Acknowledgment.—The authors are indebted to Dr. Nagy and his associates for all the analyses, to Dr. Nelson and Miss Cassie for the infrared spectra, to Prof. Robert S. Harris for the biological results and to Research Corporation–Milas–M.I.T. Fund for financial support of this investigation.

RECEIVED JUNE 6, 1957

A NEW SYNTHESIS OF THE CHROMIUM HEXACARBONYL

Sir:

We wish to report a new synthesis of chromium hexacarbonyl starting from easily available chromium compounds which appear to have been converted now for the first time, into the hexacarbonyl.

At present the only well described method for this synthesis is the "Grignard method" discovered by Job and Cassal[1] and substantially improved by Owen and co-workers.[2] Recently Fischer and Hafner[3] synthesized the carbonyl starting from chromium bis-cyclopentadienyl (no yield reported). Both these valuable methods suffer from some disadvantages such as the unsatisfactory over-all yields,[4] or the requirement of a rather

(1) A. Job and A. Cassal, *Compt. rend.*, **183**, 392 (1926).

(2) B. B. Owen, J. English, Jr., H. G. Cassidy and C. Vanderbilt Dundon, THIS JOURNAL, **69**, 1723 (1947).

Digitized by Arya Samaj Foundation Chennai and eGangotri

involved procedure for preparing the suitable starting material.

We have now observed[5] that chromic acetylacetonate, chromic and chromous salts of organic acids such as acetic and 2-ethylhexanoic can be reduced easily and converted into the hexacarbonyl under high pressure of carbon monoxide if pyridine or related bases are employed as a reaction medium.

Our method consists in dissolving (or suspending) any one of the above compounds in pyridine, containing catalytic amounts of halogens or halogenated substances. The mixture is then treated at 80–170° with an excess of powdered magnesium or zinc and 100–300 atm. of carbon monoxide. When soluble chromium compounds are employed the yields are as high as 80–90%.

We believe the base to play an essential role in the synthesis because intermediate pyridine-containing complexes are formed in the course of the reaction.

It is also noteworthy that the hexacarbonyl as such is still present in substantial quantities in the end-products of the reaction. This seems not to happen in the synthesis by the Grignard method, the hexacarbonyl, in this case, being produced uniquely after the hydrolysis of the reaction mixtures.[4]

Experimental.—Chromium acetylacetonate (17.5 g.), magnesium (4.5 g.) and 80 g. of a 2% solution of iodine in dry pyridine are charged in a stainless steel oscillating autoclave of 500-ml. capacity. After removal of air, oscillation is started and pure oxygen-free carbon monoxide is compressed into the vessel up to a pressure of 190 atm. The autoclave is then warmed to 160° within one hour and maintained at this temperature (± 2°) for six hours, while pressure drops from 325 to 285 atm. After cooling and venting, the hexacarbonyl and the other reaction products are quantitatively transferred into a 3-liter two-necked distillation flask with the aid of a large amount of water. On distillation of the mixture, the white hexacarbonyl is drained off. The distillate is filtered, washed with chilled methanol and paper dried. Sublimation of the powder at 70–75° at 15 mm. affords 9.0 g. of pure chromium hexacarbonyl in coarse crystals (yield 82%).

PHOSPHATE TRANSFER CATALYZED BY PHOSPHOGLYCERIC ACID MUTASE

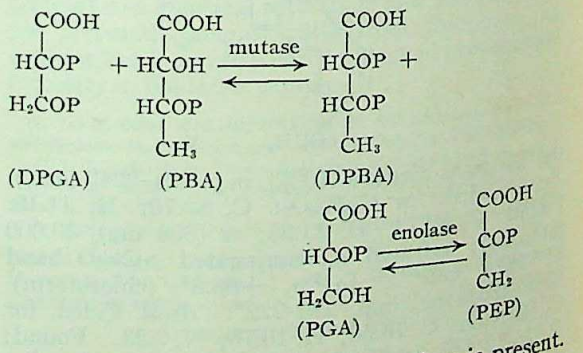
Sir:

The activation of partially purified muscle phosphoglyceric acid mutase by diphosphoglyceric acid (DPGA) was reported by Sutherland, *et al.*,[1] and we have undertaken the further study of this process with the crystalline enzyme, which was obtained from purified muscle enzyme[2] by employing the conditions found by Rodwell, *et al.*,[3] for the crystallization of the yeast mutase. In order to eliminate the possibility of DPGA contamination of the monophosphate substrate, synthetic phosphoenolpyruvate (PEP)[4] recrystallized as the cyclohexylamine salt[5] was used, and 2-phosphoglyceric acid (2PGA) was generated from it with crystalline enolase. Mutase activity was detected by its effect on the absorbance at 240 mμ of the equilibrated mixture, (PEP $\overset{\text{enolase}}{\rightleftharpoons}$ 2PGA $\overset{\text{mutase}}{\rightleftharpoons}$ 3PGA).

Synthetic DPGA[6] activated the mutase over the range 10^{-4} to 10^{-7} M, and the K_m for the conditions used was 2×10^{-6} M. The enzyme also exhibited activity under the same conditions when no DPGA was added. This activity was proportional to the amount of enzyme added and corresponded to 5% of the activity displayed when the enzyme was saturated with DPGA. The same order of activity was observed when the substrate was synthetic 3PGA,[7] although the presence of DPGA in trace amounts is here possible. In the latter case the activity was followed by the formation of PEP.

These results are indicative of two forms of the mutase, one which requires DPGA activation and one which does not. The enzyme, like phosphoglucomutase,[8] probably exists in a nonphosphorylated and a phosphorylated form. The latter species could exhibit activity in the absence of DPGA, and DPGA would activate by donating one of its phosphate groups to the nonphosphorylated form.

In experiments testing the specificity of DPGA as a donor of phosphate groups, we made use of the *erythro*-2,3-dihydroxybutyric acid monophosphates (DPBA)[9]; which have been shown to be active substrates for the mutase[2] but not for enolase.[5] The acceptance of phosphate from DPGA by PBA results in the formation of a mixture of the phosphoglyceric acid isomers (2PGA and 3PGA) which



are in part converted to PEP if enolase is present.

In this experiment the formation of PGA from DPGA occurs only in the presence of PBA (Fig. 1, lines Ia, b) to an extent dependent on DPGA concentration if PBA is in excess (Fig. 1, lines IIa, b),

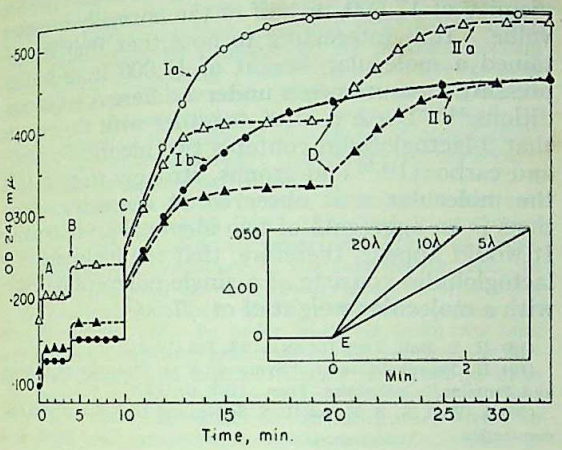

Fig. 1.—Spectrophotometric demonstration of the transfer of phosphate from DPGA to 2PBA and 3PBA: each 1 cm. cuvette contained 1 ml. of 0.1 *M* imidazole–HCl buffer, *p*H 7.0, 0.015 *M* in $MgCl_2$. To Ia and Ib was added 0.2 ml. of 0.015 *M* DPGA; to IIa was added 0.1 ml. of 0.15 *M* 2PBA; and to IIb, 0.1 ml. of 0.15 *M* 3PBA. At time A, enolase was added to each cuvette; then mutase was added at time B. At time C, 0.1 ml. of 0.15 *M* 2PBA was added to Ia, and 0.1 ml. of 0.15 *M* 3PBA was added to Ib. At the same time, 0.1 ml. of 0.015 *M* DPGA was added to both IIa and IIb. A further 0.1 ml. of DPGA was added to IIa and IIb at time D. Insert: Demonstration of the dependence of rate on mutase concentration. Cuvettes contain: 1 ml. of buffer, 0.1 ml. of 0.015 *M* DPGA, 0.1 ml. of 0.15 *M* 2PBA, 0.02 ml. of enolase and 1.76 ml. of H_2O. At E the quantities of mutase indicated on the curves were added and the 240 mμ adsorbance followed with the energy recording adaptor to the Beckman DU spectrophotometer.

and at a rate proportional to the mutase concentration, (Fig. 1, insert). The formation of PEP has been confirmed by paper chromatography of the reaction mixture in 2-propanol, ammonia, water (70:10:20). With the acid molybdate spray, spots corresponding to PEP, PGA-PBA (no separation) and a diphosphate corresponding to synthetic DPBA[10] are found. Synthetic DPBA can replace DPGA as a mutase activator, although ten times the concentration is required for comparable activity.

This series of reactions independently supports the conclusion[1] that DPGA donates one of its phosphate groups during its role in the enzymatic interconversion of the two monophosphoglyceric acid isomers. To show that DPGA donates directly to the enzyme would require the demonstration of phosphorus on the enzyme in equilibrium with the phosphorus on the substrate, but as the formation of a phosphate diester (between DPGA and PGA) as an intermediate in the phosphate transfer appears unlikely,[11] the series of reaction (a) and (b) satisfactorily explains the results.

THE MOLECULAR WEIGHT OF β-LACTOGLOBULIN

Sir:

The generally accepted molecular weight of β-lactoglobulin is in the vicinity of 35,000.[1,2,3,4] In the course of a detailed study of the association properties of this protein as a function of *p*H, it has been found that the weight of its disperse units is strongly dependent on *p*H.[5,6,7] In the *p*H regions below 3.5 and above 7.5, its sedimentation constant, measured at a protein concentration of 10 g./l., decreases from a value of $S_{20,w} = 2.85$ to $S_{20,w} = 2.25$, indicating that there occurs either a decrease in molecular weight or an expansion of the molecule, as in the case of serum albumin.[8,9,10,11,12]

In order to clarify this question, light scattering measurements were carried out on β-lactoglobulin as a function of *p*H. These show[7] that below *p*H 3.5 the molecule of β-lactoglobulin dissociates into units smaller than 35,000, probably into two portions of equal weight. These data are in qualitative agreement with the results of Rands and Tanford,[13] who also observed a similar decrease in the molecular weight of this protein at low *p*H. Because of the rapid re-equilibration of the dissociation with dilution, however, the light scattering data curve strongly upward in the low concentration range, and it is not possible to extrapolate them to a reliable value of the weight average molecular weight. As a result, ultracentrifugal determinations of the molecular weight were carried out by the Archibald technique,[14,15,16] under conditions of strong dissociation.

TABLE I

pH	Temp., °C.	Speed	Prot. concn., g./l.	Concn. at menisicus, g./l.	$\frac{1}{cx}\frac{dc}{dx}$ extrapd.	Mol. wt.
1.64	24.8	42,040	10.7	0.25	3.30 ± 0.20	16,900 ± 1000
				0.1	3.49 ± .20	17,900 ± 1000
2.01	23.7	39,460	13.2	2.8	3.75 ± .30	20,300 ± 1600
				0.36	3.23 ± .20	17,500 ± 1100
				0.1	3.22 ± .10	17,400 ± 500
2.08	25.0	20,410	12.1	5.4	1.047 ± .02	22,700 ± 500
				4.7	1.054 ± .03	22,900 ± 700

Solutions of β-lactoglobulin were prepared under the desired conditions of *p*H and ionic strength, and centrifuged in a Spinco Model E analytical ultracentrifuge. In each case, the protein solution was centrifuged in one Kel-F cell, while pure solvent was centrifuged in an identical cell used in place of the counterbalance. The menisci of the two were made to coincide by weighing in the proper amount of liquid into each cell, as suggested by Singer.[17] In this manner, the correct base line was obtained directly on each ultracentrifugal pattern. The weight average molecular weight at the meniscus was calculated at various times late in the run, so that the equilibrium be close to total dissociation. Some of the results obtained in a 0.1 Γ/2 NaCl-HCl medium are presented in the table.

These data show that the molecular weight of the dissociated species of β-lactoglobulin is in the vicinity of 17,500, or half of the normally accepted value. It is interesting to note that Bull has obtained a molecular weight of 17,000 from surface pressure measurements under a different set of conditions.[18] These results, together with the reports that β-lactoglobulin contains two identical amino[19] and carboxyl[19,20] end groups, strongly suggest that the molecular unit observed at isoelectric conditions is an aggregate of two identical protein units. It would appear, therefore, that the molecule of β-lactoglobulin consists of a single polypeptide chain with a molecular weight of *ca.* 17,500.

BOOK REVIEWS

Biochemical Problems of Lipids. Proceedings of the Second International Conference held at the University of Ghent 27–30 July, 1955, organized with the collaboration of the "Vlaamse Chemische Vereniging" of Belgium, under the presidency of Professor R. Ruyssen. Editors, G. POPJÁK and E. LE BRETON. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1956. xvi + 509 pp. 16 × 25.5 cm. Price, $10.75.

This volume contains about 80 papers including a discussion of the nomenclature of the enzymes concerned in fatty acid metabolism. The languages used were English, French and German. There were present about 250 scientists representing 20 nationalities.

The papers are arranged in four sections as they were presented at the meetings: (1) physical and chemical properties of the lipids—methods of separation, structure; (2) metabolism and biosynthesis, enzyme systems; (3) phospholipids and transport; (4) miscellaneous problems.

An excellent outline of the work covered is given in the introduction by President R. Ruyssen. Among his comments are remarks about the complex chemical constitution of the lipids and their behavior as amphophilic substances. The knowledge of structure and composition of the natural phospholipids has much increased due almost entirely to new methods of separation and identification, such as countercurrent distribution, chromatography and spectrophotometry. Knowledge of the enzyme systems and their isolation as discussed in the conference puts us now in position to describe precisely most of the reactions in the fatty acid cycle. The part taken by the phospholipids in the transport of the fatty acids is now due for a reconsideration. Also thereby, new light has been thrown on fat absorption, [illegible] quantities of thermal power either exothermic or endother-

It would be impossible in a brief outline to mention the topics presented and their discussion by the attending members. It is sufficient to say that practically every phase of lipid structure, behavior and metabolism has been brought out and examined so that a reader gets a comprehensive picture of the present state of the problems connected with the lipids. A fact which detracts a little from the book as a publication is the repetition of the last three papers of section (1) together with an occasional extra page. Of course, this does not affect the value of the material from a scientific point of view.

The book will be of interest, not only to the purely lipid chemists, but since the lipids in nature combine with most known biochemical substances, forming aggregates of great size and complexity, it should interest all biochemists as well as those whose main interest is in the huge molecules which constitute living matter.

Microcalorimétrie. Applications Physico-Chimiques et Biologiques. By E. CALVET, Professeur à la Faculté des Sciences de Marseille, and H. PRAT, Professeur a l'Université de Montréal. Masson et Cie., Editeurs, 120, Boulevard Saint-Germain, Paris-6e, France. 1956. viii + 395 pp. 17 × 25 cm. Price, Broché, 4.500 fr. Cartonné toile, 5.200 fr.

Microcalorimetry comprises the measurement of small

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

mic as produced in chemical reactions. In the apparatus developed by Calvet, Prat and co-workers the sensitivity has been increased to the point where the incredibly small power of 0.2 microwatt (1.5 cal./yr.) can be recognized. The fundamental idea which makes this possible was originally proposed by A. Tian in Marseille in 1923 (whose apparatus was used by Calvet for his doctoral research). Tian suggested that the heat generated or adsorbed in the reaction under study be compensated by electrical cooling (Peltier Effect) or heating (Joule Effect). The present authors over a period of twenty years have developed the apparatus to the sensitivity mentioned above and by means of ingenious innovations as well as of sound theoretical analyses of error brought the science of microcalorimetry to a high state of perfection.

The book has been written in three sections, the first two by Calvet and the third by Prat. The first on apparatus and methods gives detailed mathematical analyses of errors, heat leaks, thermal unbalance in the calorimeter, etc., as well as a description of the calorimeter, methods of forming the thermocouple junctions, electrical circuits (which are relatively simple), etc. In order to avoid unknown heat losses due to temperature gradients along the exterior surface of calorimeter and interior surface of jacket (a difficulty commonly overlooked by many calorimetrists), Calvet covers nearly the whole surface of the calorimeter with thin silver plates each connected to a thermocouple. Thus in his calorimeter heat leaks are magnified, but controlled and measured. This is perhaps the outstanding feature of his technique. It would be interesting to know how such a scheme works at high temperatures where heat exchange by radiation becomes dominant.

The second part describes the special methods and results of calorimetric studies of heats of solution, dilution, mixing, gelatinization, esterification, hydrolysis, saponification, immersion, decomposition and hydration (especially of cements). A large and important part of this section is devoted to the description not only of total heats but also of kinetic heat effects. The apparatus can also be used for specific heat and thermal conductance measurements although in these two fields the special advantages of the Tian-Calvet calorimeter are not so marked.

The final part describes chiefly Prat's work on biological systems such as heat effects of germination and respiration of seeds, bacteria, tissues, invertebrates and vertebrates. Of especial interest here are the kinetic heat effects which make it possible to recognize and measure quantitatively different stages in growth cycles as well as the effects produced on the organisms by herbicides, hormones, variations of temperature and humidity, etc.

The authors make no attempt to review the whole subject of microcalorimetry, their purpose in writing this book being to expound their own techniques. A general bibliography is given as well as indices and a table of contents. F. D. Rossini in his capacity of President of the Commission of Chemical Thermodynamics of the I. U. P. A. C. generously contributed an appreciative preface.

MALCOLM DOLE

Treatise on Inorganic Chemistry. Volume II. Sub-Groups of the Periodic Table and General Topics. By H. REMY, Professor of Inorganic Chemistry, University of Hamburg, (Germany). Translated by J. S. Anderson, F.R.S., Professor of Inorganic Chemistry, University of Melbourne (Australia), Formerly Deputy Chief Officer, Atomic Energy Research Establishment, Harwell (England). Edited by J. KLEINBERG, Professor of Inorganic Chemistry, University of Kansas, Lawrence, Kansas (U.S.A.). D. Van Nostrand Co., Inc., 126 Alexander Street, Princeton, New Jersey. 1956. xxviii + 800 pp. 18 × 25.5 cm. Price, $17.75.

The English translation of this famous German textbook by Professor Remy is a welcome addition to the number of treatises in inorganic chemistry which have appeared in the last few years. Professor Anderson who has translated this book has been successful in keeping basic objectives of Professor Remy intact.

As the title indicates, a large part of this book pertains to the treatment of the various groups in relation to their position in the periodic table. However, several chapters have been added which treat subjects of great present interest.

The first chapter is a discussion of the metals and the intermetallic phases emphasizing the theoretical and practical aspects of this subject. Chapters 2, 3, 4, 5 and 6 discuss the first five periods of the transition elements. Chapter 7 discusses the 8th sub-group divided into the metals of the iron series and the metals of the platinum series. This division, unfortunately, produces a loss of some of the significance of the electronic structure in the sub-groups of group VIII. Chapters 8 and 9 discuss the 1st and 2nd subgroup of the periodic system and chapter 10 discusses the Lanthanum group.

Chapters 2 through 10 start with a general discussion of the groups such as their valence, basicity of the hydroxides, oxides and salts, properties of the metals, alloys, etc. Much of this discussion is of the type which still adheres to the memory type discussion which was so typical of German treatises. The other parts of the chapter consist of the discussion of the physical and chemical properties of the metals and their compounds including their analytical chemistry. Energy relationships which are so important in discussion of trends in the groups are unfortunately not included for most groups. In many cases certain aspects of a group are discussed in great detail whereas other parts are just barely mentioned. Some compounds are discussed as Werner type complexes although this has not been fully established.

The rest of the chapters consider general phenomena important in inorganic chemistry. Chapter 11, for example, considers radioactivity and isotopes, and chapter 12, isotopes of the stable elements; chapter 13, artificial radioactivity in nuclear chemistry and chapter 14, the Transuranic elements in general. This discussion covers about 150 pages and is quite well organized and presented. Chapter 15 considers geochemistry in general and could possibly be included in this group.

Chapter 16 discusses colloids and surface; chapter 17, catalysis and reaction kinetics; chapter 18, reactions in nonaqueous solutions and chapter 19, reactions of solid substances. These chapters are well organized but consider phenomena which can, because of space limitation, be only discussed superficially. In such a case, naturally, the specific interest of the author determines the treatment of the subject matter.

In general, this second volume of Remy's Treatise on Inorganic Chemistry is a very welcome addition to the shelf of general reference books in inorganic chemistry. The author, the translator and the American editor are to be congratulated for having undertaken to make this reference book available to those research chemists in inorganic chemistry who are not too familiar with the German language.

DEPARTMENT OF CHEMISTRY
TULANE UNIVERSITY
NEW ORLEANS, LOUISIANA

HANS B. JONASSEN

Organic Analysis. Volume III. Editorial Board: JOHN MITCHELL, JR., I. M. KOLTHOFF, E. S. PROSKAUER and A. WEISSBERGER. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1956. viii + 546 pp. 16 × 23.5 cm. Price, $11.50.

This latest publication in the series "Organic Analysis" marks another forward step in the projection originally set forth by its editors of consolidating and critically evaluating the extensive and widely scattered literature of the field. It is gratifying to note in this connection that the contributors to Volume III have completed their assignments with distinction.

The book contains six chapters, the first four of which deal with functional group analyses (1. Organic Acids, 2. Organic Anhydrides, 3. Amines and Amides, and 4. Olefinic Unsaturation), the fifth with a relatively new instrumental technique, analytical mass spectrometry, and the sixth with synthetic organic resin coatings. The chapters are all of uniformly high quality, their treatment showing ample evidence of both painstaking scholarly care and of broad

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

practical experience with the subject matter in hand. The coverage of the many and varied chemical and instrumental techniques pertinent to the above mentioned functional groups is inclusive and well documented: there is a generous selection of proven methods accompanied by procedural details and tabular surveys of compounds to which the methods apply. The chapter on olefinic unsaturation, certainly the largest undertaking in the book, is probably unique in its breadth and excellence, and is one which will be welcomed by organic chemists generally. The fifth chapter opens with a clear and concise theoretical discussion of mass spectrometry, but appropriately limits its treatment of specific applications to those of interest to the structural organic chemist. Because of the expensive equipment which this method entails this chapter is addressed unfortunately to a rather restricted audience. The last chapter is a survey of a variety of separation procedures and determinations which have been applied successfully in the field of resin coatings. As such the information in it will no doubt find daily use in the laboratories engaged in the field, and will definitely come as a boon to the analyst who is confronted with a problem in it only occasionally. In summary, this is a useful volume indeed, and is highly recommended as an addition to the library of the organic analyst.

Department of Chemistry
Massachusetts Institute of Technology
Cambridge 39, Massachusetts Stephen M. Nagy

Rheology. Theory and Applications. Volume I. Edited by Frederick R. Eirich, Polytechnic Institute of Brooklyn, Brooklyn, New York. Academic Press, Inc., Publishers, 111 Fifth Avenue, New York 3, N. Y. 1956. xiii + 761 pp. 16.5 × 23.5 cm. Price, $20.00.

The importance of rheology to the chemist is constantly growing, with both the variety of materials available for various purposes and the demands of the applications in which these materials are put to use. Rheology, originally the science of flow, has become the science of the response of materials or objects to many kinds of steady or cyclical stresses. Its subject matter ranges from the viscosities of very dilute polymer solutions through the behavior of lubricating oils, paints, printing inks, doughs, plastics, fibers and rubbers, to the deformation of metals and the behavior under stress of soil and concrete.

The chief cause of this increase in practical importance has been the extensive development of the science of rheology itself, particularly during the last ten or fifteen years. The science is in need of systematization and of standardization of terminology and nomenclature. There is need for books, both systematic introductions and also advanced expositions of the progress of the science on its many fronts. This present book is in the latter category; it might well be called a source book of theoretical and applied rheology. Many of the scientists who have contributed most heavily to the recent development of the science have written chapters summarizing their special fields.

After an introduction by Professor Eirich, Volume I contains chapters by M. Reiner and by William Prager on the mathematical analysis of rheological behavior; by D. C. Drucker on plastic behavior in metals; by G. J. Dienes on "Crystal Properties and Imperfections"; by J. M. and W. G. Burgers on "Dislocations in Crystals"; and by J. Fleeman and G. J. Dienes on "Mechanical Properties of Metals." Next is a chapter by R. B. Dow on rheological behavior under high pressures. A. Bondi then writes on "Theories of Viscosity." R. S. Rivlin summarizes the mathematical theory of large plastic strains, chiefly his own work. There then follow five chapters dealing chiefly with the rheology of high polymers: by T. Alfrey, Jr., and E. F. Gurnee ("Dynamics of Viscoelastic Behavior"); T. G. Fox, Serge Gratch and S. Loshaek ("Viscosity Relations for Polymers in Bulk and in Concentrated Solution"); J. Riseman and J. G. Kirkwood ("The Statistical Mechanical Theory of Irreversible Processes in Solutions of Macromolecules"); H. L. Frisch and R. Simha ("The Viscosity of Colloidal Suspensions and Macromolecular Solutions"); and A. Peterlin ("Streaming and Stress Birefringence"). Finally come a mathematical study by [illegible]

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Newtonian liquids, by J. G. Oldroyd, and a brief chapter by R. B. Lindsay on "Acoustics and the Liquid State." The announced contents of Volumes II and III lists roughly as many chapters for each of these volumes, with the chapters somewhat more specialized and, in Volume III, of a more applied nature.

The chapters of Volume I differ considerably among themselves in plan, in thoroughness and in level of difficulty. This reviewer was more at home in the chapters on polymers and found some of them quite useful. With the many additional chapters announced for the subsequent volumes the coverage of polymer rheology will be relatively complete. In contrast the treatment of metals appears not to be extended into later volumes. The chapters on metals in the first volume appear to be of high quality, though outside this reviewer's field of competence.

In view of the nature, scope and price of this volume, and of the set, this reviewer considers that it can be recommended particularly for purchase by libraries of universities and of colleges strong in technical work and by industrial libraries in a large segment of chemical and related industry. The case is somewhat different for the individual chemist. Those working actively in applications of rheology, having considerable knowledge of the field, may find this compilation of authorative summaries of great value. For the beginning worker in the field, or the chemist in another field wanting orientation in rheology, the work has several drawbacks—its length, the thoroughness and comparative difficulty of some of the treatments, the lack of correlation between the chapters with consequent repetition and variation in terminology, notation and viewpoint, and a lack of unity and coherence in the work as a whole which is an unavoidable consequence of this type of authorship.

American Viscose Corporation
Marcus Hook, Pennsylvania M. T. O'Shaughnessy

An Investigation on Promoted Iron Catalysts for the Synthesis of Ammonia. Second Edition. By Anders Nielsen. Jul. Gjellerups Forlag, Copenhagen, Denmark. 1956. 233 pp. 16 × 24 cm. Price, paper bound, 28.00 Danish Kroner; cloth bound, 33.00 Danish Kroner.

During the past five decades the synthesis and decomposition of ammonia on the surface of solid catalysts has been of intense interest to fundamental and applied scientists. Some of the complexities of heterogeneous catalysis have been resolved, and the industrial development of the ammonia synthesis has been accelerated. Nielsen's book presents data of major importance in the rational design of industrial equipment as well as data and discussions pertinent to an understanding of the mechanism and kinetics of the synthesis. A brief introduction outlining the subject matter and purposes of the book is in Chapter I. The second chapter contains thermodynamic data on the equilibrium concentration of ammonia in $3H_2 + 1N_2$ as a function of pressure and temperature, on the heat of reaction at 500° and various pressures, on compressibility of $3H_2 + 1N_2$ at 10° and 100–400 atmospheres, on the solubility of H_2, N_2, A and CH_4 in liquid NH_3 and on the vapor phase composition of $3H_2 + N_2$ equilibrated with liquid NH_3 at various temperatures and pressures. After a brief description of laboratory catalyst pretesting apparatus in Chapter 3, the following chapter presents data on the per cent. conversion, the efficiency factor (ratios of actual partial pressure of NH_3 to equilibrium partial pressure of NH_3), and space–time–yield as a function of temperature, pressure, space velocity. Chapter 4 also contains data on the effect of the ratio of H_2 to N_2, the partial pressures of inert gases, the per cent. of NH_3 in the feed gas; and includes discussion of the differences between laboratory and industrial converters particularly with respect to temperature gradients and turbulence, and the effect of particle size of catalyst with regard to the extent of reduction and the limitation of reaction velocity by diffusion to and from the surface of the catalyst.

The great utility and limitations of Temkin and Pyshev's equation for the rate of the synthesis are demonstrated in Chapter 5 by an analysis of the variation in rate constants with pressure and temperature. The limitations encountered when the NH_3 partial pressure is low, when diffusion

Digitized by Arya Samaj Foundation Chennai and eGangotri

into and out of the catalyst granule is rate determining, and the decrease in the rate constants with increasing pressure and with decreasing H_2 to N_2 ratio, are of particular significance. The magnitude of the change in the rate constants with pressure in is not the same for all catalysts, being lowest for the doubly promoted Al_2O_3–K_2O–Fe_3O_4 catalyst.

In Chapter 6 are presented the properties of various catalysts which are of industrial importance such as temperature stability, effect of promoters, the characteristics of reversible poisoning by O_2, H_2O, CO, CO_2 and more permanent poisoning by S, As; the optimum reduction procedures, and the effect of particle size on activity and on pressure-drop in industrial reactors. The extent of reduction is of critical importance to the activity of the catalyst. Virtually complete reduction is desirable because of the poisoning action of H_2O, and it is obtained by the use of very high space velocities of the reducing gas and the highest temperatures consistent with minimum deterioration of the catalyst by sintering. Promoters such as Al_2O_3, CaO and K_2O markedly lower the rate of reduction of Fe_3O_4.

X-Ray diffraction patterns of various catalysts before and after reduction are presented and discussed in Chapter 7. The distribution of Al_2O_3 in the spinel lattice of Fe_3O_4 is uniform and this accounts for the structural promotion of Al_2O_3. Whether CaO, or MgO are "dissolved" in the Fe_3O_4 is not yet determined. K_2O remains largely on the surface of the reduced catalysts, and its promotional activity probably is related to its effect on the thermionic work function of the surface and consequently on the rate and extent of activated adsorption of nitrogen (the rate determining step in the synthesis).

Chapters 8 and 9 are concerned with the details of the reaction mechanism as determined by critical experiments on surface properties, the energetics of chemisorption of H_2 and N_2 and measurements of the rates of nitrogen isotope exchange reactions. The data and discussion are of critical importance to an understanding of heterogeneous catalytic reactions. Although structural heterogeneity of catalyst surfaces exists and is effective in the selectivity of certain catalysts, and although surface interaction of chemisorbed molecules and atoms also contributes to energetics of the surface reactions, nevertheless neither of these factors is adequate to explain the changes in heat of adsorption with extent of surface coverage. Boudart's calculations of the influence of the electrical double layer which is formed on a catalyst surface by a fully or partially ionized adsorptive bond show large changes in thermionic work-function and adequately large decreases in heat of adsorption with increase in the fraction of the surface covered.

Nielsen's book is a valuable one for both scientists and engineers who are interested in heterogeneous catalysis.

H. H. Storch

Organo-metallic Compounds. By G. E. Coates, M.A., D.Sc., F.R.I.C., Professor of Chemistry in the University of Durham. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. 1956. viii + 197 pp. 13 × 19 cm. Price, $2.50.

This little book deals with organometallic compounds, defined as substances containing a metal to carbon bond. Alkoxides and other compounds in which metal atoms are bonded to organic systems *via* oxygen, nitrogen or sulfur, and which are often referred to as organometallic compounds, are excluded. A further restriction on the scope of the book is the entire omission of the organic chemistry of silicon, phosphorus and arsenic, on the reasonable grounds that their inclusion in a book of this size would impair the treatment of the other elements.

The author deals with the compounds of the alkali metals, and of the elements of Groups II, III and IV, of antimony and bismuth, and of the transition elements. Whilst the book is written in a rather terse style and is not particularly readable, it is, however, well worth close study, since it contains a wealth of information and the large numbers of references to the original literature given at the end of the chapters, although not exhaustive, are most useful.

In addition to the preparations, properties and reactions of compounds, the structural side is quite adequately dealt with considering the scope of the book. There are but few errors and, although the views expressed in some sections now need modification, the book is fairly well up to date—almost an impossibility in this field at the present time. The final section on cyclopentadienyl compounds is one of the weakest, and the discussion of bonding in ferrocene and similar compounds is far from illuminating. Metal–benzene derivatives are mentioned only in a footnote.

On its information content alone this book is a worthwhile addition to one's library and it has the additional merit of being handy for the pocket.

Chimie Physique Nucléaire Appliquée. By Jacques Errera, Professeur a l'Universite de Bruxelles. Masson et Cie., Éditeurs, Librairies de l'Academie de Medecine. 120 Boulevard Saint-Germain, Paris VI, France. 1956. 226 pp. 16.4 × 24.8 cm. Price, 2.100 fr.

This little book covers applications of radioisotopes to areas where physico-chemical methods are common. The contents of the several chapters (and their lengths in pages) are approximately as follows: the atom and the nucleus (14); nuclear reactions (19); fission, reactors, nuclear power (36); fusion reactions (3); military applications of nuclear energy (4); fields of application for nuclear reactions (4); detection of nuclear radiations (20); units of radioactivity (4); preparation of radioisotopes (5); comparison of usefulness of stable and radioactive tracers (2); health protection (9); applications to pure and applied science (81); list of elements and table of useful radioisotopes (4). The text is written on a semi-technical level.

Of the 150-odd references and illustration credits in the book, 2 are to British journals, 2 to a Belgian article, 1 to a recent British compendium, and the remainder to current American textbooks, monographs and journals. The book seems to be largely a collection of review and summary material published elsewhere. The book can be recommended to students who are preparing for their pre-doctoral French examinations.

Palladium Hydride. I. The Thermodynamic Properties of Pd_2H between 273 and 345°K.[1]

BY DONALD M. NACE AND J. G. ASTON

RECEIVED FEBRUARY 13, 1957

The 30° absorption isotherm for hydrogen dissolved in a highly active palladium black has been measured and found to agree very closely with an equilibrium desorption isotherm obtained previously by Gillespie and Hall. Partial molar heats of desorption for the system palladium–hydrogen have been calculated from the isotherms. Partial molar heats of absorption and desorption of hydrogen from palladium hydride also have been measured in an adiabatic calorimeter. These values are used to calculate the free energy and the entropy change associated with the formation of Pd_2H from the elements at 30°. Agreement between the calorimetric heats and those calculated from the temperature coefficient of the equilibrium pressure establishes a reasonable criterion of equilibrium for the system.

Introduction

Palladium is a rapid exothermic absorber of large volumes of hydrogen. Although this phenomenon has been the subject of many previous investigations,[2,3] no entirely satisfactory explanation of the nature of the bonding force has been established. The phase equilibria of the hydrogen–palladium system have been extensively investigated for different forms of palladium (wire, foil, sponge and black). Hysteresis effects have been quite evident in all the isotherms, especially those for temperatures below 160°.

By using a special heat treatment technique, Gillespie and Hall[4] obtained, at temperatures as low as 0 and 30°, apparently true equilibrium isotherms which are located between the usually different absorption and desorption curves. The equilibrium isotherm is interpreted as indicating two solid solutions; one is a hydrogen-poor solution (α-phase), the other is a hydrogen-rich solution (β-phase) of approximate composition Pd_2H. For both α- and β-phases X-ray analysis identifies the palladium atom array as being face-centered cubic, the α-phase having a parameter of 3.886 Å., and the β a parameter of 4.020 Å.[5]

The data presented in this paper were compiled for the purpose of calculating the entropy for the system Pd_2H at near room temperature. Such a value is needed in order to determine the absolute entropy of Pd_2H at 0°K. from a third law study. It is best that this be determined on the sample used for the third law study. Therefore, a series of equilibrium pressure and heat of absorption measurements have been made on a *very active* palladium black between 273 and 345°K.

Materials.—The palladium used is a special grade of palladium black obtained from Baker and Company, Newark, New Jersey. This extremely active palladium is made for their own research purposes, so the method of preparation is not available. The purity is given as 99.9%. Although the density of bulk palladium is 12.0 g./cc., the packed density of this black powder is only 0.6 g./cc. One sample, weighing 34.277 g., was sealed into a gold calorimeter and used for all of the experimental work. The sample was never heated over 100° because the material supposedly sinters at higher temperatures. Any possible oxide of palladium was reduced initially by adding hydrogen to the sample and then degassing at 98°. Following this reduction, the sample was exposed only to very pure helium, nitrogen and hydrogen.

High purity hydrogen made by electrolysis and purified by liquefying and then compressing into a high pressure cylinder was used throughout. All portions of the hydrogen allowed to react with the palladium were first passed through a trap packed with activated charcoal and immersed in a liquid nitrogen-bath.

Apparatus.—The container for the palladium black sample is a closed gold cylinder fitted at the top with a gold inlet tube and having an internal volume of 55.6 cc. Connection between the gold calorimeter and a glass vacuum system is made through a platinum–rhodium tube which has an inside diameter of 0.0292 in. and which is gold welded inside the calorimeter inlet tube. The calorimeter contains a 2.5 in. long re-entrant well which is gold welded in the center of the cylinder bottom. The re-entrant well is designed for insertion of a platinum resistance thermometer.

Volumes of gas are measured in a calibrated 3-liter Pyrex bulb set up inside a 50-gallon insulated stirred water-bath which is kept at room temperature. Mercury from a storage tank immersed in the water-bath can be raised into or lowered from the 3-liter bulb in order to transfer the gas to the calorimeter. The system is patterned after one described by Giauque and Johnston.[6] The temperature of the water is measured on a mercury thermometer which has been calibrated against a platinum resistance thermometer. The pressure of the gas is measured using a 13 mm. bore, copper cased, mercury manometer. The mercury levels and meniscus heights were referred to a stainless steel, calibrated meter bar by means of a Gaertner Scientific Corporation M901 cathetometer.

The calorimeter vessel was immersed in the inner bath of a double constant temperature bath for the isothermal pressure–composition study and the pressure–temperature studies at fixed composition. The inner bath consists of a 1000-cc. insulated Pyrex beaker equipped with a Transite lid and provided with a stirrer, a calibrated platinum resistance thermometer, an uncalibrated platinum resistance thermometer, and a six-watt light bulb. The uncalibrated resistance thermometer was used to control the temperature by means of a Wheatstone bridge arrangement in which any unbalance of the bridge resulting from a temperature change in the bath of 0.001° or more is detected by a type R galvanometer. A light beam reflected from the galvanometer mirror activates a photocell relay circuit which turns on or off the six-watt bulb. Glycerol was used as the medium in both inner and outer baths. The outer bath was controlled by means of a mercury thermostat at a few tenths of a degree below the temperature of the inner bath. Measured fluctuations of temperature in the inner bath amounted to ±0.002°.

Heats of absorption and desorption were measured in the same gold calorimeter vessel after it had been incorporated in an assembly designed for adiabatic operation with high vacuum insulation. This adiabatic assembly is described in the following paper.[7] Temperatures are measured with a strain-free platinum resistance thermometer, Pt-G-5, based on the International Temperature Scale. The calorimeter was held adiabatic during the addition of gas and until equilibrium was established, or in many cases, until pressure and temperature changes were small enough to allow extrapolation to an approximate equilibrium. The heat of absorption per mole of hydrogen is calculated from the same expression used for heats of adsorption, namely[8]

$$q = \frac{C_p \Delta T}{n} - \frac{V_{cal} \Delta P}{n} \qquad (1)$$

where ΔT is the temperature rise, n is the number of moles of hydrogen absorbed, ΔP is the change in pressure during absorption and V_{cal} is the dead space volume of the calorimeter. The calorimeter was cooled between increments of hydrogen added so that the mean temperature for each rise was about 30°. The mean heat capacity of the system before and after absorption of hydrogen, C_p, was interpolated to the mean temperature for the temperature rise. The measured heat capacities have been corrected for the heat of desorption, which is assumed to be equal in magnitude to the measured heat of absorption but negative in sign, and the heat of compression. The equation for making these corrections to the measured values is

$$C_p = C_m - \frac{(-q)}{\Delta T}(\Delta n) + \frac{V_{cal} \Delta P}{\Delta T} \qquad (2)$$

where C_m is the measured heat capacity and Δn is the increase in the number of moles of gas in the dead space.

After each measurement of heat evolved by a given quantity of gas, the calorimeter was cooled to the initial temperature and one or two heat capacity measurements were made between the initial and final temperatures of the heat of absorption measurement. The heat of absorption was calculated by a series of reiterations of eq. 1 and 2 since q and C_p appear in both equations.

The Absorption Isotherm.—A 30° isotherm for the absorption of hydrogen in palladium black was determined in the isothermal apparatus. The isotherm is shown as the solid curve in Fig. 1 where it is compared with the 30° isotherm obtained by Gillespie and Hall.[4] Since the Gillespie and Hall isotherm is a desorption isotherm brought to equilibrium by the use of a 360° heat treatment prior to each pressure measurement, the similarity between these isotherms indicates that true equilibrium has also been reached in the absorption isotherm of this paper. Equilibrium, as revealed by the constant pressure portion of the isotherm, has never reportedly been obtained for the absorption of hydrogen in palladium below 160° without a heat treatment. The reason for the lack of hysteresis in the present investigation is undoubtedly inherent in the extremely finely divided state of the palladium black used. Pressure equilibrium for the isotherm was obtained in two to six hours after addition of a hydrogen increment. Three of the experimental points of the isotherm were obtained after allowing the pressure to come to equilibrium overnight, but the pressure increased only 0.02 mm. after the second hour. The pressure during the horizontal portion of the isotherm varies only ±0.20 mm. from an average of 17.35 mm. This value is 1.45 mm. (ΔF = 51 cal.) below the value obtained by Gillespie and Hall.

After sufficient hydrogen had been absorbed in the palladium to pass the second break in the isotherm, about 12% of the hydrogen was desorbed. The pressure fell to a low value quite rapidly, and the calorimeter had to be heated to 80° in order to desorb such a large quantity of hydrogen. This desorption curve, as shown in Fig. 1, is identical with that obtained by Gillespie and Hall on desorption of hydrogen where the 360° heat treatment was not previously applied.[4] No increase in pressure occurred over a period of four days after desorption of hydrogen. By heating the system again and holding it at 80° for 24 hours, the pressure after the system was cooled to 30° differed from that before the second heat treatment by only 0.10 mm. Reabsorption of hydrogen raises the pressure to a point where it coincides with the original absorption isotherm. A second set of desorption and reabsorption isotherms is shown in Fig. 1.

Isosteric Heats of Desorption.—The palladium hydride at a composition of about 0.40 atom of hydrogen per atom of palladium was heated to 45° and pressures were measured at a series of temperatures from 45 to 75°. The temperature was controlled with an accuracy of ±0.002° and

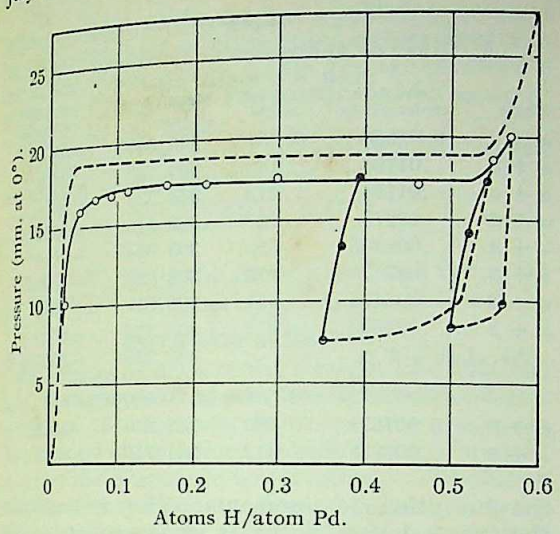

Fig. 1.—Isotherm at 30° for hydrogen in palladium: solid curves, data of present investigation; open circles, absorption; half-filled circles, desorption; filled circles, absorption following desorption; dashed curve, data of Gillespie and Hall.

pressures determined within ±0.04 mm. A plot of $\log p$ *vs.* $1/T$ for the equilibrium pressure data over this 30° temperature range is shown in Fig. 2 (open circles). On a large scale plot no curvature is evident. The slope of this line corresponds to a heat of desorption of 8870 cal./mole of hydrogen, which agrees very closely with the value of 8860 cal./mole obtained by Gillespie and Hall[4] from their 30 and 80° equilibrium values (line with no points in Fig. 2). However, it was found that on decreasing the temperature from 75 to 45°, the pressure values did not fall on the same straight line but established a new straight line (filled circles). The palladium hydride was heated again, and the equilibrium pressure was measured at several temperatures between 45 and 75° (half-filled circles). Pressures also were measured at several temperatures on cooling to 50°. All points obtained after the first 75° heating lay on the second straight line. The 14 experimental points from 55 to 75° were least squared to fit a straight line. The heat of desorption calculated is 9440.8 cal./mole of hydrogen. The most probable error in the experimental data corresponds to ±0.1 mm. pressure at 75° or ±0.5 mm. at 55°. The probable error in the heat of desorption is ±0.9 cal./mole of hydrogen if equilibrium could be assumed.

In the process of measuring heats of absorption and heat capacities in the adiabatic calorimeter, additional pressure–temperature data were observed. Log p *vs.* $1/T$ plots of the data obtained are shown in Fig. 3. The sample of palladium hydride had been completely degassed prior to these measurements and hydrogen added until the final composition corresponded to 0.487 atom H per atom Pd (open circles). It was during this addition of hydrogen that calorimetric heats of absorption also were measured. The isosteric heat calculated on the basis of the slope of this line is 9330 cal./mole. After a period of two months

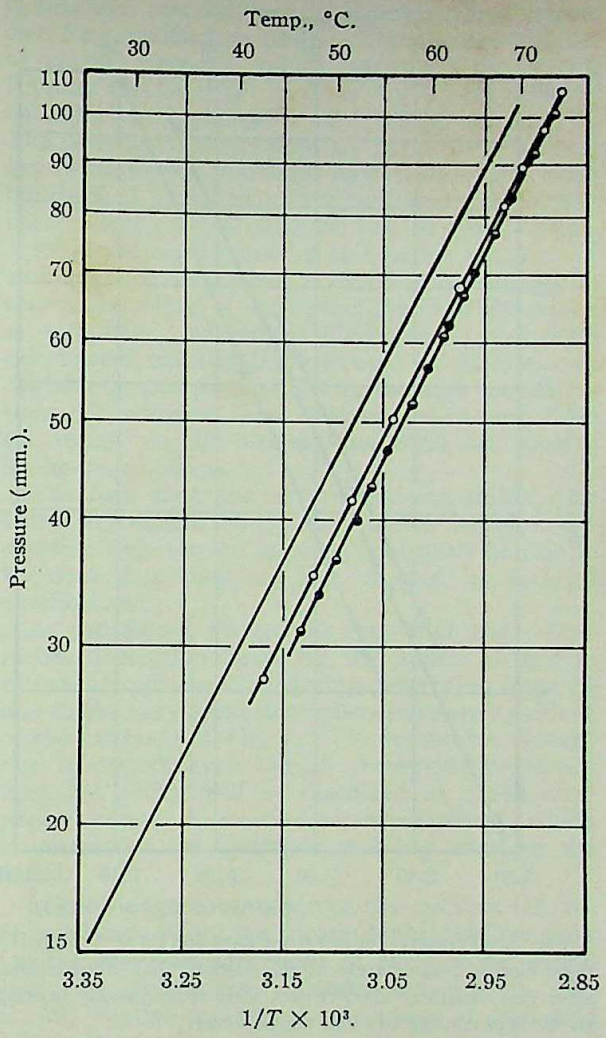

Fig. 2.—Pressure–temperature data for Pd + 0.2 H_2: open circles, preheated to 35° only; filled circles, preheated to 75° and temperature lowered to point; half-filled circles, preheated to 75°, cooled to 45°, and then raised to point; line without points, data of Gillespie and Hall.

during which time the sample was subjected to temperatures from 15 to 300°K., pressures were again measured from 12 to 73° (half-filled circles). The plot of these data gives an isosteric heat of 9640 cal./mole. However, after heating to 73° and cooling to room temperature (filled circles), the corresponding isosteric heat is 10,300 cal./mole.

This variation of the isosteric heats must be due to lack of internal equilibrium.

Calorimetric Heats of Absorption and Desorption.—Heats of absorption were measured calorimetrically at 30° at various concentrations of hydrogen. Heats of desorption of hydrogen from palladium hydride were measured at 68°. The heat determinations are listed in Table I.

The heat of absorption of hydrogen remained constant over the entire mixed phase region of palladium hydride. The average value of the heat is −9605 cal./mole at an average temperature of 30.195°. The average deviation of the heat of absorption is ±45 cal./mole and of the temperature is ±0.146°.

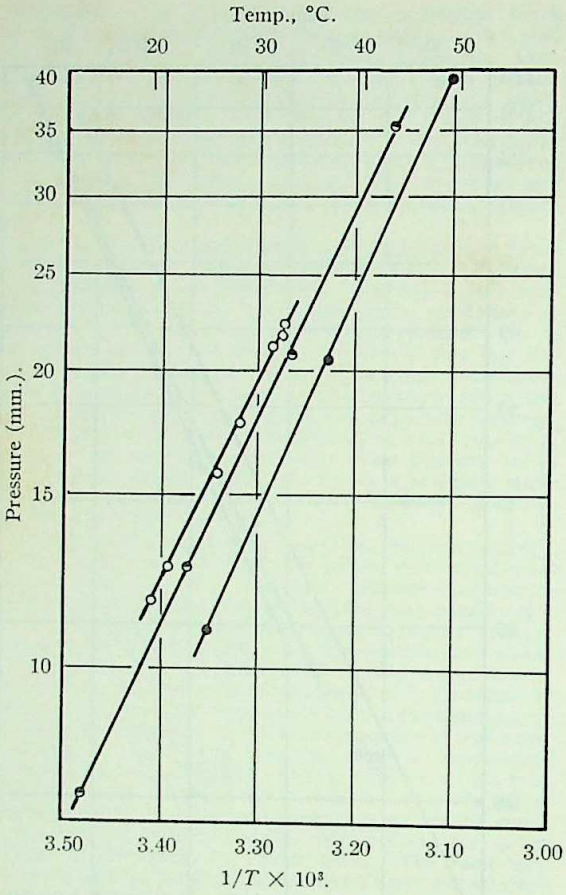

Fig. 3.—Pressure–temperature data for Pd + 0.2435 H_2: open circles, immediately after addition; half-filled circles, after two months; filled circles, after subsequently heating to 73° and cooling to room temperature.

The heats of desorption do not agree well with those of absorption or with each other; this is due undoubtedly to a great lack of equilibrium during desorption, whereas there is good equilibrium for the absorption.

The heat of the reaction

$$4Pd + H_2\,(1\text{ atm.}) = 2Pd_2H \qquad (3)$$

is the total heat of absorption of hydrogen from pure palladium to the composition of Pd_2H based on a mole of hydrogen. The one determination of the α-phase heat evolution resulted in a value of 8948 cal./mole; the average heat evolution during formation of β-phase Pd_2H is 9605 cal./mole. Since the α-phase heat evolution, which occurs up to the atomic ratio 0.125, corresponds to one-quarter of the over-all reaction to form Pd_2H, the value of $\Delta H°$ corresponding to equation 3 is given by

$$\Delta H° = {}^1/_4(-8948) + {}^3/_4(-9605) = -9440 \pm 45\text{ cal./mole} \qquad (4)$$

Since the heats of absorption are measured directly, lack of thermodynamic equilibrium should not greatly affect them, particularly when the equilibrium during absorption is as good as it was in these measurements. The fact that the isosteric heats are even close to the measured values is an indication of relatively good equilibrium in
